The family *Coronaviridae* comprises two genera, *Coronavirus* and *Torovirus*, and is classified with the families *Arteriviridae* and *Roniviridae* in the order *Nidovirales*. Members of the *Coronaviridae* share the common feature of pleomorphic, enveloped virions with diameters of 126–160 nm and prominent surface projections. The nucleocapsid is helical and contains a single molecule of linear, positive-sense ssRNA. Coronavirus-like particles have been isolated from a common carp from Japan showing petecchial hemorrhages on the skin and abdomen. A similar virus has also been isolated from moribund colored carp (*Cyprinus carpio*) with ulcerative dermal lesions. The investigators were able to grow the virus in epithelioma papulosum cyprini (EPC) cells and produce the same disease in carp injected with the tissue culture grown virus. Further characterization of these virus isolates was never carried out and there was no confirmation that they are, indeed, coronaviruses.

Recently, a novel virus with morphological features resembling those found in rhabdo-, corona-, and baculoviruses has been detected during the routine diagnostic screening of white bream (*Blicca bjoerkna*) in Germany. Ultrastructural studies indicated that the cell-free virions contain of a rod-shaped nucleocapsid similar to that seen in baculoviruses. Virions are bacilliform-shaped structures somewhat reminiscent of plant rhabdoviruses with an envelope containing coronavirus-like spikes. Sequence analysis has indicated that the 26.6 kbp white bream virus (WBV) contains five open reading frames, ORF1a, -1b, -2, -3, and -4, which are produced from a 'nested' set of 3′-coterminal mRNAs. The largest mRNA is of genome length. ORF1a and ORF1b form the viral replicase gene. ORF1a encodes several membrane domains, a putative ADP-ribose 1′-phospatase, and a chymotrypsin-like serine protease. ORF1b encodes the putative polymerase, helicase, ribose methyltransferase, exoribonuclease, and endoribonuclease activities. These characteristics are consistent with classification of WBV in the order *Nidovirales*. Phylogenetic analyses of the helicase and polymerase core domains indicate that WBV is more closely related to toroviruses than to coronaviruses and it has been suggested that a new nidovirus genus *Bafinivirus* be established (from bacilliform fish nidoviruses).

Togaviridae

The family *Togaviridae* comprises the genera *Alphavirus* and *Rubivirus* among the vertebrate viruses. These viruses have spherical virions, 70 nm in diameter, with a lipid envelope containing glycoprotein peplomers and a ssRNA genome which is capped at the 5′-end and polyadenylated at the 3′-end. Salmonid alphaviruses (SAVs) cause mortality in salmon and trout in Europe (Norway, France, UK, and Ireland). At least three subtypes of SAV exist: Salmon pancreas disease virus (SPDV/SAV-1) in Atlantic salmon; sleeping disease virus (SDV/SAV-2) in rainbow trout; and Norwegian salmonid alphavirus (NSAV/SAV-3). An early study on the evolutionary relationships of the alphaviruses has indicated that SAVs represent a separate and distant group in the genus *Alphavirus*.

Pancreas disease, due to SPDV (SAV-1) infection, was first described in Scotland in Atlantic salmon. It occurs during the first year at sea following transfer of young fish from freshwater tanks. The fish become anorexic and exhibit sluggish swimming activity with mortality rates reaching 10–50%. Histological examination of the affected fish has shown pancreatic acinar necrosis, and cardiac and skeletal myopathy. In rainbow trout, SDV (SAV-2) infection is characterized by the unusual behavior that fish lie on their side at the bottom on the tank. The lesion responsible for this behavior is red and white muscle degeneration. The histological lesions are similar to those observed in SPDV infection with progressive pancreatic necrosis and atrophy, mulifocal cardiomyopathy and muscle degeneration.

Caliciviridae

San Miguel sea lion virus (SMSV) is classified in the species *Vesicular exanthema of swine virus* in the genus *Vesivirus* in the family *Caliciviridae*. Investigators have found that the serotype 7 strain of the virus (SMSV-7), isolated from the opaleye fish (*Girella nigrigans*), can produce vesicular exanthema in swine. Thus, it is a virus that can jump from fish to mammals. The same serotype has also been reported in elephant seals and a sea lion trematode. Tissue culture grown serotype 5 SMSV injected into opaleye replicated to high titer 15 °C, producing $10^{7.6}$ $TCID_{50}$ per gram of spleen. There is no apparent disease in opaleye caused by this virus.

SMSV virions are nonenveloped with icosahedral symmetry and are 27–40 nm in diameter. The genome consists of a 7.5–8.0 kbp linear, positive-sense ssRNA that contains a covalently linked protein (VPg) attached to its 5′-end. The 3′-end of the genome is polyadenylated. The nonstructural polypeptides are encoded as a polyprotein in the 5′-end of the genomic RNA, while the single structural protein is encoded in the 3′-end. The identity of nonstructural polypeptides 2C (RNA helicase), 3C (cysteine protease), and 3D (RNA-dependent RNA polymerase) has been suggested by similarity to highly conserved amino acid motifs in the nonstructural proteins of the picornavirus superfamily. Phylogenetic analysis of the capsid protein region of caliciviruses including the

Sapporo-like human caliciviruses indicate that the genus *Vesivirus* includes SMVL-1, SMSV-4, SMSV-13, SMSV-15, SMSV-17, three feline caliciviruses, and the primate calicivirus Pan-1. These viruses are distant from the human caliciviruses and the rabbit caliciviruses.

Retroviridae

The family *Retroviridae* consists of two subfamilies, the *Orthoretrovirinae*, containing six genera, and the *Spumaretrovirinae*, containing only one genus. The piscine retroviruses constitute the genus *Epsilonretrovirus*, a genus established within the *Orthoretrovirinae* to include the piscine retroviruses: walleye dermal sarcoma virus (WDSV), walleye epidermal hyperplasia virus type 1 (WEHV-1), walleye epidermal hyperplasia virus type 2 (WEHV-2), and snakehead retrovirus (SnRV). The genomes of all of these viruses have been sequenced. There are also numerous reports of C-type (retrovirus-like) particles of about 110–150 nm in epidermal papillomas of European smelt (*Osmerus eperlanus*) and in cells cultured from neurofibromas of damselfish (*Pomacentrus partitus*). A retrovirus has also been suggested as the etiological agent of plasmacytoid leukemia in Chinook salmon.

The first report of a retrovirus-like agent in fish was made in 1976 in lymphosarcoma of northern pike and muskellunge (*Esox masquinongy*). The lymphosarcoma lesions contained a reverse transcriptase-like DNA polymerase with a temperature optimum of 20 °C. The first molecular evidence for a piscine retrovirus was reported in 1992 for a type C retrovirus from dermal sarcomas that form on the surface of adult walleye. These tumors are formed on the surface of adult walleye (*Stizeostedion vitreum*) in the fall and regress in the spring. The genome of the virus (13.2 kbp) was larger than all other known retroviruses at the time. Sequence analysis indicated that WDSV contained three additional open reading frames: ORF C at the 5′ terminal end; and ORF A and ORF B at the 3′ terminal end. ORF A encodes a D-cyclin homolog (retroviral cyclin) that locates in the nucleus of tumor cells in interchromatic granule clusters. ORF C encodes a cytoplasmic protein that targets the mitochondria and is associated with apoptosis. It is expressed in regressing tumors when full-length viral RNA is synthesized. The function of the protein encoded in ORF B, which is distantly related to ORF A, remains unknown. The WDSV protease cleavage sites have been identified to contain glutamine in the P2 position. The WDSV reverse transcriptase is rapidly inactivated at temperatures greater than 15 °C; a finding that is consistent with adaptation to growth in a coldwater fish species.

Two additional retroviruses have been cloned from epidermal hyperplasias on walleye. The genome sequences indicate that they are distinctly different from each other (77% identity) and from WDSV (64% identity). Walleye epidermal hyperplasia viruses 1 and 2 (WEHV-1 and -2) have genome organizations similar to WDSV. Each of the walleye retroviruses produces lesions when a cell-free filtrate from homogenized tumors is injected in naïve walleye juveniles.

Complete nucleotide sequence and transcriptional analyses of snakehead fish retrovirus have also been reported. The proviral genome is arranged in a typical 5′-LTR-gag-pol-env-LTR-3′ retrovirus organization. There are three additional ORFs: ORF1 encoding a 52 aa protein (5.7 kDa); ORF2 encoding a 94 aa protein (11 kDa); and ORF3 encoding a 205 aa protein (24 kDa). BLAST searches for possible homologs of these proteins have not produced any meaningful matches and their functions remain unknown. The SnRV genome differs from the retroviruses of walleye in that it has no ORF between the Unique region in the 5′ LTR (U5) and the gag region. The pathogenicity of SnRV has also not been determined.

In 2006, a novel piscine retrovirus was identified in association with an outbreak of leiomyosarcoma in the swimbladders of Atlantic salmon. The swimbladder sarcoma virus (SSSV) provirus is 10.9 kbp in length with a simple *gag*, *pro-pol*, *env* gene arrangement similar to that of murine leukemia viruses. Phylogenetic analysis of pol sequences suggests that SSV is most closely related to the sequenced zebrafish endogenous retrovirus (ZFERV) and that these viruses represent a new group of piscine retroviruses.

Reoviridae

Reoviruses that infect aquatic animals are grouped in the genus *Aquareovirus* in the family *Reoviridae* and are characterized by a nonenveloped double capsid shell, 11 segments of double-stranded RNA and seven structural proteins. John Plumb isolated the first finfish reovirus, golden shiner virus, GSRV, from golden shiner (*Notemigonus crysoleucas*) in 1979. Since then, several reovirus-like agents have been reported in piscine, molluscan, and crustacean hosts. Each has 11 segments of dsRNA and grow at temperatures that reflect their host range. The aquareoviruses have been divided by RNA–RNA hybridization kinetics into six groups (A–F) and several tentative species (**Table 2**). The type species of the genus *Aquareovirus* is *Aquareovirus A* which includes striped bass (*Morone saxatilis*) reovirus (SBRV). Like other reoviruses, the aquareoviruses are ether resistant and resistant to acid to pH3.

Most aquareovirus isolates are nonpathogenic or of low virulence in their host species. Grass carp virus (GCV; species *Aquareovirus C*) is the exception and appears to be the most pathogenic aquareovirus. GCV was isolated from grass carp in the People's Republic of China, causing severe hemorrhagic disease and affecting about 85% of infected fingerling and yearling populations.

[a]Grass carp reovirus and Golden shiner reovirus are variants of the same virus. Table 2 taken from *ICTVdB-The Universal Virus Database*, version 4. http://www.ncbi.nlm.nih.gov/ICTVdb/ICTVdB.

Full-length and partial genome sequences for several members of the genus *Aquareovirus* have been reported. The complete sequence is available for several isolates of GCV, golden shiner reovirus (species *Aquareovirus C*), chum salmon (*O. keta*) reovirus (species *Aquareovirus A*), golden ide (*Leuciscus idus melanotus*) reovirus (tentative species), and striped bass reovirus (species *Aquareovirus A*). Segment 6 of the guppy reovirus has been determined and threadfin (*Eleutheronema tetradactylus*) reovirus (untyped) segments 10, 6, and 11 are available. Segment 1 encodes a putative guanylyl/methyl transferase; segment 2 encodes the RNA-dependent RNA polymerase; segment 3 encodes a dsRNA binding protein with NTPase and helicase activity; segment 4, a nonstructural protein; segment 5, a NTPase core protein; segment 6, the outer capsid protein; segment 7, a nonstructural protein; segment 8, a core protein; segment 9, a nonstructural protein; segment 10, the external capsid protein; and segment 11, a nonstructural protein. Phylogenetic comparisons of the available sequences support the current taxonomic classification of the aquareoviruses and orthoreoviruses in two different genera, a distinction that was made originally on their genome segment number and specific econiches.

Birnaviridae

Members of the *Birnaviridae* have single-shelled non-enveloped capsids and genomes comprising two segments of double-stranded RNA. There are three genera in this family: *Aquabirnavirus*, *Avibirnavirus*, and *Entomobirnavirus*. The names of each genus denote the host specificity. The larger genome segment A encodes a polyprotein containing the virion capsid protein VP2, an autocatalytic protease NS, and an internal capsid protein VP3 in the physical order 5′-VP2-NS-VP3–3′ in the positive sense. There is an additional 17 kDa protein encoded in a second reading frame at the 5′-end of RNA segment A and it has been shown to be a novel anti-apoptosis gene of the Bcl-2 family. Segment B encodes the virus RNA-dependent RNA polymerase. There is no evidence of 5′-capping of any of the viral mRNAs.

The type species of the genus *Aquabirnavirus* is *Infectious pancreatic necrosis virus* (IPNV). Infectious pancreatic necrosis is a highly contagious viral disease of salmonid fish. The disease most characteristically occurs in fry of rainbow trout, brook trout (*Salvelinus fontinalis*), brown trout (*S. trutta*), Atlantic salmon, and several species of Pacific salmon. In salmonid fish, the virus causes an acute gastroenteritis and destruction of the pancreas. The signs of the disease are typically darkening, a pronounced distended abdomen, and a spiral swimming motion. The virus has also been associated with disease in Japanese eels (*Anguilla japonica*) in which it causes nephritis, menhaden (*Brevoortia tryrranus*) in which it causes a 'spinning disease', and in yellowtail fingerlings (*Seriola quinqueradiata*). A birnavirus has been associated with hematopoietic necrosis, causing high mortalities in turbot with renal necrosis, and birnaviruses have been isolated from clams exhibiting darkened gills and gill necrosis. A nontypical apoptosis has been observed in cultured cells infected by IPNV.

Transmission of the virus can occur via the feces of piscivorous birds. Fish that survive an IPNV outbreak become IPNV carriers and continue to shed the virus for life. Most IPNV isolates are antigenically related and belong to one large serogroup A. There is only one virus in serogroup B, a clam Tellina virus. More recent studies using comparisons of the deduced VP2 amino acid sequence have identified six genogroups. Genogroup 1 (equivalent to serotype A1) comprises four subgroups: genotypes 1, 2, 3, and 4. With increased culture of marine species of fish, there have been increasing reports of mortalities in yellow tail and amberjack in Japan from marine aquabirnaviruses.

Several vaccines have been developed for IPNV, including bacterially produced capsid protein and a DNA vaccine. The protein vaccine has been moderately effective in reducing the lethal effects of IPNV infection in Atlantic salmon in Norway. However, control methods still reply on quarantine and certification of eggs/fry as disease free.

DNA Viruses of Fish

Iridoviridae

In the family *Iridoviridae*, the genera *Iridovirus*, *Lymphocystivirus*, *Ranavirus*, and *Megalocystivirus* contain all of the known iridoviruses that infect fish. Their common features are icosahedral virions, 120–350 nm in diameter, that may acquire an envelope, and a viral genome consisting of one molecule of linear dsDNA of 100–303 kbp. Lymphocystis disease was one of the first fish diseases to be described due, in large part, to the characteristic giant cells observed in the connective tissue and benign nodules in the skin of plaice (*Pleuronectes platessa*) and flounder (*Platichthys flesus*). The causative agent, lymphocystis disease virus (LCDV), has been detected in more than 140 species of freshwater, estuarine, and marine fishes.

Six iridoviruses genomes have been completely sequenced, including those of the *Lymphocystis disease virus 1* (LCDV-1, genus *Lymphocystivirus*), Chilo iridescent virus (CIV, species *Invertebrate iridescent virus 6*, genus *Iridovirus*), Tiger frog virus (TFV, species *Frog 3 virus*, genus *Ranavirus*), *Infectious spleen and kidney necrosis virus* (ISKNV, genus *Megalocystivirus*), *Abystoma tigrinum virus* (ATV, genus *Ranavirus*), and Singapore grouper iridovirus (SGIV, tentative species, genus *Ranavirus*). Comparisons of the different iridovirus genomes have revealed that many genes have been conserved during evolution and, among closely related species, the gene order is well preserved. The number of genes (ORFs) in viruses of this family range from 93 (ATV) to 468 (CIV). There are 195 ORFs in LCDV-1 and 120 ORFs in GIV.

Other iridovirus diseases of fish include epizootic hematopoietic necrosis which is caused by viruses in the species *Epizootic hematopoietic necrosis virus* (EHNV, genus *Ranavirus*) in perch and rainbow trout, European sheatfish virus (ESV, genus *Ranavirus*) in sheatfish (*Silurus glanis*), and European catfish virus (ECV, genus *Ranavirus*) in catfish. ESV and ECV are classified as the same species, *European catfish virus*. *Santee–Cooper ranavirus* (SCRV) is the species name given to three iridoviruses: largemouth bass iridovirus (LMBV), doctor fish virus (DFV-16), and guppy virus (GV-6). The white sturgeon iridovirus group (WSIV) is comprised of a group of unassigned viruses that infect sturgeon in North America and Russian sturgeon (*Acipenser guldenstadi*) in Europe. Red seabream iridoviruses (RSIV) (genus *Megalocystivirus*) causes mortality in cultured juvenile red sea bream in Japan. It has also been observed in grouper in Thailand. Two goldfish iridovirus-like viruses (goldfish virus 1 and 2, GFV-1 and -2) have been isolated from swimbladder tissue culture of healthy goldfish. Electron microscopic observations of iridoviruses in the cytoplasm of erythrocytes (viral erythrocytic necrosis, VEN) have been observed in many marine and anadromous bony fish.

Herpesviridae

Herpesviruses have been isolated from channel catfish (*Ictalurus punctatus*), common and koi carp (*C. carpio*), common goldfish (*Carassius auratus*), eel (*Anguilla* spp.), rainbow trout, masou salmon, lake trout (*S. namaycush*), sturgeon, walleye, and Japanese flounder. Channel catfish virus is the only fish herpesvirus assigned to the genus, *Ictalurivirus*, and this genus is not assigned to any of the three subfamilies (*Alphaherpesvirinae*, *Betaherpesvirinae*, and *Gammaherpesvirinae*) of the family *Herpesviridae*. The other fish herpesviruses, cyprinid herpesviruses 1 and 2 (CyHV-1 and CyHV-2), koi herpesvirus (CyHV-3), salmonid herpesvirus 1 and 2 (SalHV-1 and -2), eel herpesvirus (Anguilla herpesvirus, AngHV-1), and the acipenserid or white sturgeon herpesviruses remain as unassigned members of the family *Herpesviridae*. Electron micrographic evidence of herpesviruses has been found in sharks, eels, pike, flounder, perch, angelfish, grouper, and other fish.

The genomes of fish herpesviruses range in size from 134 to 295 kbp and the physical organization of the genome varies sufficiently to suggest that they have evolved separately from the herpesviruses of birds and mammals. The genome of *Ictalurid herpesvirus 1* (IcHV-1) or Channel catfish virus has a unique long (UL) region flanked by a substantial direct repeat that is similar to the betaherpesviruses of the genus *Roseolovirus*. The SalHV-1 genome is more similar in organization to the alphaherpesviruses of the genus *Varicellovirus* with a unique short (US) region flanked by a unique long (UL) region which is not flanked by a repeat. Phylogenetic comparisons of the individual genes including the DNA polymerase gene, the major capsid protein gene, the intercapsomeric triplex protein gene, and the DNA helicase gene indicate that the three cyprinid viruses are closely related and are distinct from IcHV-1.

These viruses are serious pathogens in their respective hosts. IcHV-1 outbreaks among juvenile catfish result in mortality and fish that survive the infection become carriers. The cyprinid herpes viruses produce a systemic disease with lesions in hematopoietic tissue in goldfish and papillomas on the caudal regions in koi carp. SalHV-2 was isolated from the ovarian fluid of masou salmon and it induces syncytia formation and lysis of

infected cells. Epithelial papillomas are induced in young masou salmon injected with tissue culture-grown virus. The acipenserid herpesviruses cause serious losses in hatchery-reared young of white sturgeon (*Acipenser transmontanus*).

Adenoviridae

Adenovirus particles have been observed in lesions in a number of fish species and have been isolated from white sturgeon, dabs (*Limanda limanda*), cod, and Japanese red sea bream. The white sturgeon adenovirus has been isolated in tissue culture and its hexon protein and protease gene sequences are available. Based on an alignment of partial DNA polymerase gene sequences of the sturgeon adenovirus and 24 other adenovirus types, it is clear that the fish adenovirus is distantly related to the other adenoviruses, and might constitute a fifth genus of the *Adenoviridae*.

Adenovirus infection in cod produces an epidermal hyperplasia. In California, white sturgeon adenovirus affects young fish in hatcheries. Infection is characterized by epithelial hyperplasia and enlarged cell nuclei. A lympholeukemia has been observed in red sea bream and papillomas have been observed in dabs infected with adenoviruses.

Glossary

Argasid Soft-skinned tick, member of the family *Argasidae*.
Arthropod Any member of the phylum Arthropoda, including insects and arachnids (spiders, scorpions, ticks, and mites).
Culicoid midge Blood-sucking midge of the genus *Culicoides*.
Instar Stage in the life cycle of arthropods, for example, egg, larva, nymph, and adult in mosquitoes; egg, larva, nymph, and adult in ticks.
Ixodid Tick with a hardened shell or scutum.
Microhabitat The environmental niche in which an organism is found.
Phlebotomine fly Blood-sucking sandfly of the genus *Phlebotomous*.
Phylogenetics The study of the genetic relatedness of organisms.
Transovarial transmission of virus Passage of virus infection through the eggs of arthropods to the succeeding generation, thus ensuring perpetuation of the virus.
Vectors Blood-sucking arthropods (mosquitoes, midges, sandflies, and ticks) which transmit viruses from one vertebrate to another.
Virion A complete virus particle with its protein coat and core of DNA or RNA nucleic acid.

Introduction

Approximately 94 viruses are currently assigned to three genera (*Flavivirus, Pestivirus*, and *Hepacivirus*) within the family *Flaviviridae* (L. *flavus* = yellow, from the type species *Yellow fever virus*, which causes jaundice); the number of viruses in the family changes with periodic discovery of new members or revision of the taxonomic status of existing viruses. Diseases of major medical and veterinary importance caused by hepaciviruses and pestiviruses are discussed elsewhere in this encyclopedia, while this article summarizes aspects pertaining only to the veterinary importance of members of the genus *Flavivirus*.

Viruses of the *Flaviviridae* have spherical virions 40–60 nm in diameter, with a tightly applied lipid envelope incorporating envelope (E) protein spikes which are glycosylated in pestiviruses and flaviviruses. The genomes consist of a single, linear molecule of positive-sense, single-stranded RNA (ssRNA), ranging in size from approximately 9.5 kbp in hepaciviruses, to 10.7 kbp in flaviviruses, and 12.5 kbp in pestiviruses. Replication takes place in the cytoplasm, with morphogenesis, transport, and maturation of virions occurring in cell membrane vesicles. A single open reading frame (ORF) in the genome is translated directly into a polyprotein which is cleaved into structural proteins, the RNA-associated internal capsid or core (C) protein, envelope proteins (E1, E2), and a membrane (M) protein, plus seven nonstructural proteins which exhibit viral polymerase and other enzymatic activities. The E proteins mediate binding of virus to host cells, are responsible for the hemagglutinating property exhibited by most flaviviruses, and constitute the major antigenic determinants of protective immunity. Viruses of the three genera are not closely related, with less than 30% nucleotide sequence homology and an absence of antigenic cross-reactivity, but they share genome organization and replication strategies. Viruses of the genera *Hepacivirus* and *Pestivirus* are most closely related structurally, and have in common a lack of arthropod vectors and the tendency to cause persistent infection in their vertebrate hosts.

The 82 recognized or tentative members of the genus *Flavivirus* include two inherent viruses of mosquitoes, cell fusion agent virus (CFAV) and Kamiti River virus (KRV), which have no known medical or veterinary significance and which may be assigned to a new genus, plus Tamana bat virus from Trinidad, which may also be assigned to a new genus. Most recently, there has been molecular identification of a tick-associated agent, Ngoye virus from Senegal, which has not as yet been successfully cultured in a laboratory host system, has no known medical or veterinary significance, and is only distantly related to existing flaviviruses. The remaining flaviviruses are antigenically related to each other and were originally assigned to serogroups on the basis of close antigenic affinities. Recent classification of the viruses based on phylogenetic analyses shows remarkable concordance with antigenic classification, and with the biological properties of the viruses, such as vertebrate host and arthropod vector associations.

About 21% of the members of the genus have been isolated from mammals only and have no known vectors (NKV viruses), a further 51% are usually transmitted by mosquitoes, and the remaining 28% appear to be transmitted principally by ticks, although definitive demonstration of transmission by arthropod vectors has been reported in a proportion of instances only. Depending on which genes are subjected to phylogenetic analysis, different conclusions may be reached with regard to the evolution of the flaviviruses, but from limited analyses of whole genome sequences it appears that NKV viruses diverged from a putative ancestor before mosquito-borne viruses, and that tick transmission is a recently acquired trait within the genus. Many flaviviruses were discovered in the course of surveys conducted on vertebrate and arthropod populations, rather than in the investigation of disease syndromes, and consequently many of the viruses have no known medical or veterinary significance. From the genetic distance which exists between the recently discovered Ngoye virus and other members of the genus, and between existing mosquito-borne viruses, it has been extrapolated that several thousand flaviviruses remain to be discovered.

Various mechanisms are postulated to ensure the persistence of arboviruses through prolonged periods of vector inactivity during winters and dry seasons, including the migration of infected vertebrate hosts, hibernation of infected adult vectors, and passage of virus through the eggs of vectors to infect the succeeding generation, so-called transovarial transmission of infection, which generally occurs with low frequency. Unlike mosquitoes, ticks feed on vertebrates in different stages (instars) of their life cycles, as larvae, nymphs, and adults, so that even in the absence of transovarial transmission of infection the perpetuation of virus can be ensured by the long intervals which intervene between the feeding of successive instars on different hosts.

Viruses transmitted by mosquitoes often cause sporadic infections which may pass unrecognized in endemic areas, but they are capable of causing explosive outbreaks when exceptionally heavy rainfall creates favorable breeding conditions for the vectors, or human manipulation of the environment, such as the building of dams and irrigation schemes, or the implementation of intensive livestock production systems, results in the juxtaposition of susceptible human or farm animal populations with vectors. Tick-borne virus infections tend to occur at endemic level within areas of vector distribution, and larger outbreaks are less immediately linked to climatic events which may favor population explosions of the wild hosts of immature ticks, but human intervention, such as changes in livestock

farming systems, can also precipitate epidemics. A few arthropod-borne flaviviruses are named for the disease syndromes with which they are associated, but most are named for the geographic location from which the initial isolate was obtained.

Mosquito-Borne Flaviviruses Causing Livestock or Wildlife Diseases

Japanese Encephalitis Virus

Japanese encephalitis virus (JEV) was first isolated in 1935 in Japan as a cause of encephalitis in humans. Severe outbreaks of human disease occur at intervals in India, China, Korea, and Japan, and lesser outbreaks or sporadic cases are recorded in Nepal, Bangladesh, Sri Lanka, Laos, Cambodia, Vietnam, the Far East provinces of the Russian Federation, Thailand, Malaysia, Singapore, Philippines, Indonesia, Papua New Guinea, Taiwan, Guam, Saipan, and Myanmar. There are four genotypes of the virus, but they are all cross-protective. The virus is transmitted by *Culex tritaeniorhyncus* and other culicine mosquitoes and circulates between the mosquitoes, water birds, particularly egrets, herons and ducks, and domestic pigs. Overt outbreaks of disease are associated with rainfall and the irrigation of rice fields. The virus infects a wide range of vertebrates, including donkeys, cattle, and dogs, but most animals do not manifest disease. There is fetal wastage and abortion in sows. Humans and horses are incidental hosts which develop encephalitis, but play no significant role in the circulation of the virus. Tens of thousands of human infections occur each year, and while less than 1% of infected persons develop encephalitis the death rate is high in such patients. Case fatality rates may exceed 50% in horses with encephalitis. The virus is not known to cause disease in wild vertebrates, but bats can circulate virus following experimental infection, and low prevalences of antibody to JEV have been found in reptiles and amphibians.

St. Louis Encephalitis Virus

St. Louis encephalitis virus (SLEV) was isolated in 1933 from human brain as the causative agent of a large outbreak of encephalitis in St. Louis, Missouri, and was subsequently found to be transmitted by culicine mosquitoes, which are capable of breeding in drainage water in urban settings. The virus is widely distributed in North, Central, and South America, but the disease is seen mainly in the USA where it was considered to be the most important arbovirus pathogen prior to the introduction of West Nile virus (WNV) in 1999. There is some regional variation in the mosquitoes involved, but the main vectors are members of the *Cx. pipiens* complex, plus *Cx. tarsalis* and *Cx. nigripalpus*. Human infection with SLEV is usually asymptomatic but a low proportion of patients develop encephalitis with an approximately 10% case fatality rate. Outbreaks of varying magnitude occur at irregular intervals throughout the USA, but there are regional differences in occurrence of the infection depending on host and breeding-site preferences of the mosquito species concerned. Asymptomatic infection occurs in domestic animals such as horses, cattle, goats, sheep, pigs, cats, dogs and poultry, as well as in wild birds and small mammals including raccoons, opossums, rodents, and bats, but only birds are thought to play a significant role in the circulation of the virus. SLEV was isolated from the brain of a gray fox with encephalitis, and forest mammals including sloths are thought to be involved in transmission cycles in South America.

West Nile Virus

Following the intial isolation of WNV from a febrile patient in Uganda in 1937, sporadic cases and outbreaks of benign febrile disease were recorded in humans in Africa, the Near East and Asia, with the largest outbreaks occurring in Israel in 1950–54 and 1957, and in South Africa in 1974. It was found that WNV is widely endemic in southern Africa in localities where the vectors, ornithophilic (bird-feeding) culicine mosquitoes, and avian hosts of the virus are present, such as at dam sites with reed beds and heronries. Outbreaks of human infection, which occur when high rainfall or hot weather favors mosquito breeding, are associated with high seroconversion rates in wild birds, and 13 species of birds in South Africa were found to support replication of the virus without developing disease. It was deduced that the widespread dispersal of the virus was associated with migrating birds. Cattle and sheep appeared to undergo inapparent infection and could also theoretically serve as hosts for infection of mosquitoes. Subsequently, limited experimental evidence was obtained to indicate that WNV is capable of causing abortion in pregnant sheep.

The occurrence of meningoencephalitis was first observed in elderly WNV patients in Israel in 1957, and subsequently also in young children in India. The occurrence of horse encephalitis was recognized in Egypt in 1962, and in 1962–66 outbreaks of meningoencephalitis were observed in both humans and horses in France. There was a marked increase in the frequency and severity of outbreaks of human disease during the 1990s, often involving horses as well, and including epidemics in Algeria, Romania, Morocco, Tunisia, Italy, Russia, France, and Israel. Moreover, the outbreaks in Romania and Israel were characterized by concurrent mortality in birds. The vectors of WNV included *Cx. univitattus* and *Cx. antennatus* in Africa and Europe, members of the *Cx. pipiens* complex in Europe and Israel, and members of the *Cx. vishnui* complex plus *Cx. fatigans* in Asia.

The presence of WNV in the Western Hemisphere was first recognized in New York in 1999, and over the next few years it spread rapidly throughout the country and beyond into Canada and South America. Vectors in North America included members of the *Cx. pipiens* complex, plus *Cx. restuans*, *Cx. tarsalis*, and *Cx. nigripalpus*. The virus circulating in the USA was found to be genetically most closely related to a WNV isolate associated with goose mortality in Israel in 1998, suggesting that the virus was imported into America from the Near East, either in an infected bird, mosquito, human, or other animal, although the exact mechanism of the introduction will probably remain unknown.

In North America, WNV infection was confirmed in more than 300 species of birds, with death rates approaching 100% in corvids (crows, magpies, and jays), and with robins constituting important hosts for the infection of the mosquito vectors. It is notable that the virus spared African bird species in the New York zoo where deaths of local species were first observed. Infection was also recorded in 30 species of mammals, reptiles, and amphibians. Approximately 10% of infected horses manifested clinical illness, with a high proportion of these developing fatal encephalitis. Vaccine for horses became available in 2005. Although fatal infections were recorded in dogs and a wolf, infection rates were low in cats and dogs. Fatal disease was observed in farmed alligators in the USA and Mexico, with infection resulting from the feeding of infected horse meat, and also from transmission between alligators in crowded conditions. Serological evidence of infection was also found in small wild animals, such as raccoons, opossums, and squirrels, but the pathogenicity of the virus for these hosts is uncertain. Serological evidence of infection was obtained in farmed Nile crocodiles in Israel in the absence of disease. The Kunjin strain of WNV transmitted by *Cx. annulirostris* mosquitoes in Australia generally causes febrile illness in humans, seldom encephalitis, and was confirmed to be associated with encephalitis in horses on one occasion only.

The increase in the frequency of neurologic infections, and the occurrence of human, horse, and bird fatalities in the Northern Hemisphere, raised the question of whether there had been a change in the pathogenicity of WNV. Phylogenetic analyses revealed that WN isolates fell into two lineages. Lineage 1 included isolates from Africa north of the equator, Europe, Asia, and North America, with Kunjin virus from Australia constituting a subtype within this lineage. Lineage 2 consisted solely of viruses from Africa and Madagascar. The findings were interpreted to support the emergence of exalted virulence in lineage 1, with lineage 2 isolates considered to be associated with endemic infection of low virulence in Africa. However, WNV belonging to lineage 2 has recently been isolated from a goshawk with fatal encephalitis in Hungary, and three additional lineages of the virus have been described from the Czech Republic, Georgia, and India. Moreover, despite the apparently low level of virus activity observed in southern Africa in recent years, WNV was isolated from the brain of a suspected rabid dog in Botswana (initially described as having an infection with Wesselsbron virus), and in South Africa from humans and a foal with encephalitis, plus an ostrich chick in a commercial flock where extensive mortalities occurred. Experiments in mice confirmed that neuroinvasive WNV strains occur within both lineage 1 and 2. Thus, it is possible that the virulence of WNV in southern Africa may previously have been underestimated, while the perceived enhanced virulence of the virus in recent epidemics in the Northern Hemisphere may partly be due to the emergence or re-emergence of existing strains of WNV in geographic locations with immunologically naive populations, high medical alertness, and active surveillance programs.

Israel Turkey Meningoencephalomyelitis Virus

A disease caused by Israel turkey meningoencephalomyelitis virus (ITV) infection in turkeys was first observed in Israel in 1958 and the causative virus isolated in 1959. ITV was later found to be transmitted by culicine mosquitoes, but was also isolated from culicoid midges, and phlebotomine sandflies were shown to be capable of transmitting the virus. In 1978 the virus was isolated as a cause of disease of turkeys in South Africa. The virus has not been found in any other country, and disease has only been reported in turkeys. The disease generally occurs seasonally, only in birds older than 10 weeks, and it is characterized by progressive paresis and paralysis, with morbidity and mortality rates ranging from 15% to 80%. Turkey breeder hens exhibit a severe drop in egg production. Vaccines are available.

Sitiawan Virus

Sitiawan virus (SITV) was recently isolated as a cause of deaths of chick embryos and broiler chickens in Malaysia. It is closely related to the mosquito-borne Tembusu virus, which has no known medical or veterinary significance.

Wesselsbron virus

Wesselsbron virus (WESSV) was identified in 1955 in South Africa as a cause of deaths of newborn lambs in a flock where a modified live vaccine against the mosquito-borne Rift Valley fever virus (RVFV) (not a flavivirus) had been administered 2 weeks previously. There was concern that the RVFV vaccine may have caused the deaths, but it was concluded that the new virus, which also proved to be transmitted by *Aedes* species mosquitoes of the subgenera *Ochlerotatus* and *Neomelanoconion*, occurred in outbreaks together with RVFV and caused similar disease in sheep,

cattle, and goats, namely, deaths of young animals and abortion in pregnant animals. Consequently, an attenuated WESSV vaccine was developed by serial intracerebral passage of virus in infant mice, and this was marketed for use together with RVFV vaccine on nonpregnant animals. During extended outbreaks of RVF in South Africa and Namibia in 1974–76 some 13.9 million doses of the live WESSV vaccine and 22 million doses of live RVFV were used indiscriminately on livestock, with resultant widespread occurrence of abortions and congenital malformations in sheep and cattle. It was confirmed experimentally that both of the vaccines were abortigenic and teratogenic. However, it subsequently became clear that WESSV is more widely endemic in southern Africa than RVFV, and although sporadic isolations of virus have been made from livestock in South Africa and Zimbabwe, mainly in association with disease of newborn lambs and calves, the virus has not been incriminated as the cause of large outbreaks of disease in farm animals, nor has a veterinary problem been described elsewhere. The vaccine, which confers lifelong immunity, continues to be marketed for use in nonpregnant sheep and goats.

Altogether, WESSV has been isolated from livestock and a gerbil in southern Africa, a camel in Nigeria, mosquitoes in South Africa, Zimbabwe, Uganda, Kenya, the Central African Republic (CAR), Cameroon, Ivory Coast, Senegal, Guinea and Thailand, a tick in CAR, naturally infected humans in South Africa, Senegal, and CAR, and from human laboratory infections in South Africa, Uganda, Nigeria, Senegal, CAR, and the USA. In addition, antibody has been found in humans and/or livestock in Malawi, Zambia, Botswana, Namibia, Angola, Mozambique, and Madagascar. The principal vectors of the virus appear to be aedine mosquitoes, and although the virus has been isolated from a tick, there is no evidence that ticks play a significant role in transmission of the virus. The few human infections recorded in South Africa were acquired from contact with infected animal tissues or mosquito bite, while human infections reported in Senegal and CAR seem to be consistently associated with mosquito bite. The virus generally causes benign febrile illness in humans, but a patient who acquired laboratory infection from the splashing of virus into an eye developed encephalitis from which he recovered without sequelae.

It cannot be excluded that WESSV or various other flaviviruses could emerge as important pathogens under particular circumstances, as occurred with WNV in North America in 1999. In this connection it should be noted that Bagaza virus has been isolated from aborted cattle fetuses on three occasions in South Africa, that WNV and Banzi virus were shown to cause abortion in experimentally infected pregnant sheep, and that Usutu virus, initially isolated from mosquitoes, a rodent and birds in the context of surveys in Africa, emerged as a cause of bird deaths in Austria in 2001.

Yellow Fever Virus

Descriptions of disease compatible with yellow fever date back to 1492. However, many medical conditions were confused in early records, and the name yellow fever was first applied to a fatal disease of humans in the Caribbean region in 1750. Shortly thereafter, the presence of the disease was recognized in South America and West Africa. Over the next 150 years the virus, introduced by infected people on ships, caused epidemics in many port cities in North America and Europe. From 1900 onwards the Walter Reed commission from the USA investigated yellow fever in Cuba and, using American military volunteers, demonstrated that the disease could be transmitted from person-to-person by *Ae. aegypti* mosquitoes, and that the infection was caused by a filterable agent present in the blood of patients (filtration was an early method used to distinguish viruses from bacteria). It was not until 1927 that yellow fever virus (YFV) was isolated in a laboratory host system, rhesus monkeys. Meanwhile, the identification of the *Ae. aegypti* vectors, which breed in small volumes of water, had facilitated the implementation of mosquito control methods which virtually eliminated circulation of YFV in urban settings. Initially, there was speculation as to whether YFV had originated in Africa or South America, but it was concluded that the virus and *Ae. aegypti* mosquitoes had been translocated from Africa in ships centuries ago. The occurrence of outbreaks of the disease on ships was well documented.

Resurgence of urban yellow fever in South America led to the discovery of jungle or sylvatic circulation of the virus in 1932. In South America, YFV circulates in the forest canopy between monkeys and *Haemagogus* species mosquitoes. Persons who live near or enter forests acquire infection and introduce it into urban environments where epidemics are generated by the circulation of YFV between humans and *Ae. aegypti* mosquitoes. In Africa, mosquitoes such as *Ae. africanus* transmit YFV between primates at forest canopy level, while mosquitoes which feed at intermediate levels, including *Ae. bromeliae* and members of the *Ae. furcifer-taylori* group, serve as link hosts to spread infection to humans which in turn serve to initiate urban transmission cycles involving *Ae. aegypti* mosquitoes. South American primates including tamarins, marmosets and howling, squirrel, owl, and spider monkeys undergo severe infection with variable mortality, while African monkeys and apes generally undergo viremic infection without overt illness. This was interpreted to indicate that there had been a longer period of co-evolution of YFV with African primates, but African YFV isolates were found to be of reduced virulence for neotropical monkeys. Asian monkeys are susceptible to severe and fatal YFV infection. Birds, reptiles, and amphibia are resistant to infection, and although several mammals including hedgehogs are capable of developing

viremia, it appears that they have limited exposure to known vectors.

Effective vaccines were developed in the 1930s and used extensively in conjunction with mosquito control to reduce the occurrence of the human disease. However, the existence of sylvatic transmission cycles precludes eradication of the virus, and since 1980 there has been a marked resurgence of the disease in Africa with outbreaks being recorded in countries extending from Senegal in the north, to Angola in the south, and eastwards to Sudan, Ethiopia, and Kenya. No recent urban outbreaks have been recorded in South America, but fairly extensive outbreaks involving sylvatic vectors have occurred in Peru and Brazil.

Many of the remaining mosquito-borne flaviviruses are believed to circulate in birds and although a few, including Rocio, Spondweni, and Zika, have been associated with human disease on occasion, they have no known veterinary significance. It should be noted, however, that many of the flaviviruses which are pathogenic for humans produce symptomatic infection in a minority of people, and it can be surmised that infections which produce similar low morbidity in farm animals are likely to pass unrecognized.

Tick-Borne Flaviviruses

It has emerged from recent phylogenetic analyses that the tick-borne flaviviruses comprise three groups: a seabird group which includes three viruses with no known medical or veterinary significance, a Kadam virus group containing a single virus known only to have been isolated from ticks removed from cattle in Uganda and a camel in Saudi Arabia, but which represents a distinct evolutionary lineage, and the so-called mammalian tick-borne group of viruses. Within the mammalian group Gadgets Gully, Royal Farm, and Karshi viruses and are more distantly related to others and are known only to have been isolated from ticks, while the remaining viruses, which were formerly clustered together in a tick-borne encephalitis antigenic complex, include important pathogens of humans and livestock. However, genetic differences between some of these latter viruses are smaller than those which exist between other flaviviruses, and hence they have been tentatively designated as types and subtypes of a proposed tick-borne encephalitis virus (TBEV) species.

Powassan Virus and Deer Tick Virus

Powassan virus (POWV) was first isolated as a cause of fatal encephalitis in a child in Ontario, Canada, in 1958. The virus was subsequently found in western Canada, and northeast, north-central and western USA. The principal vector was found to be the tick *Ixodes cookei*, and the main host for the tick and virus is believed to be the woodchuck or groundhog (*Marmota monax*). Other *Ixodes* species and squirrels have also been implicated in the circulation of the virus, and there have been isolations from other ticks including *Dermacentor andersoni*. Twelve human cases of encephalitis with four fatalities have been reported in North America. Antibody has been found in a range of animals, and virus was isolated from two dead foxes, although it was not clear that the virus had caused their deaths. The virus was experimentally shown to be capable of causing encephalitis in horses. Reportedly, POWV was isolated in 1978 from the blood of a person who had been bitten by a tick in the Maritime Province (Primorsky) in the Far East of the former Soviet Union (currently the Russian Federation), and later the virus was isolated from *Ixodes persulcatus* and other ticks and mosquitoes, and antibodies were found in birds in Primorsky. In 1996, deer tick virus (DTV) was isolated from deer ticks, *Ixodes scapularis*, in the eastern USA and found to be closely related to POWV. The white-footed mouse (*Peromyscus leucopus*) is thought to be the main host for the tick and virus, although other mammals, particularly white-tailed deer, are important hosts for the tick. As yet, no disease associations have been made for DTV. Although POWV and DTV are closely related, the results of recent phylogenetic studies confirm that the viruses circulate independently. However, the studies did not include POWV isolates from the western USA or the Russian Federation.

Kyasanur Forest Disease Virus

Kyasanur forest disease virus (KFDV) was discovered in 1957 as a cause of fatal febrile disease of humans in Karnataka State, India. The vectors are ticks of the genus *Haemaphysalis*, particularly *H. spinigera*, and two species of *Ixodes* ticks, but the virus has also been isolated from the argasid (soft-skinned) tick *Ornithodoros crossi*. Rodents are suggested to be the main hosts of the virus. About 500 human cases of the disease are recorded each year in Karanataka State, with a mortality rate of 5–10%. Infection occurs mainly in people who enter forests to gather wood, and the disease is seasonal with tick activity. Fatal disease occurs in langur and macaque monkeys in the forests, but no disease manifestations have been recorded in domestic animals. The virus has been isolated from rodents, shrews, and bats.

Omsk Hemorrhagic Fever Virus

Omsk hemorrhagic fever virus (OHFV) was isolated in 1947 from the blood of a patient with hemorrhagic disease in western Siberia in the former Soviet Union. The disease was first observed in 1941, and large numbers of cases were recorded in 1945–49. Since that time only sporadic cases have been recognized in the Omsk, Novosibirsk,

Kurgan, and Tjumen regions of western Siberia. The disease affects mostly muskrat trappers and their families. Muskrats, or musquash (*Ondatra zibethicus*), are large rodents which are trapped for their fur. They are indigenous to North America and were introduced into Siberia in 1925. No equivalent virus or disease has been found in North America. The principal vector of the virus in Siberia was found to be the tick *Dermacentor reticulatus* (syn. *D. pictus*) but the virus was also isolated from *D. marginatus* and other ticks and mites. Muskrats and local voles, some of which undergo benign infection, serve as reservoir hosts for the infection of ticks. Muskrats live in swamps, and virus which is present in the excretions of infected muskrats, or leaches into water from dead muskrats, can infect other muskrats or humans. OHFV was also found in mosquitoes and antibody in water birds, but these do not appear to play a significant role in circulation of the virus. Humans acquire infection mainly from contact with infected muskrat tissues, but also from infected water, or from tick bite.

Tick-Borne Encephalitis Virus

A human encephalitis syndrome was recognized in the far eastern provinces of the former Soviet Union at least as far back as the late nineteenth century, and has been known under a variety of names including Russian spring–summer encephalitis and Far Eastern tick-borne encephalitis. The causative agent, now named tick-borne encephalitis virus-Far Eastern subtype (TBEV-FE), was isolated from human patients in 1937 and later from its *Ixodes persulcatus* tick vectors. The virus occurs in the Primorsky, Khabarovsk, Krasnoyarsk, Altai, Tomsk, Omsk, Kemerovo, Western Siberia, Ural and Priural regions of the Russian Federation, China, and eastern Europe. After World War II the existence of a similar disease was recognized in several countries in Central Europe and adjacent parts of the Soviet Union, and a second virus, tick-borne encephalitis virus-European subtype (TBEV-Eu), was isolated from humans and *Ix. ricinus* ticks. Slight antigenic differences were shown to occur between the two viruses, and TBEV-Eu had human case fatality rates of 0.5–2.0%, in contrast to 5–20% for TBEV-FE. It has since been established that TBEV-Eu occurs in Albania, Austria, Belarus, Bornholm Island of Denmark, Bosnia, Bulgaria, China, Croatia, Czech Republic, Estonia, Finland, France, Germany, Greece, Hungary, Italy, Kazakhstan, Latvia, Lithuania, Norway, Poland, Romania, Russia, Slovakia, Slovenia, Sweden, Switzerland, Turkey, and Ukraine, although the distribution tends to be focal, dependent on suitable tick habitat. The *Ix. persulcatus* tick vector of TBEV-FE is distributed across nontropical Asia from Japan to eastern Europe, where there is overlap with the distribution of the *Ix. ricinus* vector of TBEV-Eu which extends across western Europe to the British Isles and Ireland. Other tick species play a minor role in transmission of the TBEV viruses. Phylogenetic analyses in the 1990s revealed the existence of a third subtype of virus, tick-borne encephalitis virus-Siberian subtype (TBEV-Sib), which is transmitted by *Ix. persulcatus* in the Irkutsk region of Siberia and has similar virulence for humans as does TBEV-FE. It was deduced that the TBEVs evolved in a cline in a westerly direction across the Eurasian continent over the past few thousand years. However, TBEV-FE and TBEV-Sib infections have recently been detected in Europe.

All three subtypes of TBEVs are believed to circulate between ticks and small vertebrates such as field mice and voles which undergo benign viremic infection. Antibody is also found in larger vertebrates such as squirrels, deer, badgers, and farm animals which develop low-grade viremia and are believed not to constitute a significant source of virus for infection of ticks. About 5000–10 000 cases of human disease are recorded each year, mainly in the Russian Federation, with the lowest incidence occurring in Austria where there is widespread use of vaccine. Humans acquire TBEV infection from tick bite, or from the ingestion of unpasteurized infected milk of sheep, goats, and cows. Less than 5% of humans develop symptomatic infection, but high death rates occur in patients who develop nervous disease. There may be neurological sequelae in those who recover, and a few patients develop chronic infections. A fatal hemorrhagic syndrome of humans has been described in the Novosibirsk region of Siberia in association with TBEV-FE infection. Recently, fatal TBEV-Eu infection was reported in captive monkeys in Germany which were inadvertently exposed to ticks.

Louping Ill Virus

Descriptions of a sheep disease conforming to louping ill (Scottish dialect *louping* = leaping) date back more than two centuries in Scotland, but it was not until 1929 that the causative virus was isolated, and shortly thereafter shown to be transmitted by the tick *Ix. ricinus*. Other species of ticks can be infected but do not appear to play a significant role in the transmission of the virus. Louping ill virus (LIV) occurs in hill sheep farming areas of Britain and Ireland where there is suitable microhabitat for the ticks. Phylogenetic evidence suggests that the virus was probably originally introduced into Ireland from western Europe as a result of the livestock trade, and successively evolved as Louping ill virus-Ireland (LIV-Ir), and Louping ill virus-British (LIV-Brit) as it spreads through Wales, England, Scotland, and into Norway.

LIV causes fatal encephalomyelitis in a proportion of sheep depending on age and predisposing factors, including concurrent infection with agents such as the tick-borne parasite *Ehrlichia phagocytophila*. In areas with high challenge

rates the disease is seen most frequently in lambs once they have lost their maternal immunity, but in areas with low tick burdens primary infection and disease may be seen in sheep of all ages. Infection is less frequently associated with disease in cattle, horses, pigs, farmed red deer, dogs, red grouse, and humans. Infection also occurs in roe deer, mountain hares, feral goats, voles, shrews, and field mice. The only recognized disease problem in wild vertebrates exists in red grouse (*Lagopus lagopus scotticus*), which have a commercial hunting value, and it has been demonstrated that the chicks can acquire infection from ingesting ticks. Sheep and red grouse are the only hosts which develop sufficiently intense viremia for the infection of ticks. However, it has been shown experimentally that the so-called phenomenon of nonviremic transmission of infection between ticks feeding on the same host, facilitated by factors present in tick saliva, occurs with LIV-infected and noninfected ticks co-feeding on mountain hares, which are important hosts of *Ix. ricinus* ticks. The same phenomenon has been demonstrated with TBEV-Eu, and this implies that there should be reassessment of the role of vertebrate hosts in the circulation of tick-borne viruses.

Spanish sheep encephalitis virus, Turkish sheep encephalitis virus, and Greek goat encephalitis virus are recently recognized subtypes of TBEV analogous to LIV that have been associated with encephalitis in sheep and goats in Spain, Greece, Bulgaria, and Turkey, but their distribution and epidemiology are as yet incompletely understood.

Negishi Virus

A virus given the name Negishi virus (NEGV) was isolated in 1948 from a cerebrospinal fluid sample from a child near Tokyo with suspected Japanese encephalitis, and was found to be antigenically related to the tick-borne encephalitis group of flaviviruses. There were no further isolations of NEGV in Japan and recently the virus was found to be genetically closely related to LIV. However, in 1993 a virus was isolated from a patient with encephalitis in Hokkaido, the northern island of Japan where *Ix. persulcatus* ticks occur, and subsequently the virus was also obtained from ticks and blood samples from dogs in Hokkaido. The new isolates proved to be phylogenetically most closely related to TBEV-FE.

Glossary

Cirrhosis Disease of the liver, with fibrosis and distortion of the cellular architecture.
Enzootic A disease or maintenance transmission cycle which occurs in a continuous manner among nonhuman animals within a certain geographic zone.
Epizootic Above average activity or occurrence of disease or pathogenic agent among nonhuman animals.
Sylvatic Located in forested regions.
Thrombocytopenia A reduction in the normal quantity of circulating blood platelets.
Zoonosis A disease of animals communicable to man.

General Features

The family *Flaviviridae* includes three genera, *Flavivirus, Pestivirus,* and *Hepacivirus,* that together comprise approximately 80 known viruses (**Table 1**), many of which cause diseases in human or animal hosts. Viruses in these genera are antigenically distinct from viruses in other genera and overall sequence homology is approximately 20%. The flaviviruses constitute the largest genera within the family, including arthropod-borne viruses that cause encephalitis and hemorrhagic fever. Pestiviruses exhibit a host range that includes pigs and ruminants. Hepaciviruses cause chronic liver disease in humans. Flaviviruses were originally classified as the 'group A' members of the family *Togaviridae*, distinguished serologically from 'group A' arboviruses (e.g., equine encephalitis viruses) but later assigned as constituting a unique family of viruses. Although vector associations together with antigenic properties previously served to classify the *Flaviviridae*, modern taxonomy based on nucleotide sequencing has been used to establish their phylogenetic and evolutionary relationships.

Members of the *Flaviviridae* are enveloped viruses which share a common genome organization and replication strategy. Their virions are small, spherical particles containing the capsid–genome complex and membrane-associated envelope proteins, which confer antigenic properties. The genomes are small, single-stranded, plus-sense RNA molecules ranging in size from 9.6 to 12.3 kbp. Viral proteins are encoded within a single long open reading frame that contains the structural proteins, followed by nonstructural proteins (protease(s), RNA helicase, RNA-dependent RNA polymerase (RdRp), other enzymatic activities involved in RNA replication, and several small hydrophobic membrane proteins).

Flaviviruses and pestiviruses exhibit generally broad cellular host range *in vitro*, whereas growth of hepaciviruses is very restricted. Entry of viruses into host cells occurs by receptor-mediated endocytosis, requiring a low pH-dependent fusion activity of the major envelope proteins. Cellular receptors involved in the entry process have been difficult to definitively identify. Viral replication occurs in association with intracellular membranes via a negative-strand RNA intermediate. Characteristic ultrastructural changes are induced in the membranes. Mature viruses are generated by budding through host intracellular membranes followed by release at the cell surface. Further details of these processes and unique features of each genus are described below.

Table 1 Taxonomy of viruses of the family *Flaviviridae*

- Genus *Flavivirus* (12 complexes[a]; 1 tentative species/subspecies)
  - Tick-borne viruses
    - Mammalian tick-borne virus complex (10 members)
    - Seabird tick-borne virus complex (3 members)
  - Mosquito-borne viruses
    - *Aroa virus* complex (4 members)
    - *Dengue virus* complex (5 members)
    - *Japanese encephalitis virus* complex (10 members)
    - *Kokobera virus* complex (2 members)
    - *Ntaya virus* complex (6 members)
    - *Spondweni virus* complex (2 members)
    - *Yellow fever virus* complex (10 members)
  - Viruses with no known arthropod vector
    - *Entebbe bat virus* complex (3 members)
    - *Modoc virus* complex (6 members)
    - *Rio Bravo* complex (7 members)
  - Tentative members of the genus
    - Alkhurma virus (1 member)
- Genus *Pestivirus* (4 species plus 1 tentative species)
  - *Border disease virus* (2 serotypes)
  - *Bovine viral diarrhea virus-1* (4 serotypes)
  - *Bovine viral diarrhea virus-2* (2 serotypes)
  - *Classical swine fever virus* (*Hog cholera virus*), (4 serotypes)
  - Tentative species in the genus
    - Pestivirus of giraffe
- Genus *Hepacivirus* (1 species)
  - *Hepatitis C virus* (6 genotypes)
  - Unassigned viruses in the family
    - Tamana bat virus
    - Cell-fusing agent
    - GB virus A
    - GBV A-like agents
    - GB virus B
    - GB virus C/Hepatitis G virus

[a]Complex refers to closely related viruses, representing genetic and antigenic clusters, and viral species in the complexes are enumerated in parentheses, or otherwise indicated. All others represent virus strains or serotypes.

Reproduced in revised form from Calisher CH and Gould EA (2003) Taxonomy of the virus family Flaviviridae. *Advances in Virus Research* 59: 1–19, with permission from Elsevier.

Flaviviruses

History and Classification

The genus includes >70 viruses, approximately 40 of which are mosquito-borne, 16 tick-borne, and 18 without a known vector. The prototypic flavivirus, yellow fever virus (from the Latin *flavus* for 'yellow'), is recognized as a human disease agent for at least the past 300 years. In the early twentieth century, the virus was isolated and characterized as an arthropod-transmitted agent, and a live-attenuated vaccine (yellow fever strain 17D) was developed. Other flaviruses causing a range of human diseases were identified within the nineteenth and twentieth centuries. The most important of these are Japanese encephalitis (JEV), West Nile virus (WNV), the tick-borne encephalitis (TBEV), and the dengue (DENV) viruses, which cause outbreaks of human disease on a large scale. Many other flaviviruses not listed in **Table 1** are causes of acute fever, meningoencephalitis, or hemorrhagic fever in humans on a regional basis throughout the world.

Based on comparative genomic sequence analysis, it is hypothesized that flaviviruses evolved as separate

tick-borne, mosquito-borne, and no-known-arthropod vector lineages, which diverged at an early point after the origin of the genus *Flavivirus* from a common ancestor whose identity remains unknown. This ancestral virus is assumed to have originated in central Africa as long ago as 10 000 years. There has been a general agreement between the phylogenetic clustering of flaviviruses and classification on the basis of serological relationships. Viruses such as the cell-fusing agent (CFA) and Tamana bat virus display homology that is distant enough to suggest a possible link among the three genera, but exact relationships remain unclear. According to this scheme, tick-borne viruses diverge first, followed by the mosquito-borne viruses. Yellow fever virus is representative of so-called Old World mosquito-borne (species *Aedes*) viruses. Additional clades, such as the dengue viruses and those of the JEV antigenic complex, vectored primarily by *Culex* mosquitoes, are believed to have diverged subsequently.

Epidemiology and Clinical Disease

The epidemiologic situation for flaviviruses involves both the appearance of new viruses, with several described in recent years, as well the emergence and re-emergence of established viruses. A number of contributing factors, such as human activities (urbanization, transportation, and land-use practices) and also natural phenomena (bird migration, host–vector relationships, and climate change), drive this process. Flaviviruses exhibit both global and regional distribution based on these various factors. Dengue has become the most significant cause of viral hemorrhagic fever globally, with a dramatic increase in prevalence of dengue involving up to 2.5 billion persons at risk and an annual infection rate of 50 million cases. JEV is regarded as the most important cause of epidemic viral encephalitis worldwide, causing up to 50 000 cases annually, and has spread from Southeast Asia to the south and west in recent years. West Nile virus, originally recognized as a cause of febrile illness primarily in Africa, the Middle East, and India, caused outbreaks of severe encephalitis in Eastern Europe and the former Soviet Union in the 1990s prior to its due appearance in the US in 1999. Since 1999, it has become distributed across North America and parts of Central and South America. In North America, it has caused annual outbreaks of encephalitic disease involving thousands of cases. Yellow fever is currently restricted to tropical Africa and South America, where it regularly causes endemic and periodic epidemic disease involving thousands of cases on a regular basis. The true incidence is believed to be underreported and may be as high as 200 000 cases per year, mainly in Africa.

Most flaviviruses are zoonotic viruses maintained in enzootic transmission cycles which depend on birds, rodents, or nonhuman primates as reservoirs, with humans usually dead-end hosts. However, dengue viruses are exceptions, due to their adaptation to humans and maintenance in urban-based areas in transmission cycles that do not require animal reservoirs as they seem to exist in sylvatic cycles in Africa and Asia.

Structure and Replication

The structure and replication of the flaviviruses have served for many years as a model for the entire family, since the first report of the genomic sequence for yellow fever virus in 1985. The use of molecular clones, together with the ease of propagating most of these viruses in cell lines *in vitro*, and the advent of modern expression systems for production and purification of viral proteins, have facilitated progress for understanding the molecular biology of the family. A number of different molecules in different cell types have been characterized as candidate receptors, including glycosaminoglycans. The best characterized receptor interaction is between dengue virus and dendritic cell (DC)-specific intercellular adhesion molecule 3 (ICAM-3)-grabbing nonintegrin (DC-SIGN), present on human dendritic cells. Fc and complement receptors can also mediate entry of the dengue viruses and several other viruses through the process of antibody-dependent enhancement occurring in the presence of subneutralizing antibody levels.

The virions contain a lipid envelope, have a buoyant density of 1.19–1.3 g ml^{-1}, and are sensitive to inactivation by heat, acid pH, organic solvents, and detergents. Currently the virion structure is best understood for dengue viruses and TBEVs. Dengue viruses, as reconstructed from cryoelectron microscopy (cryo-EM) images at 24 Å resolution, exist as a smooth particle comprised of dimeric units of the envelope (E) protein arranged in a head-to-tail fashion on its surface with icosahedral symmetry, encasing a nucleocapsid composed of capsid protein and genomic RNA (**Figure 1**). These genomes are on the order of 11 kbp (42 S sedimentation) and differ from other flavivirus genera in having a 5′ cap. The 5′ untranslated region (UTR) encodes a unique secondary RNA structure. The 3′ UTR contains conserved sequences and secondary structures, including a unique terminal stem–loop structure required for viral RNA replication (**Figure 2**). Such structures are found among both mosquito and tick-borne viruses despite differences in nucleotide sequence, arguing for conserved mechanisms relating to viral replication.

The flavivirus polyprotein undergoes co- and post-translational processing to produce the mature viral proteins. Structural proteins (capsid, prM (precursor to M), and E (envelope)) are generated by cleavage by host signalase in association with membranes of the endoplasmic reticulum, whereas nonstructural proteins (NS1, -2A, -2B, -3, -4A, -4B, and -5) are generated primarily by cleavage reactions mediated by the viral NS3 serine protease together with its NS2B cofactor. NS1 is a soluble,

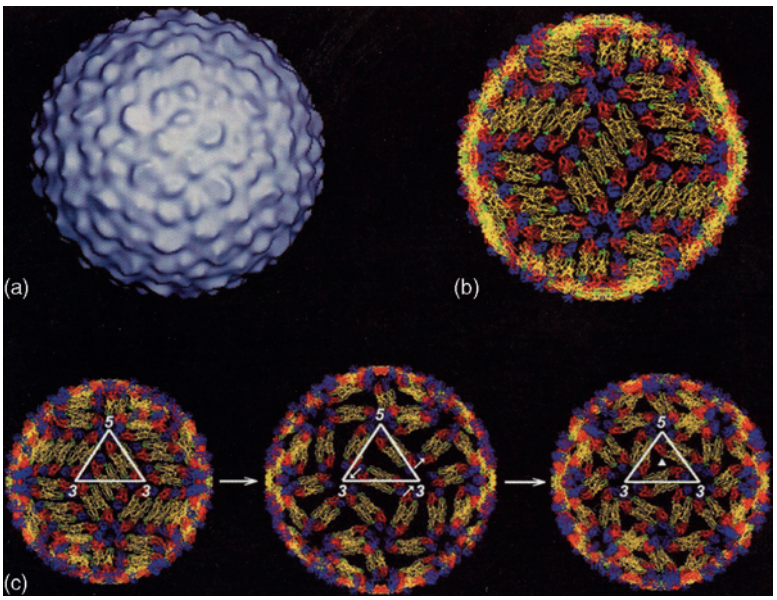

Figure 1 Structure of the dengue-2 virion as determined by cryo-EM. (a) An image reconstruction model of the virion in which the smooth surface is shown. (b) E protein dimers are displayed in the 'herringbone' arrangement, as fitted into the electron density map. (c) Acid-catalyzed rearrangement of the E protein dimers into the fusion-active state. Triangle represents the icosahedral asymmetric unit with three- and fivefold symmetry axes shown. The small arrows indicate the rotation of the E protein according to the proposed model. Figure 2 Organization and expression of the flavivirus genome. (a) RNA elements of the 5′ and 3′ noncoding regions (NCRs) flanking the open reading frame (ORF) for mosquito- and tick-borne viruses are indicated. The 5′ CAP structure and 5′ and 3′ stem–loop (SL) structure are shown. Conserved sequence elements for mosquito- and tick-borne viruses are denoted by CS, RCS, and CS, R, PR, respectively. A_n indicates a polyadenylate sequence contained within the variable region (dotted line) of some tick-borne isolates. (b) Expression and processing of the polyprotein. Cleavage events mediated by host signalase and furin-like enzyme are depicted by solid diamonds and triangle, respectively. Question mark indicates processing of NS1-2A by an unknown host enzyme. Downward arrows indicate cleaveage by the viral NS3 protease (PROT). HEL, helicase; MTase, methyltransferase. Reproduced from Lindenbach BD and Rice CM (2003) Molecular biology of the flaviviruses. *Advances in Virus Research* 59: 23–61, with permission from Elsevier.

cell surface, and intracellular protein which is involved in viral RNA synthesis, together with NS3 (protease, helicase, and NTPase activities), NS5 (methyltransferase and RdRP activities), and the hydrophobic proteins of the NS2 and NS4 regions. Viral replication occurs in association with intracellular membranes that are reorganized into packets of vesicles, convoluted membranes, and paracrystalline arrays. The capsid protein is responsible for

formation of the viral nucleocapsid. During subsequent virus maturation, prM acts as a molecular chaperone for the E protein, and undergoes a furin-like cleavage to form the fusion-competent heterodimer prM–E complex. The E protein is the major virion surface protein that harbors receptor binding and fusion activity. Structural characterization of the TBEV E protein has revealed that this protein resembles the E1 protein of the alphaviruses, both of which are designated as 'class II' viral fusion proteins, distinguished from the class I proteins typified by the influenza hemagglutin by major differences in overall fold, and a flat elongated orientation on the virion surface rather than an extended spike.

Pathogenesis

Flaviviruses are readily propagated in a variety of cell lines in culture, including cells of mammalian origin, in which cytopathic effects and plaque formation are common, as well as in mosquito-derived cells. Many of these infected cell types exhibit cell fusion and syncytia formation and are capable of supporting persistent infection. *In vivo*, flaviviruses cause syndromes in humans ranging from febrile illness to acute meningoencephalitis and hemorrhagic fever. Flaviviruses are inherently neurotropic viruses, possibly reflecting the propensity of viruses of the early phylogenetic branches to propagate in the central nervous system of arthropod vectors, and in turn, in vertebrate hosts, in which disease manifestations occur. Arthropod vectors undergo chronic infections that serve to deliver virus into enzootic and zoonotic transmission cycles that lead to infections of humans and animals. Whereas many of the encephalitic flaviviruses which typically depend on avian species as reservoirs and for amplification cycles, dengue and yellow fever viruses have adapted to primate hosts, and cause hemorrhagic fever as a primary disease manifestation. Nonhuman primates have been used for characterization of yellow fever and dengue viral infections and for evaluation of experimental vaccines for dengue viruses. Most flaviruses are pathogenic for laboratory rodents, particularly mice, which have been used as models for experimental studies of acute flavivirus encephalitis.

Flavivirus resistance is a phenomenon observed in certain inbred strains of mice, in which markedly reduced susceptibility to encephalitic strains, such as of WNV, have been observed. The genetic basis of this resistance has been mapped to a single autosomal dominant locus which encodes the Oas1B gene. It is not known yet if there is an analogous resistance mechanism that operates in humans to explain variability in susceptibility to these viruses. A recent study has also suggested a link between CCR5D32 (a common mutant allele of the chemokine and human immunodeficiency virus (HIV) receptor CCR5) and fatal WNV infection.

Flaviviruses are transmitted via feeding by chronically infected arthropod vectors. Following local replication at the site of inoculation and in regional lymph nodes, virus disseminates by viremia, with distribution to target organs in the periphery, including primarily visceral organs in the case of hemorrhagic fever viruses, and meninges, brain, and spinal cord in the case of encephalitic agents. Skin Langerhans (dendritic) cells are implicated as sites of initial virus replication as well as early spread of virus to lymphatic tissues. Monocytes and macrophages are also major targets of infection by dengue viruses. Flaviviruses also interact with many other cell types *in vivo* and elicit changes in cell surface molecules that are believed to influence pathogenesis of encephalitis and hemorrhagic fevers. Upregulation of surface molecules such as major histocompatibility complex (MHC) I and ICAM-1 has been observed.

Pathogenesis of both hemorrhagic fever due to yellow fever virus and acute encephalitis due to JEV complex and TBEV complex members are generally associated with cytopathic effects of the virus in target organs, although many viruses have been shown to induce apoptotic cell death as well. Flavivirus infections of the central nervous system, as typified by members of JEV complex or TBEV complex viruses, range from mild meningitis to severe destructive encephalitis, in which neurons of the brain and spinal cord are targeted. Mortality rates are as high as 40% and permanent neurologic effects may occur in survivors. Persistent and congenital infections have been described for some of the encephalitic viruses. Primary infection with dengue viruses either is generally characterized by flu-like illness or is asymptomatic. However, some secondary infections with heterologous serotypes result in a distinct form of hemorrhagic disease. This involves an immunopathogenic process of antibody-dependent enhancement of infection mediated by heterologous antibodies, in concert with activation of cross-reactive memory T-cells, cytokine release, and diffuse capillary leakage. This is referred to as dengue hemorrhagic fever and may be accompanied by a shock syndrome. Yellow fever causes a unique form of acute hemorrhagic fever with characteristic cytopathology in the liver and kidneys, and is fatal in up to 50% of severe cases.

Diagnosis and Prevention

Because flaviviruses may cause many different disease syndromes, disease manifestations are variable. Although diagnosis is often suspected on the basis of clinical findings, case history, and geographical distribution, a range of laboratory tests are available for determining infection with specific viruses, including virus isolation, serologic techniques (enzyme immunoassay, hemagglutination inhibition, immunofluorescence, complement fixation, dot blot immunoassays, and plaque neutralization), antigen

detection, and reverse transcriptase/polymerase chain reaction (RT/PCR) amplification. Detection of immunoglobulin M (IgM) by immunoassay is a common diagnostic test for flaviviruses, but in some cases persistence of high IgM levels from previous infections with other flaviviruses can complicate the diagnosis of recent infections. Detection of IgM antibody in cerebrospinal fluid is of use in cases of flavivirus encephalitis. RT/PCR of serum is a sensitive and rapid technique that has increasing application for flaviviruses, but must be carried out during the viremic stage, which can differ from one flavivirus infection to another. For instance, RT/PCR for dengue viruses loses sensitivity after the first week of infection due to clearance of viremia.

Outside of mosquito control measures, vaccination is the only available means of preventing flavivirus infections in humans. The live-attenuated yellow fever 17D vaccine has been used since its original development in 1936 for prevention of yellow fever and is one of the safest and most effective vaccines ever developed for human use. Inactivated vaccines are available for prevention of diseases caused by JEV and TBEV. Development of vaccines for dengue viruses and WNVs have been pursued because of the increasing public health burdens associated with these agents, but are still in investigational stages. At this time, there are no antiviral agents or other therapies licensed for treatment of flavivirus infections.

Pestiviruses

History and Classification

The genus *Pestivirus* includes four accepted species that are important causes of veterinary disease in farm animals which are of great economic consequence worldwide: *Classical swine fever virus*, *Bovine viral diarrhea virus 1* and *2*, and *Border disease virus*. The host range of pestiviruses is restricted to 'artiodactyles' (cloven-hoofed ruminants and pigs). Classical swine fever virus (CSFV) infects members of the Suidae as the natural hosts. Bovine viral diarrhea virus (BVDV) is a pathogen primarily of cattle. Classical swine fever was characterized (e.g., 'hog cholera') in the 1800s, but the viral cause not established until *c.* 1904. The diseases caused by BVDV in cattle were described in the 1940s and 1950s. Border disease virus (BDV) was discovered in 1959 in the border region of England and Wales, as a congenital viral infection affecting sheep and goats. Pestiviruses exhibit great genetic diversity, and characterization of new isolates, including those from wildlife species, about which understanding is limited, will have future impact on the classification of viruses of this genus.

Prior to use of genomic sequencing, pestiviruses were differentiated by host species of origin, and antigenic cross-reactivity prevented assignments to different serogroups, even though differences among groups could be demonstrated with monoclonal antibodies. Comparison of genomic sequences later revealed the existence of two genotypes of bovine viral diarrhea virus (BVDV-1 and BVDV-2), which became significant after it was recognized during the 1980s that BVDV-2 strains could cause a severe acute hemorrhagic syndrome, with some of the first isolations of BVDV-2 arising during BVDV1 vaccine breaks. The two genotypes are distinguishable antigenically, but not to a level which allows classification into different serotypes. Subtypes (BVDV-1a, -1b, -2a, -2b) also exist. BVDVs also display pronounced heterogeneity in phenotype (e.g., biotype and virulence type). Biotypes (cytopathic vs. noncytopathic) are defined on the basis of cytopathic effects in cultured epithelial cells. However, virulence phenotype *in vivo* correlates with the noncytopathic rather than the cytopathic biotype.

The authentic form of BDV is predominantly an ovine pathogen, although pigs are also affected. Three major genotypes have recently been identified within the BDV species, referred to as BDV-1, BDV-2, and BDV-3.

Epidemiology and Clinical Disease

BVDVs cause infections throughout the world. In the US, both BVDV-1a and BVDV-1b isolates are common, with BVDV-1b more prevalent. The prevalence of BVDV-2 appears to be greater in North America than elsewhere, and is relatively rare in Europe and Asia. However, a number of isolates have been made in South America. BVDV-2a isolates also are more predominant than BVDV-2b, which are rare. BVDV is endemic in many cattle populations, with maximum rates of persistent infection sometimes reaching 1–2%, and seropositivity as high as 65%. BVDVs also cross species barriers among animal hosts, with or without evidence of disease.

Ruminant pestiviruses frequently cause persistent infections in cattle and sheep, which serve as reservoirs for maintenance of virus, resulting in transmission from asymptomatic viremic animals to naive animals upon introduction into new herds; transmission by acutely infected animals can also occur. Contact with waste products as well as with contaminated animal feed and farm equipment may also spread infection. Animals acquire pestiviruses through the nasal and oropharyngeal tracts. Direct contact is the most efficient means of transmission. Other transmission routes may apply, as in the case of closed, nonpasturing herds which sometimes develop BVDV infections. A number of factors including the density of cattle populations and regional practices of cattle trading affect the introduction of BVDV into naive herds.

Manifestations of illnesses caused by BVDV are diverse, ranging from mild transient infections to severe acute disease involving the enteric, respiratory, and hematologic systems. Postnatally acquired infections may cause fever, diarrhea, and cough associated with virus shedding, but

seroconversion and clearance of infection leads to lifelong immunity. Persistent infections (PIs) occur after virus crosses the placenta in nonimmune animals to cause intrauterine infection early in fetal life. PI animals continuously excrete large amounts of virus and remain BVDV-antibody-negative due to immune tolerance. These animals may develop mucosal disease (MD), a fatal disease with profuse bloody diarrhea due to extensive ulceration of the gastrointestinal tract.

CSFV is the cause of a highly contagious and serious disease of pigs, and is of worldwide importance. Classical swine fever (CSF) is endemic in large portions of Asia, and has been reported in parts of Central and South America. CSF has been progressively eradicated from Western Europe, but periodic reintroduction has occurred. Eradication efforts have also generally led to control of CSF in North America and Australia. CSF can also be spread through pig products, with swill-feeding of pigs a particularly efficient means of transmission, in many regions now outlawed. Spread by semen of infected boars can also occur. CSF is an acute illness with significant mortality, but has become less common now than milder chronic forms of CSF and persistent infections following intrauterine transmission. The latter can result in stillbirth or yield piglets which develop late-onset disease.

BDV is an economically important cause of congenital infection in sheep and goats with a probable worldwide distribution; prevalence in sheep may be up to 50%. Vertical transmission results principally in abortion and stillbirth. Surviving animals are small and weak, and exhibit tremor and hairy fleece ('hairy shaker syndrome'). Infections are spread by these persistently infected animals, and can cause acute postnatal infections. Border disease can also be caused by bovine viral diarrhea disease types.

Structure and Replication

Pestivirus virions are 40–60 nm in size, contain three glycoproteins in the virion envelope complexed as disulfide-linked homo- and heterodimers, and have a buoyant density of 1.134 g ml^{-1} in sucrose. They are sensitive to heat, organic solvents, and detergents, but in contrast to flaviviruses, BVDV and CSFV are highly stable in acidic environments, although virus entry is through a low-pH endosome compartment. CD46 has been identified as a receptor for BVDV; however, glycosaminoglycans, such as heparan sulfate, may act as a receptor for cell culture-adapted BVDV and CSFV. It is believed that pestiviruses invade host cells after binding by envelope glycoproteins E^{rns} and E2. Low-density-lipoprotein receptor has also been proposed as a BVDV receptor.

The pestivirus genome is *c.* 12.3 kbp, with variant genomes of larger and smaller size generated by recombination events (**Figure 3**). Pestivirus genomes lack a 5′ cap structure, and translation is mediated by a 5′ internal ribosome entry site (IRES) element that has similarities to the hepatitis C virus (HCV) IRES. The 3′ UTR contains a short polyC tract, as well as variable and conserved regions, the latter of which encodes hairpin structures. The open reading frame codes for 4000 amino acids, and is processed into at least 12 mature proteins: N^{pro}, C, E^{rns}, E1, E2, p7, NS2, NS3, NS4A, NS4B, NS5A, and NS5B. N^{pro} is a unique N-terminal leader autoprotease, which is followed by the four structural proteins C, E^{rns}, E1, and E2. E^{rns}, which is not found in other viruses of the family, is a heavily glycosylated protein that is secreted from cells and exhibits a ribonuclease activity and a lymphocytotoxic activity that is involved in pathogenesis. E1 and E2 are integral membrane proteins that form the heterodimeric complex which mediates virus entry. Antibodies

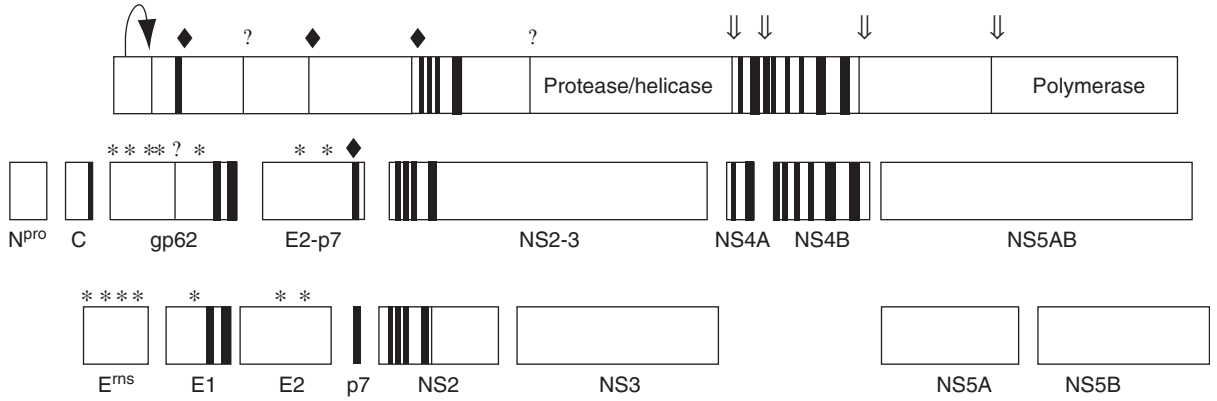

Figure 3 Pestivirus genome organization and processing, based on the cytopathic NADL strain of BVDV. Open boxes indicate mature proteins, with shaded regions representing stretches of hydrophobic amino acids. Diamonds and question marks indicate proteolytic processing by signalase and an unknown host enzyme, respectively. Downward arrows mark cleavages by the viral serine protease. The autoproteolytic cleavage by N^{pro} is shown as a curved arrow. Asterisks indicate proteins which undergo glycosylation. Reproduced from Lindenbach BD and Rice CM (2001) *Flaviviridae*: The viruses and their replication. In: Knipe DM and Howley PM (eds.) *Fields Virology,* 4th edn., vol. 1. Baltimore, MD: Lippincott Williams and Wilkins, with permission.

directed against E^{rns} and E2 confer protective immunity. The p7 protein serves as a membrane leader sequence for NS2. NS2, together with the N-terminus of NS3, is an autoprotease with specificity for the NS2–NS3 junction. This cleavage is necessary for RNA replication and pathogenesis of BVDV disease, but, paradoxically, the uncleaved NS2–NS3 precursor is required for virion formation. NS3 also has multiple functions, including protease (together with the NS4A cofactor), helicase, and nucleoside triphosphatase activities. By analogy with the hepaciviruses, NS4B is involved in cellular membrane reorganization and scaffolding for the replicase complex, which includes NS5B (RdRp). NS5A is a large, hydrophilic phosphorylated zinc metalloprotein analogous to the hepacivirus NS5A, and likely to function in the regulation of viral RNA synthesis.

Pathogenesis

Growth of pestiviruses in cell culture generates virus yields that are not robust, due to intracellular sequestration of the viral progeny and association with serum components that also cause difficulties with virus purification. Whereas susceptible cell culture systems are mainly derived from cells from the natural host species, lack of cytopathogenicity (e.g., 'noncp' biotypes) is common, in contrast to the cytopathic variants ('cp' biotypes), which arise spontaneously during infections in animal hosts.

In vivo, pestiviruses cause acute and persistent infections. BVDV causes a complex pathogenesis involving broad tissue tropism, and a propensity for high cytopathogenicity through mechanisms that remain poorly defined. There is evidence that cytopathic strains cause cell death by activating apoptosis through a double-stranded RNA (dsRNA)-dependent pathway, as well as by mechanisms related to oxidative stress. This process may underlie the development of MD associated with superinfection by a cytopathic strain.

Infection of cows by noncytopathic BVDV during the first 4 months of pregnancy can lead to birth of persistently infected calves immunologically tolerant to BVDV. Subsequently, the calves develop MD after superinfection by cp BVDV. Cytopathic strains associated with such cases are generated by mutations occurring in the genomes of noncytopathic strains, and require the production of NS3 which is cleaved from its NS2-3 precursor. This phenomenon is often a consequence of recombination events which introduce sequences allowing cleavage by host ubiquitin C-terminal hydrolase, or in other cases, by the N^{pro} autoprotease itself. Point mutations can also result in cytopathic variants. Production of NS3 is believed to be the basis for both BVDV cytopathogenicity in cell culture and pathogenesis of MD in immunologically tolerant PI calves.

Following inoculation of the mucosal surface, BVDV gains access to and replicates in lymphatic tissue, in many cases associated with leukopenia. Viremia has been experimentally demonstrated within 2–4 days. In severe cases, as in MD supervening in persistently infected calves, there is disseminated infection, mucosal ulceration, and hemorrhagic disease associated with platelet deficiency and dysfunction. Persistent viral infection is typically found in lymphoid tissue of the intestine, circulating mononuclear cells, and neurons in the central nervous system.

CSF is a disseminated infection that in its most severe form involves extensive thrombosis, endothelial damage, and severe thrombocytopenia resulting in hemorrhagic disease, necrosis, and multiorgan dysfunction. Viral infection of lymphoid tissue causes depletion of lymphocytes and germinal follicles and induces an immunosuppressive state with delayed appearance of CSF-specific antibodies. Superinfection with other pathogens can complicate the disease course.

BDV typically causes a less inflammatory disease, although a variant type of disease with necrosis of central nervous system has been described. Persistent infection of newborn lambs commonly involves widespread lymphoid infection and teratogenic lesions in multiple organs, with endocrine and neurologic abnormalities.

Diagnosis, Control, and Prevention

In the context of control programs for BVDV, diagnostic assays are employed for both surveillance at the herd and population levels, and also at the level of individual animals for identification of persistently infected animals that require elimination. Tests to determine immunity (antibody in serum or milk) as well as presence of virus are commonly done. Detection of antibodies by virus neutralization test or by antibody ELISAs are both used for diagnosis. Presence of virus can be demonstrated by virus isolation, antigen detection, or RT-PCR. Use of these assays depends on a variety of considerations, including age of animals to be tested, the epidemiological situation, and vaccination history.

Laboratory confirmation of CSFV infection has traditionally depended on virus isolation and detection of antigen in organ tissue, although more rapid techniques, such as antigen ELISA and RT-PCR, have been developed. Early diagnosis of infection based on antibody detection is limited by the slow appearance of virus-specific antibodies and lack of specificity of some antibody ELISA tests.

Vaccines have been developed against both CSFV and BVDV. However, control programs based on detection and eradication of persistently infected animals, as well as on quarantining and maintaining closed herds, have been employed to reduce the economic losses caused by these viruses. National eradication campaigns conducted in Scandinavia in the 1990s were particularly successful, facilitated by development of ELISA for detection of

BVDV antibodies. Due to the high effectiveness of these programs, the threat of reintroduction of virus into uninfected herds became apparent, and vaccination was recommended in some regions as a prophylactic measure against a resurgence of infections. Although some questions remain about the duration of protection and its efficacy in preventing fetal infection, newer vaccine regimens combined with comprehensive BVDV control programs are probably the best approach to lowering the incidence of PI in calves and reducing the problem of BVDV outbreaks. Commercial BVDV vaccines include either inactivated or modified live vaccines. Although there are some data to indicate that both antibody and cellular immune mechanisms are important for protection against BVDV infection, more studies are needed to define the protective mechanisms associated with these vaccines.

Live-attenuated vaccines for CSF have been available since the 1960s, but are not universally employed because of interference with traditional serologic methods to demonstrate absence of disease. Stamping-out policies are therefore employed as control efforts. Research into the use of marker vaccines, which do not exhibit interference in detection of infection, is ongoing, together with modeling studies to assess the impact of vaccine and eradication policies on control of disease.

Hepaciviruses

History and Classification

After serologic screening tests for the detection of hepatitis B and hepatitis A viruses were introduced in the 1970s to eliminate these viruses from human blood supplies, the role of HCVs in causing up to 90% of transfusion-associated hepatitis was recognized. The term hepatitis C virus (HCV) was coined in 1989 after identification of an RNA genome of this virus from cDNA libraries of human serum containing the infectious agent. In humans, infection with HCV commonly evolves into a chronic persistent hepatitis which can lead to progressive hepatic cirrhosis and hepatocellular carcinoma. Lack of a suitable cell culture system for propagating HCV had until only recently been a major impediment to progress in understanding the details of its replication. In addition, studies of HCV pathogenesis have been hampered by the lack of animal model systems, and progress has depended on use of clinical data from human cases, or from the use of a chimpanzee model.

Hepaciviruses display great genetic heterogeneity on a worldwide basis and are classified into six genotypes based on nucleotide sequence similarity, and further classified into multiple subtypes (identified by lowercase letters: e.g., 1a, 1b, 2a) as well as quasispecies for a given viral isolate. These divisions correspond to sequence divergence rates of *c.* 30–35%, 20–25%, and 1–10%, respectively. This level of genetic diversity has implications for the epidemiology of HCV transmission, clinical manifestations of liver disease caused by HCV, response to treatment, and development of a prophylactic vaccine.

Epidemiology and Clinical Disease

It is estimated that there are at least 170 million chronically infected HCV subjects worldwide, with prevalence varying from 0.1% to as high as 18% (Egypt). In areas where HCV has been eliminated from blood supplies by donor screening, use of illicit injectable drugs remains the most important mode of transmission. Various other forms of exposure, including occupational and sexual exposures, are involved in some cases of transmission. HCV is a primary cause of cirrhosis, a significant cause of hepatocellular carcinoma, and in the United States is the leading reason for liver transplantation. There is great variability in the spectrum of disease. Acceleration of disease is observed in persons who are older at the time of infection, and in the setting of continuous alcohol exposure, and co-infection with HIV or hepatitis B virus (HBV). Individuals who sustain infection at a younger age tend to have slower progression.

Genotypes 1, 2, and 3 are found worldwide, but with regional differences with respect to distribution. Genotypes 1a and 1b are predominant in the United States and Europe, 2a and 2b are relatively common in North America and Europe, and type 3a common in the United States and Europe among intravenous drug abusers. Genotype 4 is notable in the Middle East/North Africa region, whereas 5 is found in South Africa, and 6 in Hong Kong. Additional genotypes (e.g., 7–11) have been identified but have been proposed as variants of genotype 6. Genotypes are useful in establishing genetic markers of HCV in epidemiologic investigations and for determining modes of transmission. Differences in terms of disease potential and treatment response among genotypes also have been described, such as the relative resistance of genotype 1 to interferon alpha (IFN-α) therapy. This genotype has been associated with more aggressive liver disease as well, but it is unclear if this results from a longer duration of infection among people infected with this genotype. Genotypic differences may affect usefulness of diagnostic immunoassays for HCV antibody which are based on various portions of the HCV genome.

Structure and Replication

In contrast to those of flaviviruses and pestiviruses, hepacivirus virions have been difficult to visualize, and exhibit larger size and lower buoyant density (1.03–1.1 $g\,ml^{-1}$) as a result of association with immunoglobulins and low-density lipoproteins. HCV genomes contain a 9.6 kb

RNA which differs in some structural features from flaviviruses and pestiviruses (**Figure 4**). The 5′ UTR is the most highly conserved region of the genome and contains an IRES which mediates cap-independent translation of viral RNA. The structure of the IRES has been resolved, including studies of complexes with the ribosomal 40S subunit and the human translation factor eIF3. These efforts may facilitate the design of small molecules capable of inhibiting this critical viral factor. Because of its high sequence conservation, the 5′ UTR has also been used for development of sensitive detection assays for HCV infection. The 3′ UTR exhibits a tripartite structure, containing several unique elements, including a short variable region, a poly(U/UC) tract, and a highly conserved RNA sequence (the X-tail). A unique RNA structure, the *cis*-acting replication element (CRE) within the NS5 region, has also been identified.

The HCV polyprotein (*c.* 3000 amino acids) is processed by cellular (signalase) and viral proteases into mature viral proteins, consisting of the core, E1 and E2, the hydrophobic p7 peptide, and six nonstructural proteins (NS2, NS3, NS4A, NS4B, NS5A, and NS5B). Unique properties of several of these proteins have been characterized. The RNA-binding core protein has been associated with a range of effects on host cells, including transactivation, but the relevance to HCV pathogenesis *in vivo* is unknown. Alternative forms of core, produced by frameshifting, have been described. The E1 and E2 proteins form the heterodimeric complex of the virion that serves receptor binding, membrane fusion, and entry. These proteins exhibit the highest mutation rate at both the nucleotide and amino acid level. E2 in particular contains a hypervariable region (HVR-1) which undergoes an extremely high mutation rate and, because antibody epitopes are found within this region, it is believed that the mutations provide a mechanism for HCV to escape antibody responses involved in controlling virus infection. The small membrane-associated p7 protein forms an amantadine-sensitive ion channel which may function in the secretory pathway during virus maturation.

HCV encodes two known proteases involved in polyprotein processing, the NS2-3 autoprotease, and the NS3 serine protease, that with its NS4A cofactor mediates cleavage of the remainder of the nonstructural region. The structure of the NS3-4A protease has been solved, promoting interest in a new class of antiviral agents that target its protease activity. NS3 can also cleave adaptor proteins (Toll-like receptor-3 adaptor TRIF (TICAM-1)

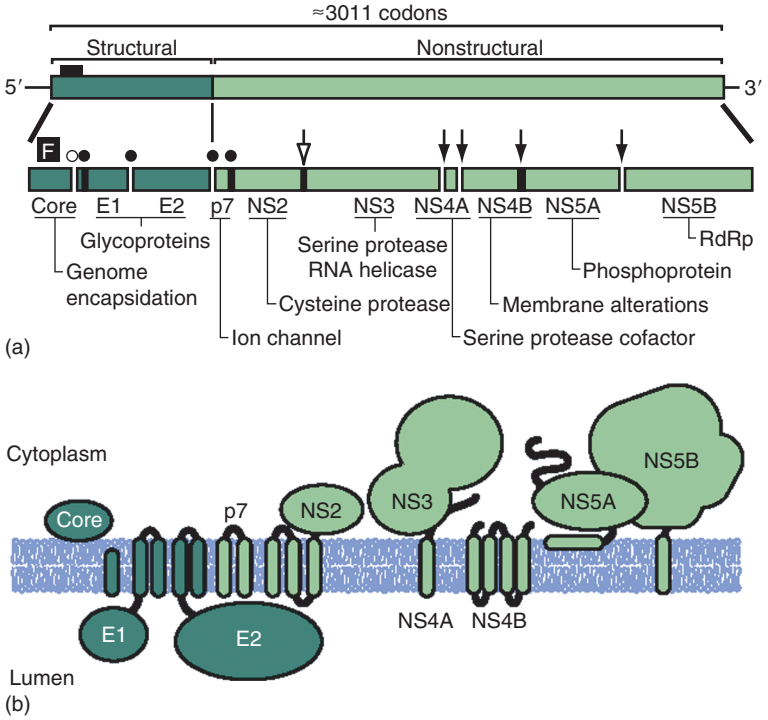

Figure 4 HCV genome organization and processing. (a) The HCV genome and polyprotein encoding structural and nonstructural genes and known functions. Closed and open circles indicate signal peptidase cleavage sites and signal peptide peptidase cleavage sites, respectively. F represents an alternative open reading frame protein produced by ribosomal frameshifting within the core region. Open and closed arrows indicate cleavage by the NS2 autoprotease and the NS3/4A serine protease, respectively. (b) Proposed topology of the HCV proteins with respect to the intracellular membrane. Reprinted by permission from Macmillan Publishers Ltd; *Nature* (Lindenbach BD and Rice CM (2005) Unravelling hepatitis C virus replication from genome to function. *Nature* 436(7053): 933–938), Copyright (2005).

and Cardiff (IPS-1, VISA, or MAVS)) required for activation of interferon regulatory factor 3, indicating a role for NS3 in downregulating the dsRNA signaling pathway that leads to induction of interferon beta and other genes involved in antiviral defense.

The NS4B protein is a mediator of the reorganization of intracellular membranes that together with other viral and host proteins generates the 'membranous web' scaffold for formation of RNA replication complexes. NS5A is a multidomain protein containing an RNA-binding activity. Differential phosphorylation of NS5A appears to have a role in regulation of HCV RNA synthesis, as a molecular switch for critical steps in the transition from RNA synthesis to virus packaging. NS5A also interacts with interferon-induced dsRNA-activated protein kinase PKR. Mutations in the domain of NS5A which affect this interaction (interferon sensitivity-determining region (ISDR) have been reported to influence the response of HCV to interferon alpha. The NS5B protein contains the RdRp activity that forms the core of the replication complex, and together with other NS3, NS5A, and cellular factors, synthesizes the genome-length plus- and minus-strand RNAs involved in the replication of the virus. NTPase and helicase activities participating in this process are encoded in the NS3 protein. Cellular proteins that have been implicated in function of the replication complex by interacting with NS5A and NS5B include VAP-A and -B (vesicle-associated membrane protein-associated proteins A and B), geranylgeranylated protein FBL-2, and cyclophilin B. These proteins appear to affect the assembly and function of the replication through such interactions such as membrane localization and RNA binding.

Recent progress in understanding HCV genome replication has been achieved through the use of HCV replicon systems. Initially established for genotype 1b, these were subgenomic constructs that encoded only the 5′ and 3′ structures and the nonstructural proteins required for viral RNA replication. Studies with additional iterations of replicons, including those for other genotypes, as well as full-length versions that exhibit efficient replicative functions *in vitro*, are excellent tools for studying the virus life cycle, in the absence of robust propagation of infectious HCV viruses in cultured cells. Crystal structures of several HCV proteins harboring key enzymatic functions, including NS3 protease, helicase, NS5A, and NS5B are known and are being applied to the development of HCV-specific antiviral agents.

The exact cell entry process for HCV has not been definitively characterized. It is believed that CD81, a tetraspanin family protein widely found on cell substrates, is involved in HCV entry, but requirements for other cell surface molecules on hepatocytes probably exist. Other proposed receptors include the LDL receptor, the class B type I scavenger receptor, mannose-binding lectins DC-SIGN and L-SIGN, heparan sulfate proteoglycans, and the asialoglycoprotein receptor. Further studies are needed to demonstrate the role of such molecules in HCV infections, and will be facilitated with new model systems such as retrovirus pseudoparticles that express HCV glycoproteins and exhibit low-pH-dependent infectivity for hepatic cell lines.

Pathogenesis and Clinical Disease

HCV causes acute and chronic forms of viral hepatitis. Acute hepatitis resembles that caused by other agents of viral hepatitis, but overt symptoms are not as frequent, despite biochemical evidence of liver disease in most subjects and appearance of HCV RNA in the serum. HCV causes persistent infection in most infected individuals, who then have chronic hepatitis throughout their lives in the absence of treatment and who remain at risk for cirrhosis and hepatocellular carcinoma. The infection is often diagnosed by screening of asymptomatic blood donors, or by the appearance of either chronic fatigue or features otherwise typical of viral hepatitis. Such individuals have persistent viremia and evidence of chronic inflammatory disease on liver biopsy.

Currently HCV is believed to cause persistent infection because primary and secondary immune responses are inadequate in breadth and magnitude to control the infection. Underlying mechanisms include the inherent difficulty in optimizing an immune response within the liver, and HCV-specific factors which suppress the host immune response, including effects of the core protein on host gene expression, inhibition of the interferon-induced protein kinase PKR by E2 and NS5A proteins, and NS3 inhibition of the dsRNA signaling pathway. The high genetic variability of HCV results in viral variants that may contribute to virus persistence through escape from antibody and from cytotoxic lymphocyte responses directed at specific epitopes.

The mechanism of liver injury associated with persistent HCV infection is believed to be immune-mediated and initiated by virus-specific T-lymphocytes which infiltrate the liver. Such cells are predominantly of a T_H-1 phenotype and produce interferon gamma and tumor necrosis factor alpha (TNF-α). Because these cytokines have been implicated in noncytolytic clearance of other viral agents in the liver, other mechanisms of hepatocyte injury and death associated with HCV have been proposed, including Fas-Fas ligand-mediated apoptosis, perforin-dependent killing by cytolytic T-cells, or TNF-α itself. HCV is not highly cytopathic for hepatocytes; however, fat deposits and eosinophilic inclusions are often seen in liver cells. In the absence of virus clearance, repeated episodes of hepatocellular injury and regeneration trigger development of hepatic fibrosis, cirrhosis, and eventual hepatocellular carcinoma. Additional factors that promote this process include coexistent infection with

other agents of viral hepatitis, alcohol intake, and iron overload. Extrahepatic manifestations can also occur in association with HCV infection, typically manifesting as skin and renal disease caused by a systemic vasculitis involving immune complexes with viral proteins.

Diagnosis and Treatment

Diagnosis of chronic hepatitis C infection is established by screening enzyme immunoassay to detect circulating antibodies to HCV proteins, followed by confirmatory determination of HCV RNA in serum, using qualitative and quantitative tests based on target (RT-PCR and transcription-mediated amplification) and signal amplification (branched DNA (bDNA)) techniques. Quantitation of serum HCV RNA helps to identify patients likely to benefit from treatment and undergo virus clearance as defined by a sustained viral response (SVR). Determination of the HCV genotype guides treatment decisions, as genotypes 1 and 4–6 are less amenable to treatment than are genotypes 2 or 3. Therapeutic trials have shown that combinations of interferons and ribavirin are more effective than is interferon alone and pegylated (long-acting) interferons have yielded improved SVR rates. An SVR is less common in patients with genotype 1 infections, high pretreatment HCV RNA levels, or advanced stages of fibrosis. Liver biopsy is used to establish the pre-treatment stage of liver disease and to facilitate decisions concerning the need for therapy. Advances in the future diagnosis and management of HCV will require close monitoring of the transmission of this infection, as well as extending treatment to populations not usually evaluated in clinical trials, and the development of new therapies, including antiviral agents targeting the viral protease and RNA polymerase.

GB Viruses

GB viruses are unassigned members of the family that include GB-A and -B, which are marmoset viruses, and GB-C, which was detected in the serum of human chronic hepatitis cases. GB-C and hepatitis G were discovered coincidentally and currently given the taxonomic assignment GBV-C/HGV. Currently there are five genotypes of this virus.

GBV-C/HGV is related to HCV, sharing 29% amino acid homology, and similarities in genome organization and structure, including a 5′ IRES, and a 3000 amino acid polyprotein but there are notable differences. GBV-C/HGV contains a capsid protein in the nucleocapsid; but this protein has not been identified. The E2 protein lacks both the extensive glycosylation and the hypervariable region found in the HCV E2 protein, which may in part explain the less frequent occurrence of persistent infection by GBV-C/HGV.

The 3′ UTR also differs from that of HCV. GBV-C/HGV is not hepatotropic, but rather replicates in mononuclear cells and bone marrow. Infection of humans is common, but no disease association has yet been identified. Instead, a beneficial effect of GBV-C/HGV infection on the outcome of HIV infection has been observed, presumably as a result of altered cellular immune responses caused by persistent infection.

Glossary

Triple gene block (TGB) protein A set of three proteins in overlapping reading frames that function together in facilitating cell-to-cell movement of plant viruses.

Introduction

The creation of the family *Flexiviridae* was approved by the International Committee on the Taxonomy of Viruses (ICTV) in 2004 to include a number of existing genera and some unassigned species of plant viruses. The family is so named because its members have flexuous, filamentous virions, and there are a number of characteristics that distinguish it from the families *Closteroviridae* and *Potyviridae*, the two other families of plant viruses that have virions of similar morphology (**Table 1**).

Main Characteristics

The chief characteristics shared by all members of the family are considered in this section.

Virion Morphology

Virions are flexuous filaments, 12–13 nm in diameter, and usually 500–1000 nm in length, depending on the genus. They are constructed from helically arranged coat protein subunits in a primary helix with a pitch of about 3.4 nm and nine to ten subunits per turn. Each particle contains a single molecule of the full-length genomic RNA. Smaller 3′ terminal subgenomic RNAs may also be encapsidated in some species, sometimes in shorter virions. In negative contrast electron microscopy the virions usually appear to be cross-banded. A typical electron micrograph is shown in **Figure 1** (for red clover vein mosaic virus, genus *Carlavirus*) but in the genera *Trichovirus* and *Vitivirus*, the virions appear to be rather more flexuous and hence resemble more those of the family *Closteroviridae*.

Genome

All members have a monopartite, positive-sense, single-stranded RNA (ssRNA) genome in the size range 5.5–9.5 kbp, depending on the species. This forms about 5–6% of the virion by weight. The RNA is capped at the 5′ terminus and there is a 3′ polyA tail.

Replication and Translation

In all members, there is a short 5′ nontranslated region followed by a single large alpha-like replication protein (145–250 kDa). This contains (in this order) conserved methyltransferase, helicase, and RNA-dependent RNA polymerase (RdRp) motifs and appears to be the only protein required for replication, which is believed to take place in the cytoplasm. Translation of the smaller open reading frames (ORFs) downstream occurs from one or more 3′ terminal subgenomic mRNAs. In some species, there is a 'leaky scanning' mechanism that ensures that two or three different proteins are translated from the same mRNA.

Genomic Organization

Genomic organization varies between genera but there are up to six ORFs ordered from 5′ to 3′:

1. a large alpha-like replication protein (see above);
2. one or more cell-to-cell movement proteins (MPs): in some genera there is a single MP of the '30K' superfamily

Table 1 Characteristics of the families of filamentous plant viruses[a]

Family	*Genome size (kbp)*	*RNAs*[b]	*ORFs*	*Translation strategy*[c]	*5′ end VPg*[d]	*3′-polyA*
Closteroviridae[e]	15–20	1, 2, or 3	10+	Subgenomic	No	No
Flexiviridae	5.5–9.5	1	2–6	Subgenomic	No	Yes
Potyviridae	9–12	1 or 2	1 or 2	Polyprotein	Yes	Yes

[a]All these have ssRNA genomes that encode in the virion (positive) sense.
[b]Numbers of genomic RNA components.
[c]Proteins are translated either from a set of nested subgenomic mRNAs or are cleaved by virus-encoded proteases from a polyprotein precursor.
[d]Presence or absence of a genome-linked protein covalently bound to the 5′ terminus of the RNA.
[e]Members of the family *Closteroviridae* have distinctive, tailed virions. The tail is constructed from a second, minor, coat protein.

(distantly related to the 30 kDa MP of tobacco mosaic virus (genus *Tobamovirus*)) while in the others there is a set of three overlapping proteins known as a 'triple gene block' (TGB);

3. a single capsid (coat) protein (CP) (21–45 kDa);
4. a final ORF (in some viruses only), which is thought to have RNA-binding properties and is probably a suppressor of gene silencing; it partially overlaps the 3′ end of the CP gene in some species.

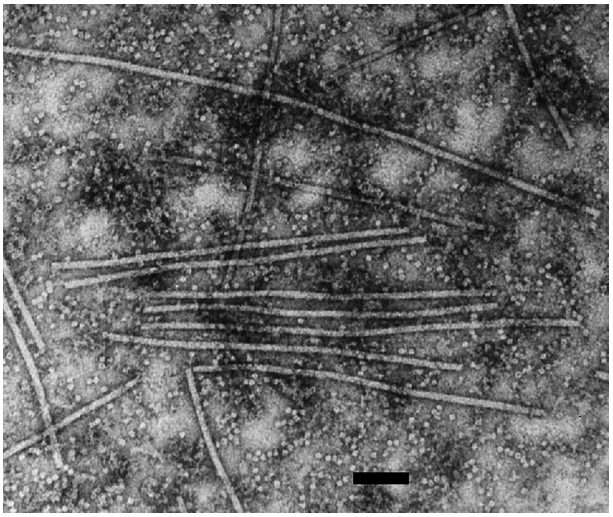

Figure 1 Electron micrograph of virions of red clover vein mosaic virus (genus *Carlavirus*), negatively stained. Scale = 100 nm.

Biological Properties

Biologically, the viruses are fairly diverse. They have been reported from a wide range of herbaceous and woody mono- and dicotyledonous plant species but the host range of individual members is usually limited. Natural infections by members of the genera *Capillovirus*, *Citrivirus*, *Foveavirus, Mandarivirus*, *Trichovirus*, and *Vitivirus* are mostly or exclusively of woody hosts. Many of the viruses have relatively mild effects upon their host. All species can be transmitted by mechanical inoculation, often readily. Many of the viruses have no known invertebrate or fungal vectors but allexiviruses and some trichoviruses are thought to be mite borne, most carlaviruses are transmitted naturally by aphids in a nonpersistent manner, and a range of vectors have been reported for different vitiviruses. Aggregates of virus particles accumulate in the cytoplasm but there are generally no distinctive cytopathic structures.

Component Genera and Species

Some properties of the nine genera included in the family and of six species that are not assigned to any genus are summarized in **Table 2**. These are mostly distinguished by the number of ORFs, the type of MP encoded, and the sizes of their virions and replication protein genes. In some genera, there are additional ORFs not present in other members of the family. These distinctions based on

Table 2 Genera and unassigned species included within the family *Flexiviridae*

Genus and unassigned species[a]	*Virion length (nm)*	*ORFs*	*MP type*[b]	*Rep (kDa)*	*CP (kDa)*
Potexvirus (28)	470–580	5	TGB	146–191	22–27
Mandarivirus (1)	650	6	TGB	187	36
Allexivirus (8)	~800	6	TGB	175–194	26–28
Carlavirus (35)	610–700	6	TGB	226–238	31–40
Foveavirus (3)	800+	5	TGB	244–247	28–45
Capillovirus (3)	640–700	2 or 3	30K	214–241	25–27
Vitivirus (4)	725–785	5	30K	195–196	18–23
Trichovirus (4)	640–760	3 or 4	30K	216–217	21–22
Citrivirus (1)[c]	960	3	30K	227	41
Banana mild mosaic virus (virus: BanMMV)	580	5	TGB	205	27
Banana virus X (virus: BanVX)	?	5	TGB	nd[d]	24
Cherry green ring mottle virus (virus: CGRMV)	1000+	5	TGB	230	30
Cherry necrotic rusty mottle virus (virus: CNRMV)	1000+	5	TGB	232	30
Potato virus T (virus: PVT)	640	3	30K	nd	24
Sugarcane striate mosaic-associated virus (virus: SCSMaV)	950	5	TGB	222	23
Possible species					
Botrytis virus X (BotV-X)	720	5	na[e]	158	44

[a]Numbers of species recognized within each genus are shown in parentheses (2006 data).
[b]Either a set of three overlapping proteins (TGB) or a single protein of the '30K' superfamily (phylogenetically related to the 30 kDa MP of *Tobacco mosaic virus*, genus *Tobamovirus*).
[c]Genus proposed in 2005 for the species *Citrus leaf blotch virus* (virus: CLBV).
[d]Not determined (only partial sequence data available).
[e]Not applicable (no MP encoded).

genome organization are also supported by phylogenetic analyses (see below). Genome organization is summarized in **Figure 2**.

A recently described mycovirus, botrytis virus X, shares many of the characteristics of the family and its CP and replication protein are phylogenetically related to members of the family *Flexiviridae*, in particular to members of the genera *Potexvirus* and *Allexivirus*. It is likely that a new genus will be proposed to accommodate this species in due course.

Phylogenetic Relationships

The relationships detected between the genera within the family and those between members of the family *Flexiviridae* and other viruses are dependent on the genome region used for analysis. This probably indicates that the viruses have arisen from reassortment of entire genes (or blocks of genes). These relationships are summarized below.

Replication Protein

A dendrogram based on the nucleotide sequence of the replication proteins (**Figure 3**) supports the taxonomic division of the family *Flexiviridae* into genera and falls into two major parts. One part contains the genera *Allexivirus*, *Mandarivirus*, and *Potexvirus* together with botrytis virus X. These proteins are the smaller ones in the family (145–195 kDa) and the plant-infecting members all have a TGB. The second part of the tree contains those viruses with larger proteins (195–250 kDa). It includes all those with a '30K'-like MP (*Capillovirus*, *Citrivirus*, *Trichovirus*,

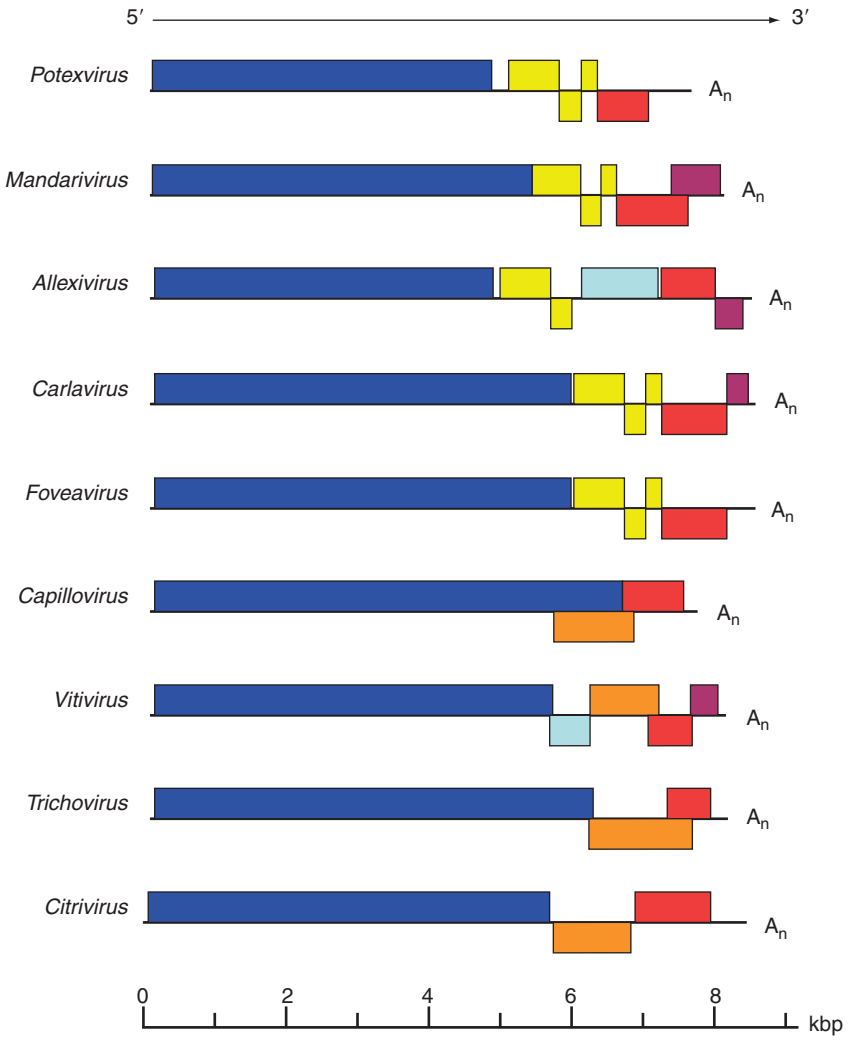

Figure 2 Diagram showing genome organization for the component genera of the family *Flexiviridae*. Blocks represent predicted ORFs. Replication proteins are shown in dark blue, '30K-like' MPs in orange, TGB proteins in yellow, CPs in red, and RNA-binding proteins in purple. ORFs of unknown function are shown in light blue.

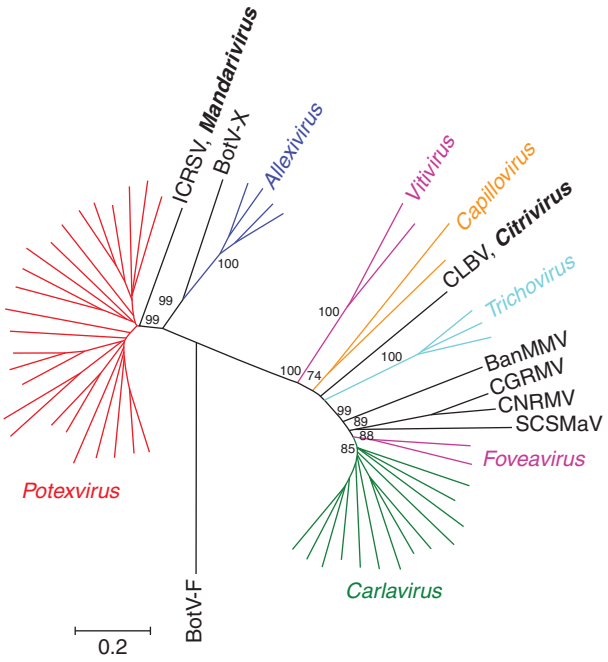

Figure 3 Phylogenetic tree of the replication proteins of all sequenced members of the family *Flexiviridae* with botrytis virus X and botrytis virus F. For abbreviations, see **Table 2**. The neighbor-joining tree is based on the codon-aligned nucleotide sequences. Values on the major branches show the percentage of trees in which this grouping occurred after bootstrapping the data (10 000 replicates). The scale bar shows the number of substitutions per base.

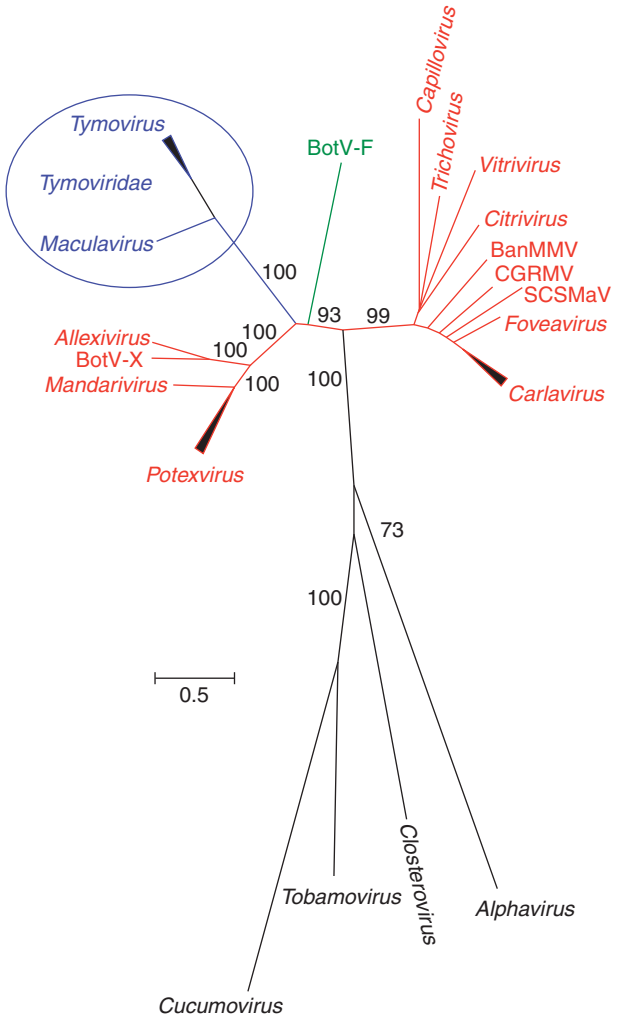

Figure 4 Phylogenetic tree of the replication proteins of selected members of the families *Flexiviridae* (in red) and *Tymoviridae* (in blue) with other related viruses. For abbreviations, see **Table 2**. The neighbor-joining tree is based on the aligned peptide sequences. Values on the major branches show the percentage of trees in which this grouping occurred after bootstrapping the data (500 replicates). The scale bar shows the number of substitutions per base.

and *Vitivirus*), together with the TGB-containing species that make up the genera *Carlavirus* and *Foveavirus* and some unassigned viruses that have foveavirus-like genome organization.

Most studies of 'longer distance' relationships between viruses have been based upon the motifs within the replication protein as these are relatively conserved within ssRNA viruses. Such studies consistently place the family *Flexiviridae* within a larger group ('alpha-like' or 'Sindbis-like' with 'type III' RdRp) that includes the family *Tymoviridae* (plant-infecting viruses that have isometric particles) and, more distantly, the families *Togaviridae*, *Bromoviridae*, *Closteroviridae,* and the rod-shaped plant viruses including the genus *Tobamovirus.* Phylogenetic analysis of the entire replication protein shows that this protein in members of the *Tymoviridae* is related to that found in the genera *Allexivirus, Mandarivirus*, and *Potexvirus* but distinct from that found in the remaining members of the family *Flexiviridae* (**Figure 4**). This might suggest that the *Tymoviridae* and *Flexiviridae* could be placed within the same family or that the current family *Flexiviridae* could be divided into two separate families. However, the relationships between other genes (see below) and differences in virion morphology and cytopathology suggest that the current classification makes better biological sense. The replication protein of the mycovirus botrytis virus F also appears to belong to the *Flexiviridae–Tymoviridae* group but falls outside any of the major groups and is probably best left unclassified at present.

Movement Protein

'30K'-like MPs occur in the genera *Capillovirus*, *Citrivirus*, *Trichovirus,* and *Vitivirus* and also in the unassigned potato virus T. The '30K' superfamily proteins are largely recognized by structural similarities rather than by primary sequence comparisons. Nonetheless, phylogenetic analysis shows that those from the family *Flexiviridae* are related to one another (although *Vitivirus* is more distant) and that

there are some similarities to the corresponding proteins in the rod-shaped plant virus genera *Furovirus*, *Tobravirus*, and *Tobamovirus* (**Figure 5**).

TGB Proteins

Within the family, the TGB proteins (for those genera that have them) are related in much the same way as their CPs. A TGB module is also found in members of the genera *Benyvirus*, *Hordeivirus*, *Pecluvirus*, and *Pomovirus*. However, the first and third proteins of the TGB of the rod-shaped viruses are considerably larger than the corresponding proteins in the family *Flexiviridae* and clearly form a separate grouping in phylogenetic analyses (**Figure 6**). In some species, notably all members of the genus *Allexivirus*, a sequence similar to that coding for the third TGB protein can be recognized but there is no standard AUG start codon and it is not known whether the protein is expressed.

Coat Protein

A phylogenetic tree of the CP sequences shows that most viruses with a '30K'-like MP in the genera *Capillovirus*, *Trichovirus*, and *Vitivirus* are only distantly related to those in the remainder of the family but that citrus leaf blotch virus, the single member of the genus *Citrivirus*, groups with a well-defined group containing all the TGB-containing members (**Figure 7**).

It is difficult to detect any significant relationship between the CPs of members of the *Flexiviridae* and those of other viruses beyond the modest similarity that occurs between the CPs of all viruses with filamentous particles.

RNA-Binding Protein

Putative RNA-binding proteins are found in the genera *Allexivirus*, *Carlavirus*, *Mandarivirus*, and *Vitivirus*. The proteins are clearly related and share a strictly conserved core amino acid sequence GxSxxAxR/KRRAx$_5$Cx$_{1-2}$Cx$_{5-13}$C. In phylogenetic analyses, the proteins from each genus cluster separately. The proteins probably act as silencing suppressors and are related to those of the closteroviruses (p23 of citrus tristeza virus and homologs in other species) (**Figure 8**).

General Comments

The limitations of phylogenetic analysis are demonstrated by the complex relationships within and outside the family

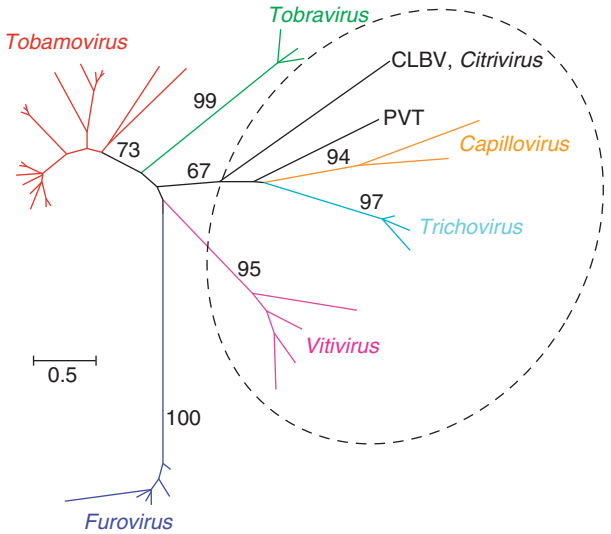

Figure 5 Phylogenetic tree of the '30K-like' MPs of the family *Flexiviridae* (in dotted oval) and the corresponding proteins of rod-shaped plant viruses. For abbreviations, see **Table 2**. The neighbor-joining tree is based on the aligned peptide sequences. Values on the major branches show the percentage of trees in which this grouping occurred after bootstrapping the data (500 replicates). The scale bar shows the number of substitutions per base.

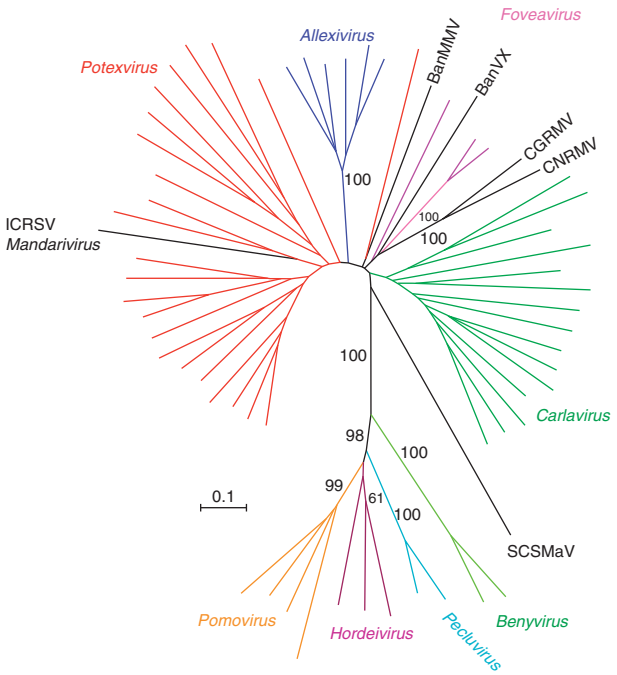

Figure 6 Phylogenetic tree of the TGB proteins of the family *Flexiviridae* and related rod-shaped plant viruses. For abbreviations, see **Table 2**. The neighbor-joining tree is based on the codon-aligned nucleotide sequences of all three proteins. Values on the major branches show the percentage of trees in which this grouping occurred after bootstrapping the data (10 000 replicates). The scale bar shows the number of substitutions per base.

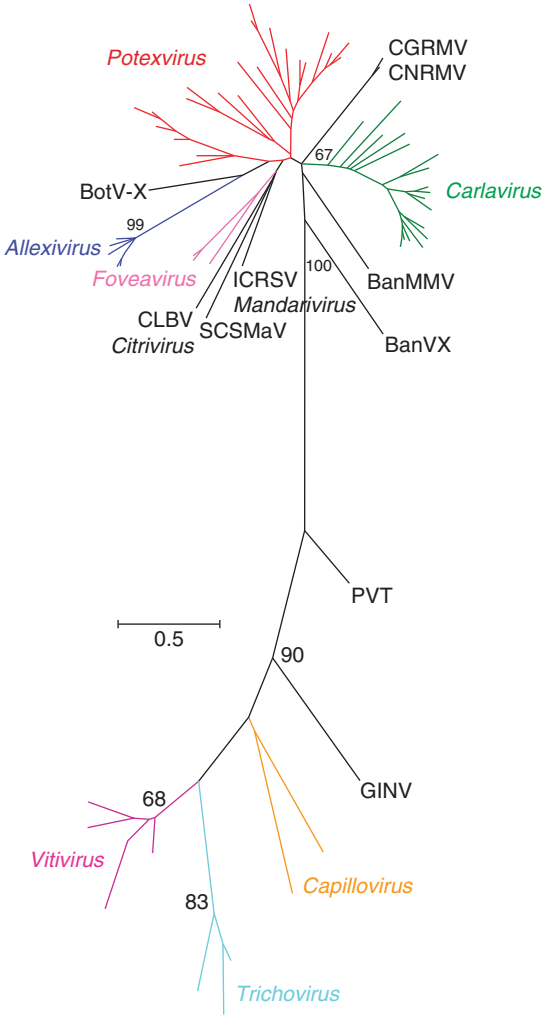

Figure 7 Phylogenetic tree of the CPs of all sequenced members of the family *Flexiviridae*. For abbreviations, see **Table 2**. The neighbor-joining tree is based on the aligned peptide sequences. Values on the major branches show the percentage of trees in which this grouping occurred after bootstrapping the data (500 replicates). The scale bar shows the number of substitutions per base.

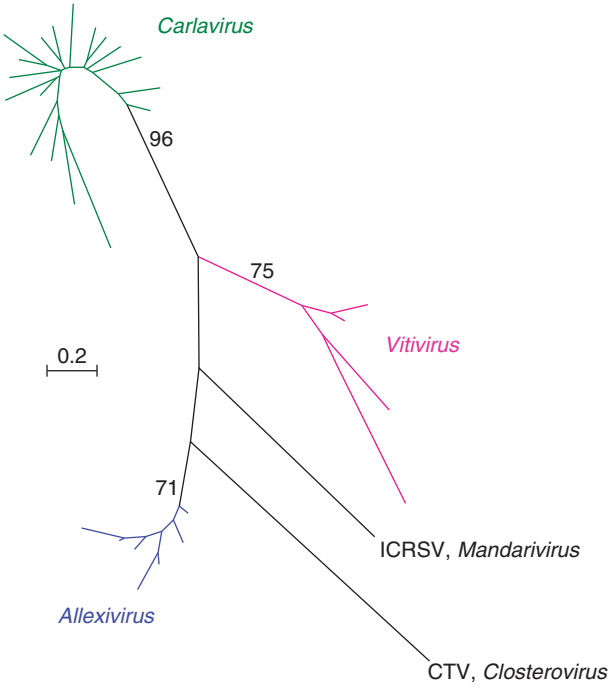

Figure 8 Phylogenetic tree of the nucleic acid-binding proteins of members of the family *Flexiviridae* and citrus tristeza virus (CTV, genus *Closterovirus*). The neighbor-joining tree is based on the aligned peptide sequences. Values on the major branches show the percentage of trees in which this grouping occurred after bootstrapping the data (500 replicates). The scale bar shows the number of substitutions per base.

that are revealed when different genes are used in the analysis (**Table 3**). In particular, there are big differences in the relative positions of the genera *Carlavirus*, *Citrivirus*, and *Foveavirus* to the rest of the family. The single virus in the genus *Mandarivirus* consistently groups with the genus *Potexvirus*, but it has a larger CP and an RNA-binding protein related to those of the genera *Allexivirus* and *Carlavirus*. Outside the family, the replication proteins are related to those found in the *Tymoviridae* and to botrytis virus F. By contrast, the movement protein(s), whether TGB or '30K'-like, are clearly related to those of the rod-shaped viruses, which are much more distantly related in their replication proteins.

Table 3 Summary of the main phylogenetic relationships within the family *Flexiviridae*

Genus	*Rep*[a]	*MP*[b]	*CP*[c]	*RNABP*[d]
Potexvirus	1	TGB	1	No
Mandarivirus	1	TGB	1	Yes
Allexivirus	1	TGB	1	Yes
(Botrytis virus X)	1	na[e]	1	No
Carlavirus	2	TGB	1	Yes
Foveavirus+[f]	2	TGB	1	No
Capillovirus	2	30K	2	No
Vitivirus	2	30K	2	Yes
Trichovirus	2	30K	2	No
Citrivirus	2	30K	1	No

[a]Type of replication protein.
[b]Either a set of three overlapping proteins (TGB) or a single protein of the '30K' superfamily.
[c]Type of coat protein.
[d]Presence of RNA-binding protein.
[e]Not applicable (no protein encoded).

Glossary

Provirus A viral DNA that is incorporated into the genetic material of a host cell.
Syncytia Structures in a monolayer cell culture formed by fusion of multiple cells that form a large cell with multiple nuclei.
Zoonotic infection An infection of animals that is transmitted to humans.

Introduction

Foamy viruses (FVs, also known as spumaretroviruses or spumaviruses) have been known for over 50 years as the cause of cytopathic effects in cell cultures derived from monkey tissues. The original name, spumaviruses, is derived from the Latin word *spuma* for the foamy appearance of infected tissue culture cells. A foamy virus was isolated from a human-derived tissue culture in 1971 and called HFV for human foamy virus. The cell culture that yielded virus was obtained from a Kenyan patient with a nasopharyngeal carcinoma. At the time, this isolate was thought to be the first human retrovirus. Isolation of HFV generated a considerable amount of interest because of its possible link with human cancer. However, subsequent work over the past decade has definitively shown that the HFV isolate is a chimpanzee virus derived from the species of chimpanzee present in East Africa. This has led to the suggestion that the Kenyan patient had acquired FV through a zoonotic infection. This chimpanzee isolate is now designated PFV for prototype foamy virus. Unless otherwise indicated, the information in this article refers specifically to PFV.

Epidemiology

FVs have been isolated from a number of hosts (**Table 1**), including all nonhuman primates (NHPs) that have been examined, as well as cats, cows, and horses. It is interesting that all species naturally infected with lentiviruses are also infected with harbor foamy viruses, although the reverse is not true. FV infection of natural hosts has not been linked to any pathologies. The widespread presence of FV suggests that it is part of the natural host microbial flora. In a small number of cases examined, infection of other species such as mice or rabbits has also failed to yield any manifestation of disease.

A large number of publications have suggested links between FVs and a variety of human diseases. However, ultimately none of these have been verified. Currently, there is no evidence of widespread infection of humans with FV. However, human infections are well documented. All the known cases can be traced to interactions with NHP. Veterinarians, primate center workers, bush meat hunters, pet owners, and people associated with monkey parks and monkey temples in Asia have been found to be infected. The frequency of infection in these high risk

groups is about 2–3% of those examined. Humans have been shown to be infected by the presence of specific antibodies, and in some cases by sequencing provirus from peripheral blood cells. In the few cases examined, human-to-human transmission has not been observed. Recent studies have shown that primate FVs can be transmitted to monkeys via blood transfusions from naturally infected animals. Whether or not this would also be true for infected human blood is not known. Limited studies have been made to determine whether humans can be infected by feline FVs from domestic cats. To date, there is no evidence for human infection by these agents.

Taxonomy and Classification

FVs are clearly retroviruses based on their genomic organization and general life cycle. However, they differ in fundamental ways from other retroviruses. These differences have led to their reclassification into a subfamily of *Retroviridae*. All other groups of retroviruses such as human immunodeficiency virus (HIV) are now called orthoretroviruses, or true retroviruses, while foamy viruses are spumaretroviruses (**Table 2**). Many aspects of their replication place FV closer to the hepadnaviruses such as human hepatitis B virus (HBV) than to orthoretroviruses.

Table 1 Foamy virus isolates

Host species	*Virus isolate*
Feline	FFV
Bovine	BFV
Equine	EFV
Rhesus macaque	SFVmac
African green monkey	SFVagm
Squirrel monkey	SFVsqu
Galago	SFVgal
Chimpanzee	SFVcpz
Spider monkey	SFVspm
Capuchin monkey	SFVcap
Baboon	SFVbab
Orangutan	SFVora
Gorilla	SFVgor
Marmoset	SFVmar
Human (not a natural host)	PFV (chimpanzee origin)

Viral Infections

Primate FV have been shown to have a very broad host range in tissue culture, with almost all vertebrate cell types being susceptible. In tissue culture, many cell types are lytically infected with virus. Such infected cells fuse to form large multinucleated cells, or syncytia. These syncytia rapidly die. Infected cells become filled with large numbers of vesicles, giving the cell cultures a foamy appearance (hence the name). An example of an FV-infected tissue culture is shown in **Figure 1**, using a hamster-derived indicator cell line in which infected cells stain blue. The arrows indicate multinucleate syncytia. However, some cell types in culture, including some human hematopoietic cell lines, are not killed after infection. Cell lines such as human Jurkat T cells are infected, evidenced by the presence of full-length viral DNA in the chromosomes. Few or no virions are produced from Jurkat cells, and there is no apparent effect on the health of the cells. These cell types are latently infected, and the infection persists indefinitely. The inability of virus to replicate in such persistent cultures may be caused by a transcriptional block. It appears that viral replication in tissue culture cells is invariably associated with cell death. However, it is not known whether or not this is true *in vivo*.

FV infections of organisms are lifelong in all species examined, including humans. There are no documented examples of viral clearance. Antibodies to viral proteins are present at all times after initial infection. Virus is believed to be transmitted between individuals through saliva. NHPs acquire the virus through biting or grooming. Young animals are not infected, and appear to be resistant to virus infection because of acquisition of maternal antibodies. Once such antibodies wane, serum conversion is rapid, and by 3 years of age, most animals are infected. In some populations of NHPs, infection reaches nearly 100% in adult animals. In naturally infected NHPs, viral DNA sequences can be found in most tissues, at very low levels. However, viral replication has only been documented in oral mucosal tissues, and virus is present in saliva. It is likely that FVs are latent in most tissues, and viral replication is confined to a small subset of cells in the oral mucosa. Such infected cells could secreted into saliva and be responsible for viral transmission.

Table 2 Classification of retroviruses (family *Retroviridae*)

Subfamily	*Genus*	*Type species*
Orthoretrovirinae (Orthoretrovirus)	*Alpharetrovirus*	*Avian leukosis virus*
	Betaretrovirus	*Mouse mammary tumor virus*
	Gammaretrovirus	*Murine leukemia virus*
	Deltaretrovirus	*Bovine leukemia virus*
	Epsilonretrovirus	*Walleye dermal sarcoma virus*
	Lentivirus	*Human immunodeficiency virus*
Spumaretrovirinae (Spumavirus)	*Spumavirus*	*Simian foamy virus*

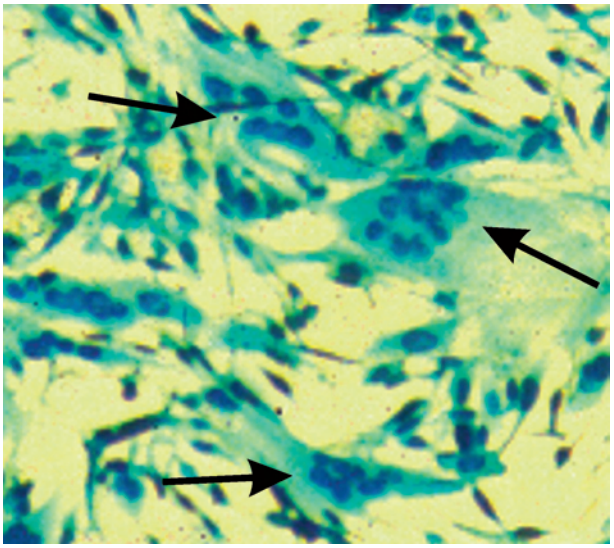

Figure 1 Baby hamster kidney indicator cells infected with PFV. These cells contain an indicator gene that turns the cell nuclei blue after staining when the viral transactivator Tas is present. The arrows point to multinucleate syncytia formed by PFV infection.

Virion Properties

FVs resemble other retroviruses in that they are fairly pleotropic in morphology, with large extracellular spikes. One distinct difference is that the FV core is electron lucent rather than condensed into a spherical core as in murine leukemia virus or into a cone-shaped core as in HIV (**Figure 2**(**a**), red arrow). The morphology of mature, infectious FV resembles that of immature gammaretroviruses. Foamy virions have a density of about 1.16 gm ml^{-1}, as do orthoretroviruses. The infectious particles are surrounded by long spikes, composed of the viral glycoproteins encoded by the *env* gene (**Figure 2**(**a**), purple dotted arrow). Like most retroviruses, FV bud from cellular membranes (**Figure 2**(**b**), black arrow). Most often budding is from intracellular membranes, and the majority of virions remain cell associated. A cartoon of an FV particle is shown in **Figure 2**(**c**). Virions are composed of two large structural proteins (Gag, blue ovals), surrounded by glycoprotein spikes (green). Particles contain the viral enzymes, including reverse transcriptase, encoded in the Pol protein (red). Like orthoretroviruses, FVs package RNA, but unlike

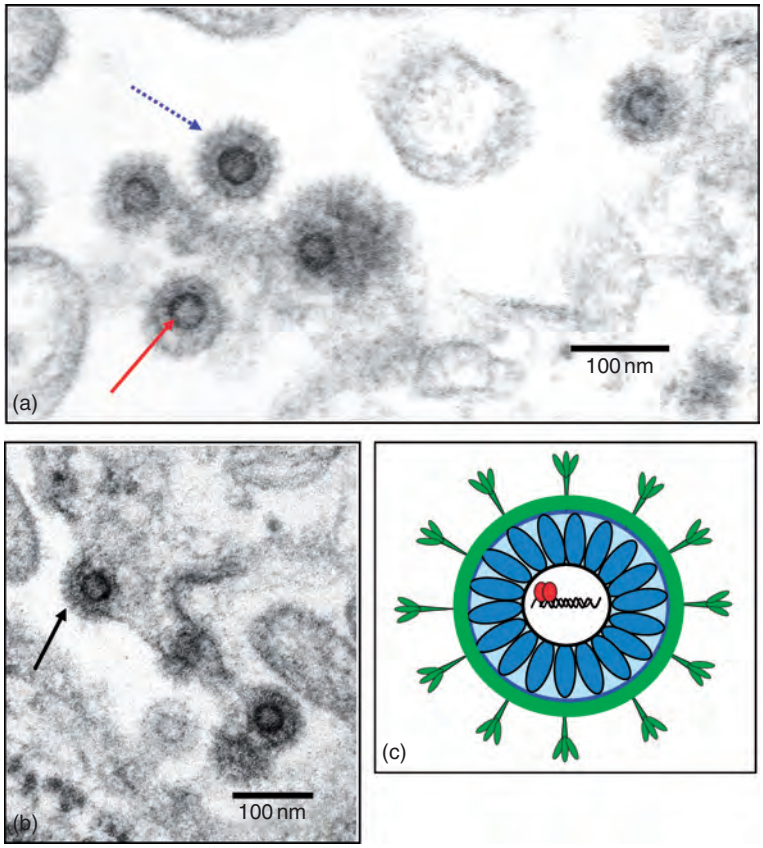

Figure 2 Morphology of foamy virus particles. (a, b) Negatively stained electron micrographs of tissue culture cells infected with PFV. (a) Intracellular particles; (b) budding particle; (c) depiction of a mature particle. The viral Gag proteins are shown in blue, the Env proteins in green, and the Pol proteins in red. The DNA genome is indicated by the black helix.

orthoretroviruses, the infectious genome of FVs is double-stranded DNA (dsDNA) (depicted by black lines), implying that reverse transcription occurs during assembly and/or budding (see below). Because of the mechanism of Pol synthesis, there are many fewer Pol molecules per foamy virion compared to the orthoretroviruses.

Genome and Protein Organization and Expression

Foamy viruses are complex retroviruses. Their genomes are greater than 12 kb (**Figure 3**(**a**)), placing them among the largest retroviruses. They encode the three genes common to all retroviruses (*gag*, *pol*, and *env*), as well as additional genes (*tas* and *tas*/*bel2* encoding Bet), whose gene products are not virion associated (**Figure 3**(**b**)). The Gag, Pol, and Env gene products are all polyproteins that are cleaved by proteases to smaller mature products. The Gag and Pol precursor proteins are cleaved by the viral protease (PR) encoded within the Pol protein (cleavage sites are indicated by the yellow arrows), whereas the Env precursor protein is cleaved by a cellular furin-like protease (indicated by the white arrows). The Gag protein is synthesized from an RNA that is indistinguishable from the viral genome. The Pol and Env proteins are synthesized from spliced mRNAs that utilize the same 5′ splice site (5′ss) but different 3′ splice sites (**Figure 3**(**c**)). Synthesis of Env from a spliced mRNA is common to all retroviruses. In contrast, synthesis of Pol from a spliced RNA is unique to FV. Orthoretroviruses synthesize Pol as a Gag–Pol read-through protein from genomic RNA. Since the orthoretrovirus precursor Pol protein has Gag determinants, it is co-assembled with Pol into virions. Lack of Gag determinants on FV Pol (**Figure 3**(**d**)) indicates that Pol encapsidation into virions occurs by a different mechanism. Tas and Bet are synthesized from a second promoter (IP) and Bet is made from a spliced mRNA joining part of *tas* to *bel2* (**Figure 3**(**c**)).

There are several noticeable differences in organization of the FV Gag, Pol, and Env proteins compared to orthoretroviruses (**Figure 3**(**b**)). The FV Gag is only cleaved once by PR at a site near the C-terminus and there are no mature cleavage products analogous to the matrix, capsid, or nucleocapsid proteins of orthoretroviruses.

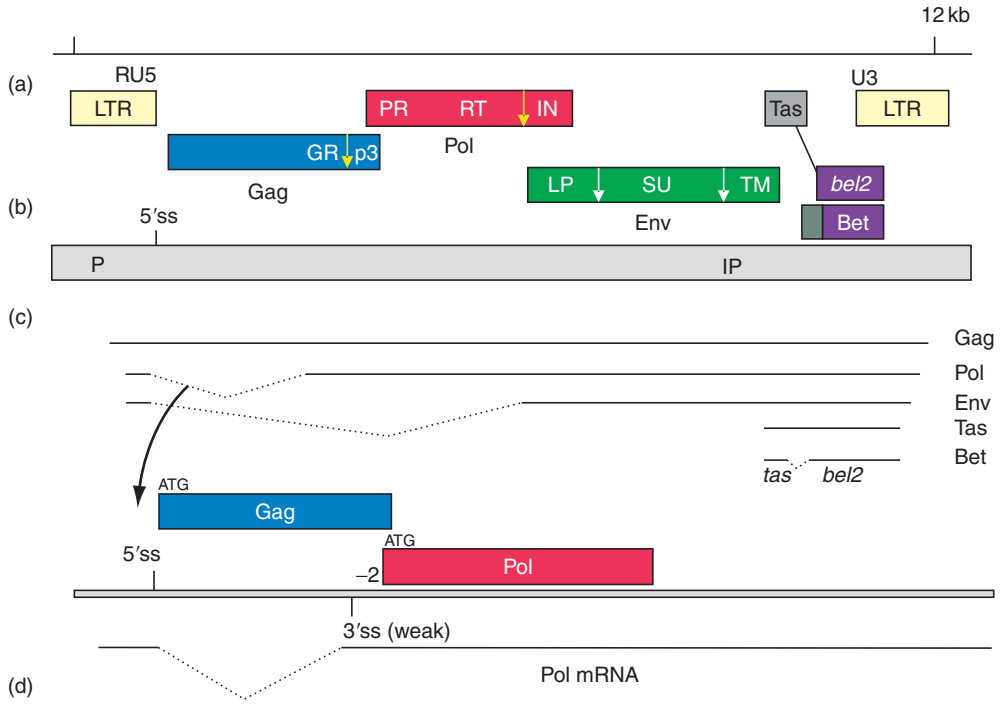

Figure 3 Viral genome. (a, b) The size of the PFV proviral genome and all of the gene products. The long terminal repeats (LTRs) contain the regulatory elements created by reverse transcription of the viral genomic RNA, duplicating RU5 and U3. The yellow arrows show sites of cleavage by the viral protease, the white arrows show sites of cleavage by a cellular protease. The Gag gene encodes the structural proteins. GR indicates three glycine-arginine-rich regions. One cleavage event occurs releasing a 3 kDa peptide (p3). The Pol gene contains the three enzymatic domains, protease (PR), reverse transcriptase (RT), and integrase (IN). The Env gene contains three domains, leader peptide (LP) unique to foamy viruses, surface (SU), and TM (transmembrane). Tas is the viral transactivator protein, and Bet is made from two exons, Tas and *bel2*. The function of Bet is not completely understood. (c) The location of the two viral promoters; The canonical retroviral promoter (P) in the LTR and the unique internal promoter (IP) encoded within the *env* gene. 5′ss indicates the major splice site. Indicated below are the major mRNAs. (d) The unique spliced mRNA that gives rise to the Pol protein. ATG indicates the start sites for translation. Adapted from Linial ML (1999) Foamy viruses are unconventional retroviruses. *Journal of Virology* 73: 1747–1755, with permission from American Society for Microbiology.

FV Gag lacks the hallmarks of other retroviral Gag proteins such as the cysteine–histidine boxes and the major homology region (MHR). The only distinct feature of FV Gag is the presence of three glycine-arginine-rich (GR) boxes near the C-terminus of the protein. These are involved in assembly and/or RNA binding. Most retroviral Gag proteins have a post-translational modification that adds a myristylation signal at the N-terminus. However, this does not occur in foamy viruses. The Pol protein encodes the four enzymatic activities associated with all retroviruses: PR, reverse transcriptase (RT) with its associated RNase H activity (RH), and integrase (IN). However, only one cleavage occurs in Pol, leading to a PR–RT (RH) fusion protein and an IN protein. The Env protein is composed of three subunits. In addition to the usual surface (SU) and transmembrane (TM) proteins, there is an N-terminal leader peptide (LP). The LP is equivalent to the signal peptide of other retroviruses that is cleaved and discarded. However, in FV, the LP is incorporated into particles with the same stoichiometry as SU and TM. In orthoretroviruses, the signal peptide is not incorporated into particles.

FVs also encode two proteins which are not found in virions, Tas and Bet. They are translated from mRNAs transcribed from the internal promoter located within the *env* coding region (IP; **Figure 3(c)**). Tas is a transcriptional transactivator, which binds to sequences in both the long terminal repeat (LTR) promoter and the IP, although the sites have different sequences. The IP has a higher affinity for Tas, and is activated first after infection. When additional Tas is synthesized from the IP, the level becomes high enough to allow transcription from the LTR and production of the virion proteins Gag, Pol, and Env. A block at the transcriptional level, preventing sufficient Tas to be synthesized to allow LTR transcription, is thought to occur in latent infections. Some latently infected cells can be activated by protein kinase C pathway activators, leading to viral production and ultimately to cell death. The second nonstructural protein, Bet, is an approximately 60 kDa protein with no obvious functional domains. Although all foamy virus Bet proteins have some similarities, there are no other proteins encoded by any organism with homology. Although the function of Bet is unknown, there are many tantalizing findings. Bet is both nuclear and cytoplasmic, and is also released from cells. It can be taken up by uninfected cells and there is some evidence that it can prevent infection. Although primate foamy virus Bet has not been found to be required for viral infectivity, it does appear to be required for replication of feline FV in some tissue culture cells. The role of Bet in infections of animals has not been assessed. Overexpression of Bet appears to have some effect on activation of the LTR promoter by Tas. Most recently, a number of groups have shown that Bet can inhibit the antiretroviral effects of the host protein APOBEC3, which is also an inhibitor of HIV and other retroviruses. However, the exact function(s) of Bet in viral replication *in vitro* and *in vivo* remains to be determined.

Viral Life Cycle

An overview of the FV life cycle is depicted in **Figure 4**. The steps in viral replication that differ in some aspects from those of orthoretroviruses are shown in red text. Some aspects of the viral life cycle are similar to that of the Hepadnaviruses such as hepatitis B virus (HBV), as indicated below.

1. *Viral entry.* The receptor(s) have not been identified for any foamy viruses. Identification is made difficult by the lack of cells that are resistant which could be used for selection. FV entry has been shown to use a pH-dependent endocytic pathway that is resistant to chloroquine, showing

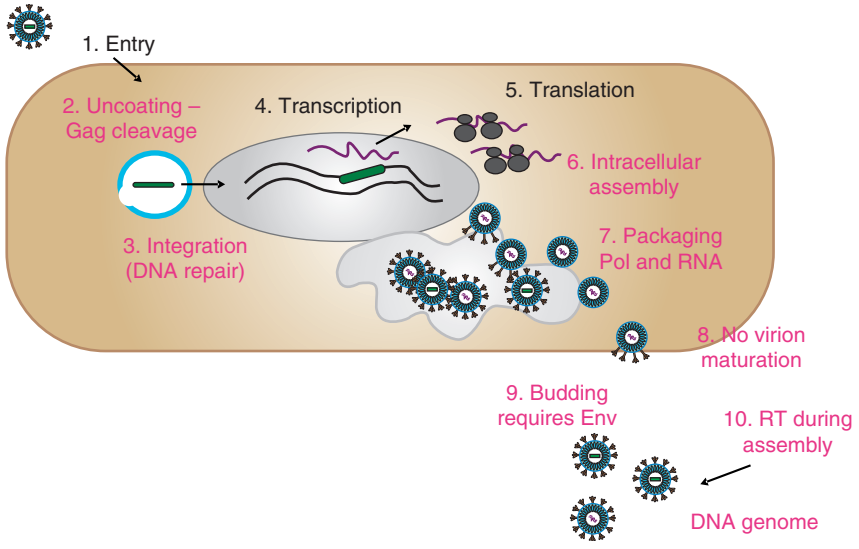

Figure 4 Viral life cycle. The major events in FV replication are indicated, with the steps that differ from orthoretroviruses indicated in red. For details, see text.

that the details of entry differ from that of the well-studied vesicular stomatitis virus.

2. *Uncoating.* FV Gag proteins are only cleaved once upon assembly/release by the viral protease PR. However, during viral entry, at least one additional PR cleavage occurs, which is required for infectivity. Presumably, this cleavage is important for uncoating of the viral capsid to release viral nucleic acid. Incoming particles traffic to the cellular microtubule organizing center (MTOC).

3. *Integration.* Although virions contain both RNA and DNA, the infectious genome is double-stranded linear DNA, reverse transcription having occurred late in the replication cycle (step 10, below). FVs share the property of packaging RNA but having DNA genomes with HBV. FV integration appears to occur in a manner similar to orthoretroviruses, although some repair of the dsDNA may occur at this step. The viral integrase (IN) is required for productive infection.

4 and 5. *Transcription and translation.* These occur as in other retroviruses using cellular machinery. As noted above, FV transcription from the two promoters requires the viral DNA binding protein Tas. Unlike other complex retroviruses in the genera *Deltaretrovirus* and *Lentivirus*, no viral proteins have been shown to be involved in RNA splicing and/or export of unspliced RNA from the nucleus. A region in the LTR which is present in both *gag* and subgenomic RNAs is necessary for efficient translation of Gag and Pol proteins.

6–8. *FV assembly and Pol and RNA packaging.* FV assembly occurs intracellularly, rather than at the plasma membrane, in a manner similar to that of Mason–Pfizer monkey virus (MPMV), a type D simian retrovirus. Like MPMV, FV Gag contains a cytoplasmic targeting and retention signal (CTRS) that is required for viral assembly. Newly synthesized Gag traffics to the MTOC which appears to be involved at some stage of viral assembly. RNA is incorporated into particles through a specific region of the RNA that interacts with one or more of the arginine-rich GR boxes. The RNA sequence is not exclusively located near the 5′ of the RNA where orthoretroviral packaging sequences (psi) are located. The FV psi sequence is more complex, and appears to include additional sequences encoded within the *pol* gene. The FV Pol protein is synthesized from a spliced mRNA and lacks Gag sequences. Thus, encapsidation is not through Gag assembly domains. Instead, viral RNA is required for Pol packaging. The Pol encapsidation sequences, like psi, are complex and involve both the U5 region of the LTR as well as sequences at the 3′ end of the *pol* gene. Protein–protein interactions of Gag and Pol may be required for Pol encapsidation. Because of the requirement for RNA sequences for binding, fewer Pol particles are packaged than in orthoretroviruses. As described above, cleavage of Gag into smaller subunits does not occur. This probably is responsible for the morphology of infectious virions that resemble immature retroviruses lacking a condensed core.

9. *Budding.* Orthoretroviral particles can bud from cells in the absence of the envelope glycoproteins, although the presence of Env can increase the efficiency of their release. In contrast, FVs absolutely require Env proteins to bud from cells, reminiscent of HBV. The component of FV Env that is required for particle egress has been mapped to the N-terminus of the LP protein. In the absence of LP intracellular particles accumulate. In general, FV budding is quite inefficient with a vast majority of infectivity remaining cell associated. It is likely that transmission from infected to naive animals occurs via cell-associated virus, rather than free virus.

10. *Reverse transcription.* Unlike orthoretroviruses but similar to HBVs, reverse transcription of the FV RNA genome occurs during assembly. The mechanism of reverse transcription appears to be identical to that of orthoretroviruses, using a $tRNA_{lys1,2}$ as a primer. Budded virions contain full-length dsDNA that it is required for infectivity. DNA extracted from virions has been shown to be infectious when fused into cells. The RT is unique in that it also contains the protease domain. FV RT is highly active and processive *in vitro.*

Viral Genetics and Evolution

FVs are the most ancient of retroviruses, and of all RNA viruses. It is estimated that they have been present in NHP populations for over 60 million years and in Old World primates for over 30 million years. They appear to have cospeciated with their hosts. The lack of significant homologies to orthoretroviruses in their Gag proteins, suggest that they may have evolved separately from orthoretroviruses. FV viral genomes are very stable and there is much less sequence diversity than seen with other retroviruses, either within or between species. The viral RT appears to be as error prone as that of other retroviruses, so the low sequence diversity may reflect the lower total viral load per animal, as replication is confined to the oral mucosa. It is assumed that FVs undergo recombination and reassortment as seen in the other genera, but this has not been studied.

Viral Vectors

Orthoretroviruses, including murine leukemia virus and HIV, have been developed into vectors for gene therapy applications. The large genome size, the broad host range, and especially the nonpathogenic nature of FV, have made them excellent candidates for gene therapy vector development. While simian and feline FVs have been developed as vectors, most work has been concentrated on PFV. Vector development has been the impetus for much of the present information about the replication

and infection by FVs. FVs are rather stable. They cannot complete replication in nondividing tissue culture cells. If nondividing cells are infected, FVs can apparently persist in the quiescent cells until the cells become activated. At that time, viral infection proceeds and the FV genome integrates into the host chromosome. Viral integrations into normal human cells do not occur preferentially within genes although there is a significant preference for GC-rich regions of the genome.

Thus far, it has not been possible to create stable packaging cell lines which contain all of the viral gene products. Instead, as in the case of HIV, cells are transfected with three vectors encoding separately the *gag*, *pol*, or *env* genes, and a fourth vector encoding the gene of interest embedded in an RNA containing the RNA and Pol packaging sequences. FV cannot be pseudotyped with vesicular stomatis virus glycoproteins (VSV G), so the cognate FV Env protein is used. This has an equally broad host range as VSV G. The vectors do not use the viral promoters, so the Tas gene product is not required. Resulting replication-defective FV vectors have been successfully used in both mice and dogs to repopulate all hematopoeitic cell lineages with the gene encoded by the vectors. This indicates that the vectors can integrate into early hematopoietic stem cells. Work proceeds on using FV vectors to repair genetic defects, and also to interfere with the replication of pathogens, such as HIV. Thus far, no human trials with FV vectors have been reported.

Future Perspectives

There are currently two major foci of current foamy virus research. The first is the continued development and refinement of vectors for a variety of applications. The published results thus far have been encouraging and human trials are probably not far away. The second area is surveillance of human populations at risk for FV infection. The progenitors of HIV are apparently not pathogenic in their natural hosts, and the human pathogen arose by recombination between two monkey viruses with a chimpanzee intermediate host. There are obvious parallels with FVs, where humans are increasingly in contact with NHP harboring a variety of FV. Future studies need to determine whether or not humans shed virus in saliva, and if human-to-human transmission can be documented. But many other interesting questions remain to be determined. It is not known how FVs have adapted so perfectly to their hosts, while maintaining the ability to be highly cytopathic, at least *in vitro*. The intricate control mechanisms could reveal new strategies for dealing with other cytopathic retroviruses such as HIV. There are many unanswered questions about the unique FV replication pathway. How is Pol packaged into virions? Why is FV RT activated during assembly whereas HIV RT is not activated until after infection of new cells? What is the FV receptor? Where do the interactions between Gag and Env occur and how do they allow viruses to bud from cells? We have just begun to scratch the surface in unraveling the replication of these fascinating retroviruses.

Foot and Mouth Disease Viruses

D J Rowlands, University of Leeds, Leeds, UK

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Serotype Animals recovered from infection with a virus belonging to a given serotype are resistant to subsequent infection with viruses belonging to that serotype but are still susceptible to infection with viruses belonging to any of the other serotypes.

History

The earliest account that clearly describes foot-and-mouth disease (FMD) was made by Fracastorius in 1546 and it is still today one of the most important diseases of domestic livestock.

It was the first animal disease demonstrated to be caused by a filterable agent in 1897 by Loeffler and Frosch, who also demonstrated the presence of neutralizing antibody in serum. It is also the first virus for which serotype differences were recognized. Further milestones were the demonstration by Waldemann and Pope in 1921 that guinea pigs could be infected and by Skinner in 1951 that it caused a lethal infection in suckling mice. Subsequently, cultivation of the virus in tissue culture cells has enabled studies of viral structure and replication and also the large-scale production of vaccines.

Taxonomy and Classification

Foot-and-mouth disease viruses (FMDVs) are a species within the genus *Aphthovirus* of the family *Picornaviridae*. The nature and organization of the genome, mode of replication, and structure of the virion are, in general, similar to other viruses in the family. The subdivision of the *Picornaviridae* into four genera, *Enterovirus*, *Rhinovirus*, *Cardiovirus*, and *Aphthovirus*, was originally based on physicochemical properties such as susceptibility to acid inactivation, buoyant density of CsCl solution, and the nucleotide composition. Analyses of evolutionary relationships by nucleotide sequence comparisons have largely endorsed the original classifications; however, the family has now expanded to include nine genera. Of special note is the recent inclusion of equine rhinitis A virus (ERAV) in the genus *Aphthovirus*. Properties which distinguish the FMDVs are: (1) extreme sensitivity to acid inactivation (<pH 6.8 in low ionic strength buffer); (2) high buoyant density in CsCl (1.43–1.50 g cm^{-3}); (3) possession of a poly(C) tract in the 5′ untranslated region (UTR) of the RNA (a property shared with some cardioviruses); (4) three separately encoded VPg proteins; (5) the use of two alternative in-frame protein translation initiation sites; and (6) a leader protease protein located in the N-terminal region of the polyprotein.

Properties of the Virion

As for other picornaviruses, FMDV particles are nonenveloped icosahedrons comprising 60 copies each of four structural proteins, VP1–VP4, encapsidating a single copy of the single-stranded positive-sense genomic RNA. The crystallographic structure of the virus (**Figure 1**) has shown that the three larger proteins (VP1–VP3) have the eight-stranded antiparallel β-barrel folding motif seen in other picornaviruses and some plant viruses. VP4 is disposed on the inner surface of the particle. In common with other picornaviruses, VP1 molecules are located around the axes of fivefold symmetry whereas VP2 and VP3 alternate around the two- and threefold symmetry axes. Heat or acid degradation of the particles results in dissociation into pentameric subunits, consisting of five copies each of VP1–VP3, with release of the RNA and VP4.

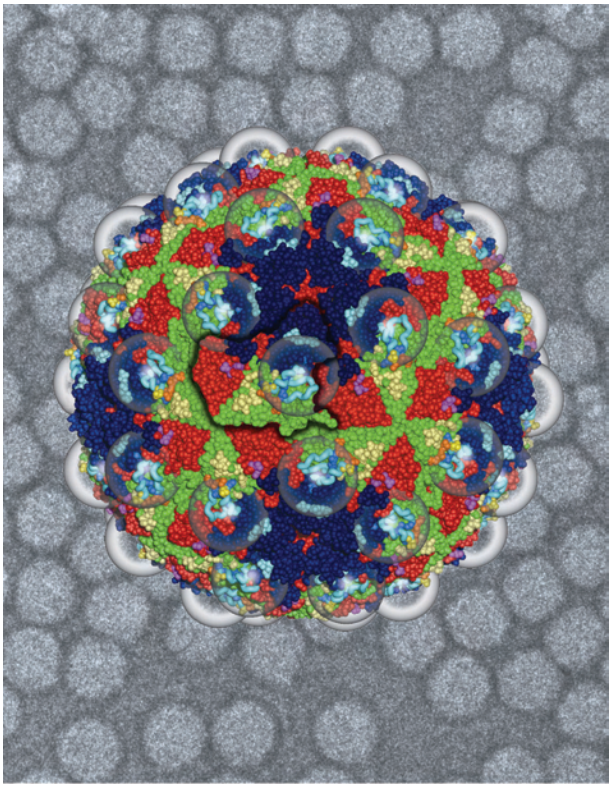

Figure 1 CPK rendition of reduced FMDV, serotype O superimposed on a cryoelectron micrograph of particles. Color codes: VP1, blue; VP2, green; VP3, red (VP4 is internal and not visible in these views). The VP1 G–H loop is shown as a worm in cyan with the Arg-Gly-Asp residues in orange CPK. Antigenic residues are color-coded according to their classification into sites: sites 1 and 5 (mid-blue), site 2 (pale yellow), site 3 (light blue), site 4 (magenta). The potential occupancy of the mobile VP1 G–H loop is modeled by a transparent sphere centered at the midpoint between the two ends of the loop. A protomeric subunit is outlined in black. Courtesy of E. Fry and D. Stuart.

Several features of the structure are unique to FMDV. The protein shell is generally thinner and the external surface is smoother than in other picornaviruses. This is a result of the smaller sizes of VP1–VP3 (VP1 213, VP2 218, VP3 220 amino acids for serotype O1 virus) compared to other picornaviruses. The truncations are in the loop regions linking the core elements of the β barrels, which in other picornaviruses form prominent features at the outer surface. The deep grooves or pits encircling the fivefold axes of many picornaviruses are not present in FMDV and the position equivalent to these invaginations

is occupied by the C-terminal portion of VP1. An important exception to the generally smooth contours of the surface of FMDV is provided by the G–H loop of VP1 (**Figure 1**). This large loop extends from about residue 130 to 160 of which residues around 135–158 are too disordered to be visible in electron density maps. In serotype O1 viruses, the disorder of the VP1 G–H loop is induced by a disulfide bond between the cystine residues VP2 130 and VP1 134. Under reducing conditions this bond is broken and the G–H loop collapses onto the surface of the virus in an ordered configuration. This feature includes an immunodominant antigenic site to which a high proportion of virus-neutralizing antibodies are directed. Also, synthetic peptides representing sequences from this region are immunogenic and can induce protective immunity. The sequence of this region is variable both in composition and length between different viruses with the exception of a highly conserved receptor binding motif which includes the triplet, Arg, Gly, Asp (see the section titled 'Cell attachment and entry').

Properties of the Genome

The genome consists of a single molecule of single-stranded positive-sense RNA, which is infectious. The order of the gene products on the genome is basically similar to other picornaviruses but there are some unique features (**Figure 2**). The genomic RNA terminates at the 5′ untranslated end with a small protein, VPg, linked by a phosphodiester bond through a Tyr. There is a variable length of poly(A) tract at the 3′ end. Uniquely, the FMDV genome encodes three distinct VPgs, which are used with equal efficiency. The reasons for this gene triplication are unknown. In fact, virus derived from an infectious cDNA clone from which one or two of the VPg copies had been deleted is still infectious, although RNA synthesis is reduced. The 5′ UTR is exceptionally long (*c.* 1300 nt), even by picornavirus standards (**Figure 3**). There is an uninterrupted poly(C) tract of 100–200 residues, depending on the virus isolate, located *c.* 400 nt from the 5′ end. The function of the poly(C) tract is unknown and it is not present in ERAV. There is evidence from FMDV and mengovirus (a cardiovirus) that the length of poly(C) is related to pathogenicity.

The sequence between the 5′ end and the poly(C) tract has a high degree of secondary structure and is predicted to fold into an almost complete hairpin. Its function is unknown but by analogy to the highly structured 5′ sequence of poliovirus RNA it is likely to be involved in the control of RNA replication. To the 3′ side of the poly(C) tract there are a variable number of repeat domains that are predicted to fold as pseudoknot structures. The 3′ 435 nucleotides of the 5′ UTR fold into a series of stem/loop structures similar to those present in the equivalent region of cardiovirus 5′ UTRs and function as an internal ribosome entry site (IRES) to initiate protein synthesis. A stem/loop structure (*cre* – *cis*-active replication element), located between the pseudoknots and the IRES, functions as a template for the uridylation of VPg, which is an essential step in the initiation of viral RNA synthesis.

Protein Products

The protein-coding region is a continuous open reading frame of 6999 or 6915 nt for FMDV serotype A[10],

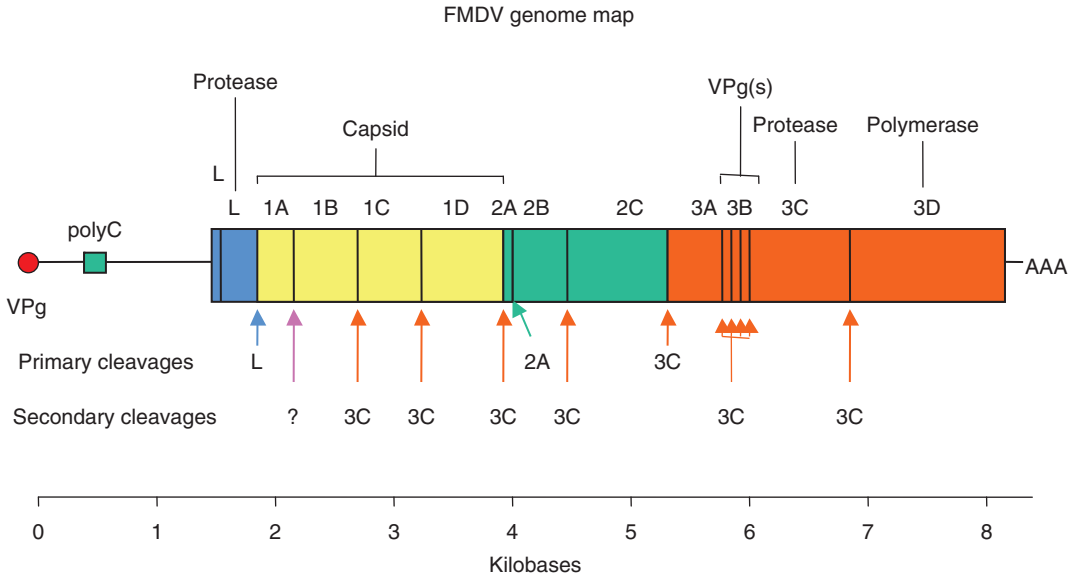

Figure 2 Genome map of FMDV. Boxed region is the polyprotein translation product with processing sites arrowed.

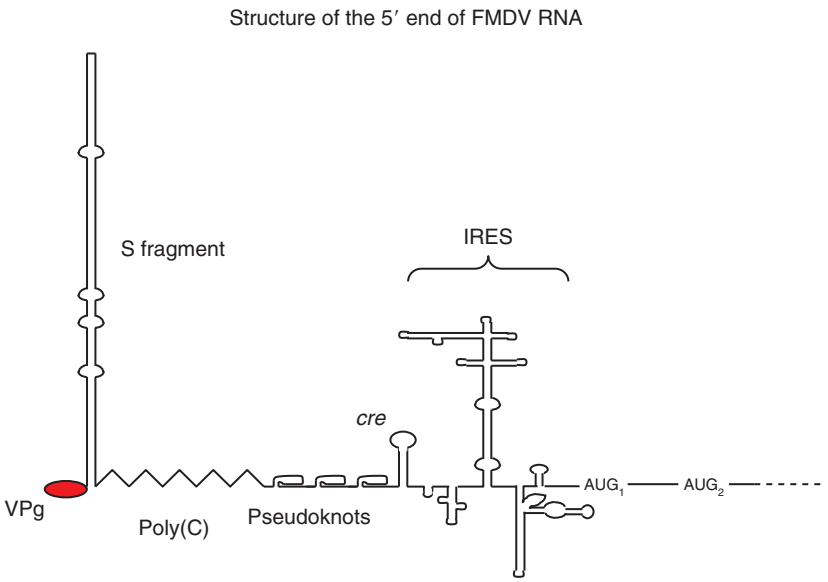

Figure 3 Secondary structure prediction for the 5′ UTR of FMDV RNA with major functional motifs individually labeled.

depending on which of two functional in-frame initiation codons is used. The order of the gene products is shown in **Figure 2**.

Leader protein. The leader protein(s), Lab and Lb, which precede the structural proteins, have a proteolytic function which cleaves at the L–P1 junction and also affects the cell translation machinery (see the section titled 'Translation'). Lb can perform all of the known functions of L and the significance of Lab is unknown, although presence of two polyprotein initiation sites is completely conserved. The L proteins are not essential for virus viability since virus derived from an infectious clone with deleted L domain can replicate. However, it has an attenuated phenotype and has been proposed as a candidate live vaccine.

P1 region. The P1 region consists of the structural proteins 1A, 1B, 1C, and 1D, which are equivalent to VP4, VP2, VP3, and VP1, respectively.

P2 region. The 2A protein is vestigial in size compared to other picornaviruses, being only 18 amino acids long, but it enables the nascent separation of the polyprotein at the 2A–2B junction. 2C has a nucleoside triphosphate binding motif and it appears to have a role in RNA replication since amino acid changes in this protein can relieve the inhibition of RNA synthesis seen in the presence of guanidine. The precursor protein 2BC influences membrane trafficking in infected cells, a role performed by 3A in poliovirus.

P3 region. The role of 3A in FMDV is unclear but it does not seem to function in a similar manner to the 3A protein of poliovirus, which serves as a membrane-bound donor of VPg during viral RNA synthesis.

3B or VPg occurs as three tandem copies of 23, 24, and 24 amino acids. Although differing in sequence, each is rich in Pro, Arg, and Lys residues and has a single Tyr at position 3. Each of the individual VPg molecules is highly conserved between the A, O, and C serotype viruses. The VPg molecules are post-translationally modified to function as primers in RNA synthesis (see next section). All encapsidated RNA molecules terminate with a VPg molecule and each of the three forms is found in equal abundance. Actively translating viral RNA lacks VPg, and cell extracts contain an enzyme that cleaves the phosphodiester bond to produce RNA terminating with a 5′-monophosphate. The observation that all virion-associated RNA terminates in VPg suggests that it may have a role in the selection of molecules for encapsidation. Mutagenesis experiments with an infectious cDNA clone have provided some support for this conclusion.

$3C^{pro}$ is the protease responsible for the majority of the processing cleavages. In common with other picornaviruses, sequence analysis suggests that the catalytic site of $3C^{pro}$ is related to trypsin, a serine protease, but with the replacement of the nucleophilic serine residue with cysteine.

$3D^{pol}$ is the RNA-dependent RNA polymerase responsible for RNA replication and VPg uridylation (see next section). The crystal structure has been solved in the apo form and in complex with primer and template.

The 3CD precursor has a distinct function as a catalyst for the $3D^{pol}$-mediated uridylation of VPg.

The molecular structures of virus particles, L^{pro}, $3C^{pro}$, $3D^{pro}$, and precursor 3CD have all been determined by X-ray crystallography.

RNA Replication

RNA of infecting virus functions as a template for the synthesis of a negative-sense complementary strand, which

serves, in turn, as template for the synthesis of positive-sense strands, identical to the original infecting molecule. Positive strands are synthesized in a complex structure (replicative intermediate (RI)) consisting of a single negative-strand template and several (around six) nascent positive strands. RNA synthesis is asymmetrical in favor of positive strands. A proportion of the negative-strand templates occur as full-length double-stranded hybrids (replicative form (RF)) and appear to take no further part in RNA synthesis. RF molecules accumulate in the cell during viral replication. Each RNA replication event is initiated by priming with a uridylated VPg molecule.

A single molecule of viral RNA is sufficient to initiate infection, which implies that it can function sequentially as a template for translation, to produce the polymerase enzyme(s), and as a template for RNA replication. Single-stranded viral RNA is infectious in the presence of inhibitors of host cell DNA-dependent RNA polymerase. Double-stranded viral RNA is also infectious but not in the presence of inhibitors of the cellular polymerases.

Translation

FMDV RNA is efficiently translated in a cell-free system (rabbit reticulocyte lysate) to produce protein products similar to those found in infected cells. The 435 nucleotides upstream of the first AUG initiation codon are folded into a complex structure similar to that of the equivalent region of cardiovirus RNAs. This sequence acts as an IRES, allowing initiation of translation in the absence of the host cell cap-binding complex. The rate of total protein synthesis in virus-infected cells does not change until its decline toward the end of the growth cycle, when cytopathic effects (CPEs) are apparent. There is, however, a marked change in the profile of proteins produced. When viral replication is maximal, virtually no host cell proteins are produced. This 'swap-over' of translation from host to viral products is similar to the situation in cardiovirus-infected cells and differs from the kinetics of translation following infection of cells with entero- or rhinoviruses. In the latter, infection results in a rapid shutdown of host cell protein translation, which is followed later by a resumption of protein synthesis due to the increasing production of viral proteins. The shutdown induced by entero- and rhinoviruses is largely, if not entirely, due to a virus-induced cleavage of a host protein, p220 or eIF4G, an important component of the cap-binding complex required for the initiation of translation of host mRNAs. In these viruses, eIF4G cleavage is indirectly induced by $2A^{pro}$ protease. Cardioviruses do not induce eIF4G cleavage and appear to simply outcompete host mRNAs for utilization of the translation machinery. Although the kinetics of protein translation in FMDV-infected cells resemble those of cardiovirus-infected cells, eIF4G is cleaved. In contrast to entero- and rhinoviruses, FMDV cleavage of eIF4G is not induced by 2A but by L. $3C^{pro}$ can also cleave eIF4G but at a different site from L^{pro} and later in the infection cycle. Inhibition of host cell protein synthesis is likely to be of advantage to the virus both by removing competition for access to the translation machinery and also by inhibiting the expression of innate immunity response genes in infected cells.

Post-Translation Processing

The polyprotein translation product of FMDV RNA is proteolytically processed by three of four virus-encoded enzyme activities (**Figure 2**). Three of the cleavages occur nascently on the growing polypeptide chain. The first separates L from P1, the structural protein precursor, and is carried out by leader protein. The cleavage is within a Lys-Gly dipeptide and probably occurs normally in *cis* but can also occur in *trans*. L–P1 cleavage is the only processing step which is inhibited by the tripeptide D-Val-Phe-Lys-CH_2Cl. Both Lb and Lab are proteolytically active.

The second primary cleavage occurs at the junction of 2A and 2B and is catalyzed by the 18-amino-acid 2A sequence. There is good evidence that the mechanism of 'cleavage' at the 2A/2B junction involves a novel process of interrupted translation, referred to as ribosomal skipping, rather than proteolytic cleavage.

The third primary cleavage is between 2C and 3A and is catalyzed by $3C^{pro}$ protease. This protease is responsible for all other processing cleavages, apart from that which generates VP2 (1B) and VP4 (1A) from the precursor VP0 (1AB). Many cleavages catalyzed by $3C^{pro}$ protease occur at Glu-Gly junctions but other dipeptides are recognized and $3C^{pro}$ of FMDV is the most promiscuous of the picornavirus proteases. The cleavage event to produce VP2 and VP4 from the precursor, VP0, occurs in the final stages of virus maturation. The mechanism of this cleavage is not known.

Virus Assembly and Release

A variety of assembly intermediates containing equimolar amounts of VP1, VP2, and VP0 are detected in infected cells. These correspond to monomer and pentamer subunits of the icosahedral capsid and 75S empty particles, which lack viral RNA but possess antigenic properties similar to mature viral particles. Following pulse-labeling experiments, empty particles can be 'chased' into viral particles, but it has not been shown that they are on the direct morphogenetic pathway. All encapsidated RNA

terminates with VPg, suggesting that this plays a role in selection. Altered VPg molecules within an infectious cDNA clone are less efficiently encapsidated.

Paracrystalline arrays of virus are visible in infected cells and are released by lysis of the cell. There is evidence that some viral particles are secreted prior to cell disruption.

Cell Attachment and Entry

The large mobile G–H loop of VP1 located at the surface of FMDV particles mediates their binding to susceptible cells. The sequence of the loop contains a highly conserved motif, Arg, Gly, Asp, which is the hallmark of ligands for a number of heterodimeric cell surface molecules called integrins. Synthetic peptides including this sequence can compete with virus for cell attachment and treatment of the virus with proteolytic enzymes such as trypsin, which cleave within the G–H loop, also prevents virus binding. Although the virus can bind to a number of integrins there is good evidence that $\alpha_v\beta_6$ is the preferred receptor *in vivo*.

Following attachment the virus is internalized by endocytosis and release of the RNA is triggered by acidification in early endosomes. Reduction of the pH below ~6.8 seems to be all that is required to initiate the infection process and the mechanism by which the genome is delivered to the cytoplasm is unknown. Many tissue-culture-adapted strains of the virus have evolved *in vitro* to use heparin sulfate at cell surface as an alternative receptor.

Geographic Distribution

FMD occurs widely and is endemic in many countries, especially in tropical regions (**Figures 4** and **5**). North America, Australia, New Zealand, and Japan are free of the disease and maintain this status by rigorous application of import controls and quarantine. Mass vaccination campaigns have virtually eliminated the virus from some areas, for example, Europe, but have been less effective in others, largely due to logistical problems of vaccine distribution and the techniques of animal husbandry employed. The global distribution of the serotypes is shown in **Figures 4** and **5**.

Host Range and Viral Propagation

The virus typically infects cloven-hoofed species with domestic cattle being the most susceptible. Domestic pigs are also important hosts and are particularly effective in propagating the disease, since they secrete large quantities of virus in the form of aerosols. In sheep and goats, the clinical manifestations of infection are usually less

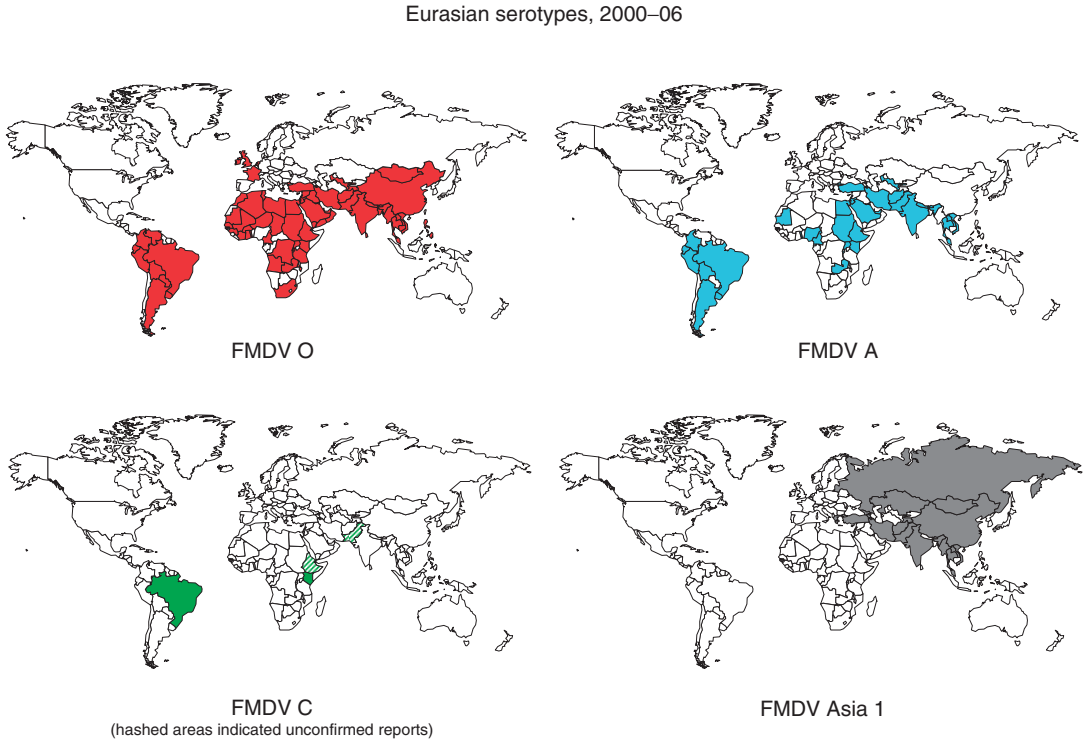

Figure 4 Global distribution of FMDV serotypes O, A, C, and Asia 1 between 2000 and 2006. Courtesy of N. Knowles.

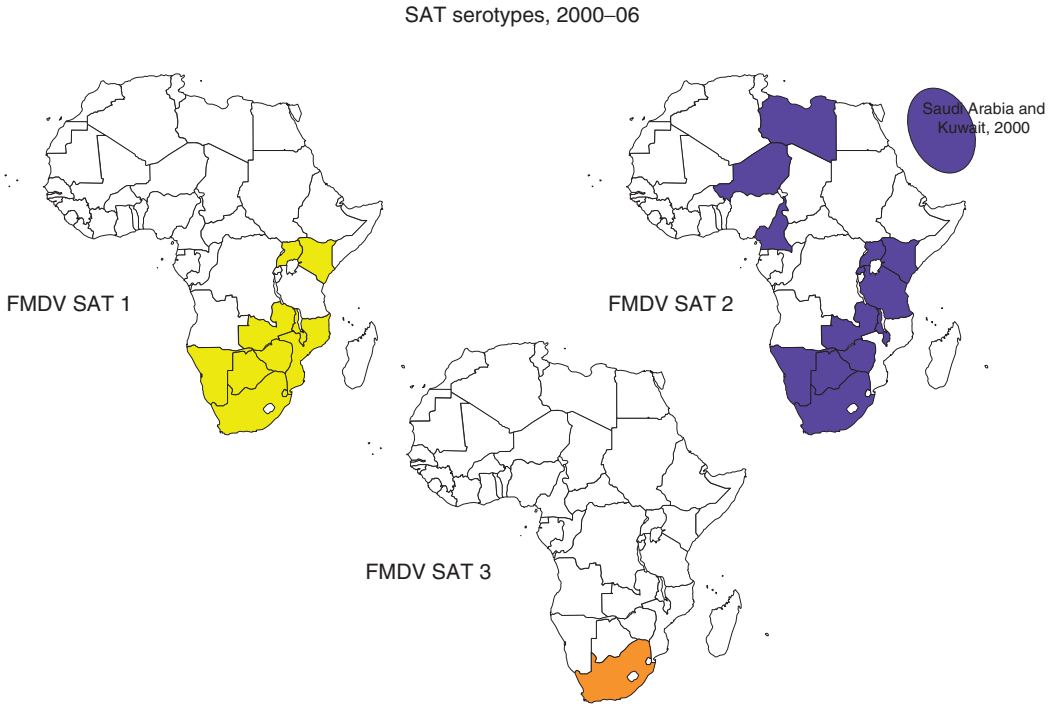

Figure 5 Distribution of FMDV serotypes SAT 1, SAT 2, and SAT 3 between 2000 and 2006. Courtesy of N. Knowles.

severe than those seen in cattle and pigs. Natural infection of Indian elephants and of camels has been reported. Many wild species of deer and antelope are susceptible to infection, and in African Cape buffalo infection is asymptomatic. Persistent infection with prolonged shedding of virus for months or years has been reported in wild and domestic species. A wide range of animals, including Australian marsupials and birds, have been infected under laboratory conditions and, very rarely, infection of human has been demonstrated.

The most important small animals for laboratory investigations are the guinea pig and the suckling mouse. In the former, injection of virus intradermally into plantar pads results in the formation of vesicular lesions both at the site of injection and in the mouth and the remaining feet, and so resembles the lesion distribution in naturally infected susceptible species. Intraperitoneal infection of suckling mice results in rapid death. The viruses can be propagated in primary cells and cell lines of bovine or porcine origin. Cells derived from the BHK-21 line are most widely used for research or vaccine production purposes. The virus can be titrated by plaque assay in cultured cell monolayers or by cytopathic end point dilution assay in microtiter plates.

Genetics and Evolution

In common with other RNA viruses, the mutation rate is extremely high and virus populations exist as quasispecies in which each individual genome is likely to differ from every other. Antigenic sites on the viral particle are tolerant of sequence variation, and antigenic diversity is a significant property of the virus.

In addition to evolution by the accumulation of point mutation, genomic recombination occurs at a high rate *in vitro*. The frequency and genomic location of recombinatorial events mirror the genetic relatedness of the parental viruses.

Serological Relationships and Variability

Seven serotypes of FMDV are recognized, the distinction of serotypes being that an animal convalescent from infection by virus of one serotype is fully susceptible to viruses of any of the remaining six. In addition to the major serotype differences, there is considerable antigenic variation between viruses within serotypes. The serological relationships between FMDV isolates are paralleled by genetic relationships as evidenced by RNA sequence analyses (**Figure 6**).

For epidemiological studies and vaccine strain selection, the serological relationships between field virus isolates or laboratory strains are expressed as *r* values, that is, the ratio of the neutralizing titers of immune sera against heterologous and homologous viruses. The serological relationships between virus isolates are frequently nonreciprocal, showing that closely related viruses may induce broadly cross-reactive or narrowly specific immune responses.

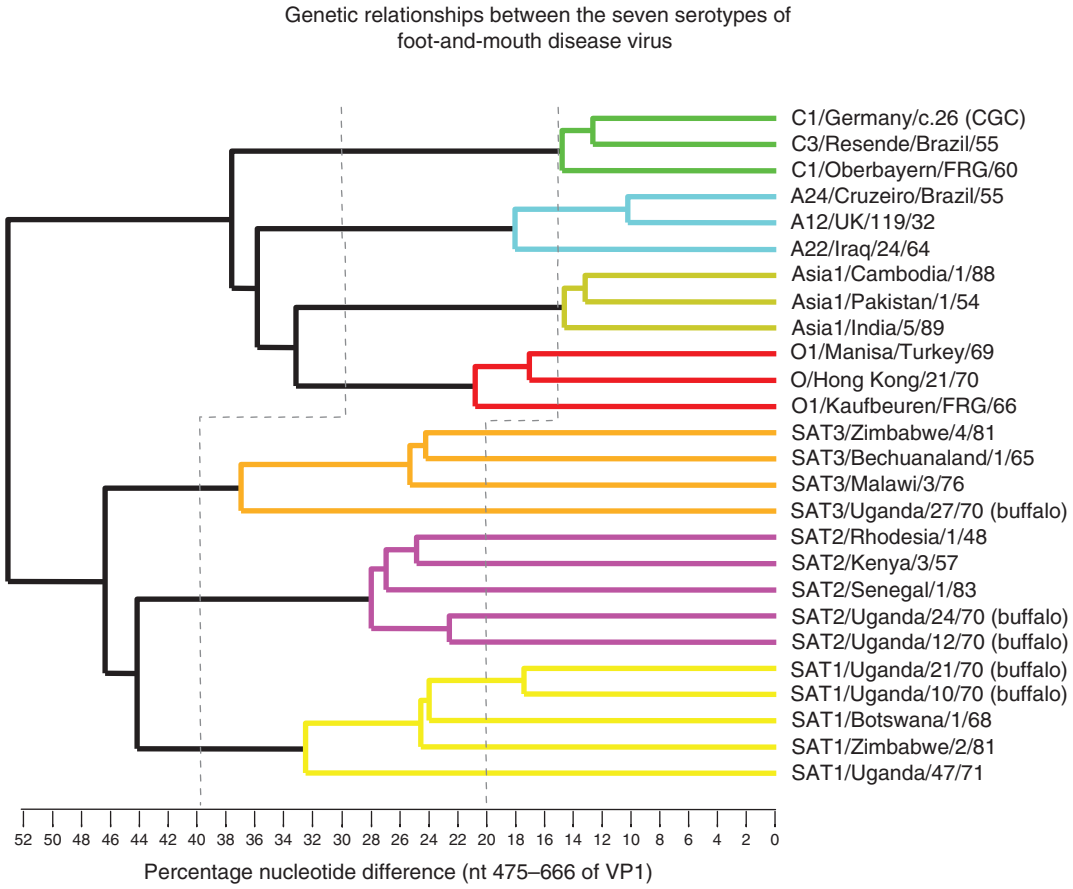

Figure 6 Genetic relatedness of FMDV strains and serotypes based on sequences within the VP1 gene. Courtesy of N. Knowles.

Complement fixation assay and enzyme-linked immunosorbent assay (ELISA) using polyclonal sera or monoclonal antibodies are also used for epidemiological studies.

Epidemiology

In regions endemic for FMD, the virus is most likely maintained in persistently infected animals. It has been shown experimentally that infected bovines can secrete virus for long periods after the initial episode of disease. In some areas the wild animal population may act as a reservoir for infection (e.g., Cape buffalo in Africa). In nonendemic areas, infection may be introduced from a variety of sources such as the importation of infected livestock, contaminated animal products such as carcasses containing bone (in contrast to meat, the postmortem acidification of bone marrow and other nonmuscular tissues is insufficient to inactivate the virus), or contaminated materials. More locally, transmission of infection is by direct transport of contaminated animals or materials or by wind-borne carriage of infectious aerosols. It is also suspected that the virus can be passively transmitted by migrating birds.

Transmission and Tissue Tropism

The principal route of infection appears to be via aerosol impinging on the pharynx and respiratory tract. Aerosols may be produced locally during feeding on contaminated foodstuff or may be transmitted over considerable distances under appropriate meteorological conditions. Pigs secrete particularly high levels of virus-contaminated aerosols. In addition to mucosal secretion, high levels of virus are found in milk. Pasture may be contaminated with virus from urine and feces.

Vesicular lesions appear in the mouth on the tongue, gums, and cheeks and later on interdigital mucosa and coronary bands of the feet. Virus can be isolated from many tissues in the body. The onset of clinical disease is usually very rapid and lesions can develop as early as 1–2 days after infection, depending on the virus strain and level of exposure.

Pathogenicity

The pathogenicity of FMDV varies according to the virus strain, host species, and age. The factors that govern the

virulence of FMDVs are poorly understood and as with most viruses are probably multifactoral. Domestic cattle are usually the most susceptible species and morbidity is usually *c.* 100% in nonvaccinated animals. Wild bovines, such as African Cape buffalo, may produce no clinical manifestations. Although the disease is rarely fatal in adult domestic animals (<5%), significant mortality may occur in young animals (*c.* 50%).

Clinical Features of Infection

Infection typically produces a rapidly progressing febrile illness and the development of often massive vesicular lesions in the mouth and on the feet. The lesions rupture with considerable loss of epithelial tissue (**Figure 7**). The resulting discomfort discourages feeding until the lesions heal by the infiltration of fibrous tissue. The severity of the disease results in long-term loss of productivity in terms of meat and milk yield, and lameness may be a serious consequence for draught animals. Abortion and chronic subfertility are also common. Other organs infected include mammary glands, pancreas, and heart.

Immune Response

Infection elicits a vigorous humoral antibody response and, after recovery, immunity to reinfection with viruses of the same serotype is prolonged. The role of cytolytic T cells in recovery is unclear.

Four antigenic sites recognized by antibodies capable of neutralizing the virus have been described. One of these is an immunodominant linear sequence comprising the G–H loop of VP1, and synthetic peptides representing this tract are effective in inducing high levels of virus-neutralizing antibody and can protect animals from infection.

Figure 7 Severe symptoms of FMD showing extensive sloughing of linguinal epithelium. Crown copyright. Reproduced from ''Foot and mouth disease: Ageing of lesions'' (Defra, 2005) by permission of the Controller of HMSO.

Antibody responses to several of the nonstructural proteins are induced during infection and these are being developed as markers to distinguish vaccinated from infected animals.

Prevention and Control

In disease-free regions, natural protection afforded by geographical barriers is rigorously reinforced by strict controls on the importation of susceptible animals and potentially contaminated materials. Where outbreaks occur sporadically, due to occasional introduction from external sources, embargoes on animal movement and slaughter of infected herds have been successful in maintaining a disease-free national herd. In endemic areas, control is by mass vaccination. Ring or barrier vaccination is also used to limit the spread of infection.

Dramatic demonstrations of the vulnerability of naive livestock to large-scale epidemics of FMD were provided by the outbreaks of serotype O virus in the UK and of serotype A virus in South America in 2001. The outbreak in the UK resulted in the slaughter of over 10 million animals (most of which were uninfected) to control spread of the disease and the cost to the country was several billions of pounds. In South America, the outbreak was controlled by the resumption of blanket vaccination of all livestock.

The first vaccines against FMD were produced by formalin inactivation of lymph drawn from lesions on the tongues of infected cattle. This source of immunizing virus was replaced by the Frenkel method of culture in fragments of epithelium stripped from the tongues of slaughtered cattle. Most vaccine in use today is produced by growing the virus in suspensions of BHK-21 cells in fermentation vessels of up to 10 000 l capacity. Approximately 2×10^9 monovalent doses of vaccine are administered annually. Aziridines have largely replaced formalin as the inactivant, since the inactivation kinetics of the latter are nonlinear and residual live virus in vaccines has occasionally been the source of outbreaks of disease. The serotype and strain composition of vaccines have to be tailored for local requirements. Inactivated virus is usually adjuvanted by adsorption onto aluminum hydroxide gel, and saponin may also be added to enhance potency. In pigs, such vaccines elicit only immunoglobulin M responses, and for this species vaccines are formulated with oil adjuvants. The use of oil-adjuvanted vaccines are now being extended to cattle.

Solid protection requires high levels of neutralizing antibodies, and, to achieve this with inactivated vaccines, immunization is repeated two to three times a year. The development of live-attenuated vaccines has largely been abandoned mainly due to the complexity of antigenic diversity and the fear of reversion to a virulent phenotype.

Future Perspectives

There is scope for developments in FMD vaccines to improve stability, cross-protective efficacy, and duration of immunity. Peptide vaccines, recombinant viral capsids, and rationally designed nonreverting attenuated viruses are potential routes by which these goals may be achieved. The production of non-biodegradable peptides and the creation of an attenuated L protein deletion mutant may be important developments. Since the massive outbreaks in the UK and in South America in 2001, there is increased interest in the development of drugs to halt the rapid spread of infection. Improved rapid diagnostic methods are being explored as is the ability to accurately distinguish infected from vaccinated animals.

As to the molecular properties of the virus, both the determination of the crystallographic structure of the particle and several of the nonstructural proteins and the cloning and manipulation of full-length infectious cDNA molecules are important steps toward understanding the unique features of the virus.

Fowlpox Virus and Other Avipoxviruses

M A Skinner, Imperial College London, London, UK

© 2008 Elsevier Ltd. All rights reserved.

Taxonomy

Fowlpox virus, the prototype of the *Avipoxvirus* genus, is the best-studied species. There are currently nine other recognized species (*Canarypox virus*, *Juncopox virus*, *Mynahpox virus, Pigeonpox virus*, *Psittacinepox virus, Quailpox virus, Sparrowpox virus, Starlingpox virus,* and *Turkeypox virus*) and three tentative species (Crowpox virus, Peacockpox virus, and Penguinpox virus). Avipoxvirus infections have been observed in more than 230 of the known 9000 species of birds, spanning 23 orders, yet little is known about the genome diversity, host range, and host specificity of the causative agents.

History

With its characteristic lesions, ubiquitous distribution among domesticated poultry, and large virion size, fowlpox virus (FWPV) was one of the earliest recognized viruses. It also played important roles in the development of modern virological techniques during the middle decades of the twentieth century. Fowlpox was one of the first diseases of livestock and poultry for which effective vaccines were developed, as early as the late 1920s. These vaccines led to effective control of the disease and its virtual eradication from commercial poultry production in temperate regions. Fowlpox remains enzootic in most tropical and subtropical regions where poultry is produced. It represents, after Newcastle disease, the second largest virus infection of backyard poultry in Africa and is thus of considerable socioeconomic importance.

Virion Structure

Like other poxviruses, the brick-shaped avipoxviruses are large enough (at $330\,\text{nm} \times 280\,\text{nm} \times 200\,\text{nm}$) to be resolved by light microscopy. Indeed, the particles were originally observed following staining with basic dyes

(such as basic fuchsin in Gimenez stain) and were termed 'elementary particles' or 'Borrel bodies'. Overall, the structure of the avipoxvirus virion is assumed to be similar to that of the much better studied vaccinia virus (VACV). Likewise, the replication cycle of the avipoxviruses is assumed to be essentially similar to that elucidated for the mammalian poxviruses. However, there are differences between avipoxviruses and the commonly studied mammalian poxviruses in the complement of structural genes and in morphogenesis of extracellular enveloped virions (described below), both indicative of significant structural differences at the molecular level. As a consequence, it is not clear which proteins are present in the envelope of avipoxvirus extracellular enveloped virus (EEV).

Genome Size and Organization

The avipoxviruses appear to have some of the largest known genomes of viruses of vertebrates, more than 300 kbp for canarypox virus (CNPV), encoding about 300 proteins. By way of comparison, this is 100 times the size of the smallest animal virus genomes and half the size of the genome of the smallest free-living bacterium. Among mammalian poxviruses, the central two-thirds of the genome generally encode conserved structural proteins and enzymes. In contrast, the terminal regions are more variable and divergent, encoding genus and species-specific, nonessential proteins, which are frequently involved in virus–host interactions affecting host–range, pathogenesis, and virulence. This general distribution holds in the avipoxviruses but, relative to the mammalian poxviruses, several large genome rearrangements (translocations, inversions, and transversions), which could have occurred in either avian or mammalian lineages (or both), have resulted in transfer of likely nonessential genes into more central locations.

Gene Complement

Although avipoxviruses appear to encode equivalents of most of the internal structural proteins of the VACV core, they lack some important proteins found on the surface of the intracellular mature virus (IMV) of VACV (such as D8 and A27), on the surface of the EEV (such as A33, A56, and B5), as well as on the surface of intracellular enveloped viruses, or IEV (such as A36).

Avipoxviruses also encode proteins not found in mammalian poxviruses, such as homologs of the host PC-1 nucleotide phosphodiesterase, DNaseII (DLAD), alpha-SNAP, and the lipid-pathway enzyme involved in Stargardt's macular dystrophy (ELOVL4). Such proteins appear to be nonessential for replication in tissue culture and are presumed to be nonstructural. Avipoxviruses also encode multiple members of several gene familes, notably the 31 ankyrin-repeat proteins encoded by FWPV (51 by CNPV) and the six copies of the massive B22 ortholog (2000 amino acid residues) found only as a single copy in some mammalian poxviruses, such as variola virus (VARV), cowpox virus (CPXV), and molluscum contagiosum virus (MOCV). The latter gene family therefore accounts for about 35 kbp of the additional sequence found in the avipoxvirus genome.

Antigens

Three major immunodominant antigens of FWPV that are recognized by murine monoclonal antibodies have been identified. They correspond to immunodominant antigens recognized by hyperimmune serum from FWPV-infected chickens and to equivalent immunodominant antigens of mammalian poxviruses. They are the 30/35 kDa IMV surface protein fpv140 (corresponding to VACV H3), the 39 kDa virion core protein fpv168 (corresponding to VACV A4), and the 63 kDa 'virion occlusion' protein fpv191 (corresponding to the p4c protein retained in very few VACV strains). Neutralizing antisera or monoclonal antibodies have not been reported.

Survival Factors

A-Type Inclusion Protein

The avipoxviruses express a number of proteins that might be considered as factors to potentiate their survival in the face of various environmental stresses. These include the A-type inclusion (ATI) protein, which forms large cytoplasmic inclusions. These inclusions can contain large assemblies of embedded virions (analogous to spheroidin inclusions in the entomopoxviruses), which would probably be better protected from dessication in desquamated dermis. It is likely that entry of avipoxviruses into the ATI requires the presence of fpv191 (p4c, virion occlusion protein) on the surface of the IMV, assuming the mechanism is as elucidated for CPXV.

Photolyase

Avipoxviruses encode photolyases (e.g., fpv158), which are capable of repairing ultraviolet (UV)-induced pyrimidine dimers in DNA in a light-dependent manner. Such lesions might be induced in viral genomic DNA when the virion is exposed to the environment in desquamated epithelium, or while the virion is near the surface of a skin lesion.

Glutathione Peroxidase

Like MOCV, avipoxviruses encode a glutathione peroxidase. Such proteins might be able to protect the virus

from environmental oxidative stress. However, the FWPV protein (fpv064) is probably not an ortholog of the MOCV protein (MC066), which is most closely related to cellular glutathione peroxidase. Instead it is probably a paralog, most closely related to cellular phospholipid hydroperoxide glutathione peroxidase. The avipoxvirus proteins might protect infected cells from the oxidative burst of immune cells or affect cell signaling pathways.

Immunomodulators

Unlike most mammalian poxviruses, but in common with MOCV, no obvious candidates for proteins interfering with the host type I interferon response have been identified. Thus the avipoxviruses lack orthologs of the VACV double-stranded RNA-binding protein (E3) and the eIF2 mimic (K3). No soluble homologs of type I interferon receptors (equivalent to VACV B18) have yet been identified in the avipoxviruses, although a soluble binding protein (e.g., fpv016) for type II interferon has been identified biochemically. Conversely, avipoxviruses also encode proteins not generally found in mammalian poxviruses, such as homologs of transforming growth factor β (e.g., fpv080), which has also been found in deerpox virus, and IL10 (e.g., CNPV018), also found in orf parapoxvirus.

No obvious soluble chemokine-binding proteins encoded by avipoxviruses have been identified, in contrast to the mammalian poxviruses. However, proteins resembling cellular serpentine chemokine receptors of the 7-transmembrane spanning G-protein-coupled receptor family are encoded by avipoxviruses (e.g., fpv021, fpv027, and fpv208), as are single copies by some mammalian poxviruses (capripoxviruses, suipoxviruses, yatapoxviruses, and deerpox virus). Like MOCV, avipoxviruses encode putative IL18-like proteins (e.g., fpv214) and chemokine-like proteins (e.g., fpv060, fpv061, fpv116, and fpv121).

Features of Avipoxviruses Shared with Molluscum Contagiosum Virus

The mammalian poxvirus to which the avipoxviruses are most closely related phylogenetically is MOCV. The avipoxviruses also share a number of other features with MOCV. For example, they lack orthologs of the VACV proteins E3 and K3 involved in evading the type I interferon response. Whereas avipoxviruses encode a family of proteins (e.g., fpv097, pfv098, fpv099, fpv107, fpv122, and fpv123) with homology to the large VARV protein B22, MOCV (like VARV and CPXV) encodes only a single protein (MC035). In CPXV, as in VARV, the gene encoding the B22 ortholog (CPXV219) is located in the variable region at the right terminus of the genome. The gene encoding the MOCV ortholog MC035 is, however, more central, located between orthologs of VACV E4L and E6R. This is syntenic with the location of FWPV genes encoding B22 orthologs fpv097, fpv098, and fpv099, also found between orthologs of VACV E4L and E6R.

Like the avipoxviruses, MOCV lacks orthologs of VACV IMV surface proteins A27 and D8 as well as EEV proteins A56 and B5 (though, unlike the avipoxviruses, MOCV does encode orthologs of VACV EEV protein A33 and IEV protein A36).

Virus Replication

Host Range Restriction

Avipoxviruses are incapable of productive replication in mammalian cell lines, including those (such as BHK-21) permissive or semipermissive for the host-range-restricted MVA variant of VACV, and those defective in the type I interferon pathway, such as Vero cells. Otherwise, the replicative cycle is largely similar to that elucidated for VACV, although considerably slower (taking about 24 h rather than 12 h). Genome transcription and replication mechanisms are essentially the same, with relatively well conserved polymerases and other enzymes. VACV promoters function well in cells infected with avipoxviruses and are frequently used to drive foreign gene expression in recombinant avipoxviruses, and the inverse appears to be true. Virus-induced shut-off of host gene expression, clearly observed with VACV, is far less dramatic with FWPV.

Genetic Reactivation

The long-recognized phenomenon of 'genetic reactivation' illustrates that many of the essential replicative components of poxviruses are interchangeable. Thus the proteins of a UV-inactivated poxvirus can rescue the genome of a heat-inactivated poxvirus, even when the two viruses are from different genera. This is well illustrated by the modern practise of rescuing naked (and often genetically manipulated) genomic DNA of a mammalian poxvirus by infection of transfected cells with FWPV. The rescued mammalian poxvirus can be recovered and amplified by passage through mammalian cells, which eliminates the rescuing FWPV due to its host range restriction.

Virion Morphogenesis

The most obvious difference between the replication cycles of avipoxviruses and that of VACV is in the formation of EEV. VACV EEV formation predominantly involves wrapping of IMV with a double membrane derived from the *trans*-Golgi network (to form IEV) followed by subsequent exocytosis to form cell-associated enveloped virus (CEV) and EEV. Avipoxviruses, however, form EEV by a more conventional pathway in

which IMV buds through the cell membrane to acquire an envelope. This difference, observed by electron microscopy (**Figure 1**), is consistent with the absence from the avipoxvirus genome of genes involved in wrapping and exocytosis in VACV.

Lipid Metabolism

There have been reports that FWPV has a profound effect on host cell lipid metabolism. It is tempting to speculate that this might be attributable to some of the unusual genes carried by FWPV, notably fpv048 encoding a protein with unusually high sequence similarity to the ELOVL4 host protein, a fatty acid elongation factor implicated in macular degeneration.

Virus Propagation

Avipoxviruses replicate only in avian cells; replication in mammalian cells is abortive and no infectious progeny are produced. Some vaccine strains of FWPV, such as the Cyanamid Webster FPV-M vaccine, even display a preference for chick embryo skin cells (CESs) over chick embryo fibroblast cells (CEFs). FWPV FP9 has been effectively adapted to CEFs but it displays a distinct preference for primary as opposed to secondary CEFs. Plaques on CEFs are not lytic, but the cytopathic effects manifest as changes in cell morphology, resulting in areas of altered refractive index with the plaques best viewed by dark field illumination. FWPV fails to plaque and replicates poorly in the recently derived chicken fibroblast cell line, DF-1. Replication is similarly poor in the chemically transformed cell line OU-2. It can be plaqued and replicated quite efficiently in quail cell lines, such as QT-35, but the presence in these cells of viable endogenous Marek's disease virus (a herpesvirus) means that their use for preparation of vaccines is not advisable. Of these possible cell substrates for avipoxvirus propagation, currently only CEFs and CESs are licensed for use in the production of human vaccines.

Publications reporting the replication of uncharacterized avipoxviruses of unknown origin in embryonic bovine tracheal cells or in BHK-21 are atypical and, until corroborated, should be viewed with caution.

Molecular Phylogenetics

The taxonomy and classification of avipoxviruses are important to the study of epidemiology and hence to

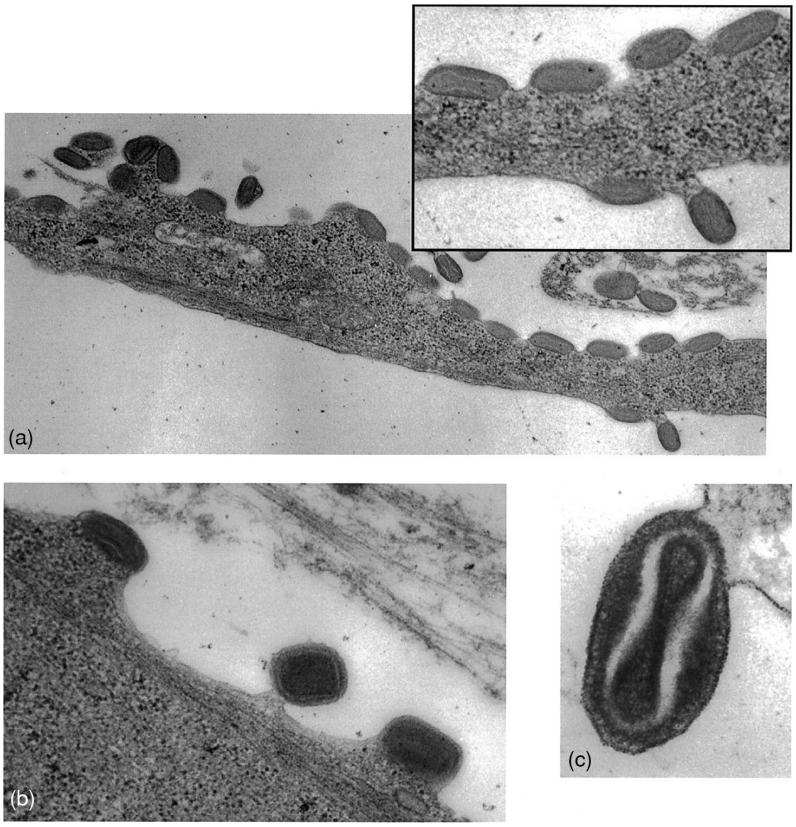

Figure 1 FWPV IMV particles budding through the membranes of infected chick embryo fibroblasts. Magnifications: (a) ×27 000 (inset ×51 000); (b) ×60 000; (c) ×170 000. Reproduced from Boulanger D, Smith T, and Skinner MA (2000) Morphogenesis and release of fowlpox virus. *Journal of General Virology* 81: 675–687, with permission from the Society for General Microbiology.

the future ability to control the diseases. Recent molecular studies confirm earlier impressions that avipoxviruses can jump species to cause disease. Thus isolation of a virus from a turkey, for instance, is not sufficient to demonstrate that turkeypox virus is the cause and, more importantly, that the outbreak can be controlled by a turkeypox virus vaccine.

Avipoxviruses can be highly diverged at the molecular level. For instance, the relatively highly conserved FWPV and CNPV P4b proteins (encoded by genes fpv167 and cnpv240, respectively) share only 64.2% amino acid sequence identity. This level of divergence is comparable to that seen between different genera of mammalian poxviruses (see **Figure 2**). In fact, recent molecular studies have demonstrated that avipoxviruses fall into three major diverged groups: (1) the FWPV-like viruses, (2) the CNPV-like viruses, and (3) the psittacinepox viruses (**Figure 2**). As their name suggests, the psittacinepox viruses have so far only been isolated from psittacines. In contrast, viruses of the FWPV-like and CNPV-like groups appear either inherently capable of infecting a wider range of birds or have evolved and adapted to be able to infect different birds. FWPV-like viruses have been isolated from turkeys, pigeons, ospreys, albatrosses, doves, and falcons. Viruses closely related to, and even barely distinguishable from, CNPV can cause disease in great tits, sparrows, stone curlews, and houbaras. CNPV-like viruses have been isolated from pigeons and starlings. A report in 2006 from Virginia in the USA indicated that one particular CNPV-like virus caused disease in a wide range of birds (robins, crows, herons, finches, doves, hawks, gnatcatchers, mockingbirds, and cardinals). It was not known whether the virus that caused the epornitic had a wider geographic distribution throughout the USA.

It is apparent that pigeonpox can be caused by two distinct types of virus, either FWPV-like or CNPV-like. The FWPV-like virus is very closely related to viruses from turkeys and osprey, and a little less closely related to those from an albatross, a falcon, and a dove. The CNPV-like virus is closely related to one from a starling. Infection of avian species outside the normal host range of the particular avipoxvirus can result in altered pathogenesis compared to that observed in the normal host. For instance, a virus which was isolated from an Andean condor (*Vultur gryphus*), in which it had caused an aggressive, diphtheritic form of the disease, produced only mild lesions in inoculated chickens. Conversely, viruses causing mild poxvirus lesions in wild birds, such as those found in 50% of short-toed larks (*Calandrella rufescens*) and 28% of Bertholet's pipits (*Anthus berthelotti*) in the Canary Islands, might cause more severe disease in naive populations of other avian species. It is, for instance, suspected that canaries might not be the natural reservoir for CNPV, which causes them a devastating disease.

Epizootiology

Evidence of poxvirus infection has been observed in many avian species but little is known about the natural host range of the causative agents, due to the lack of robust techniques for the identification and differentiation of isolates. Initially, the viruses were distinguished by their ability to cause disease in a range of test species, such

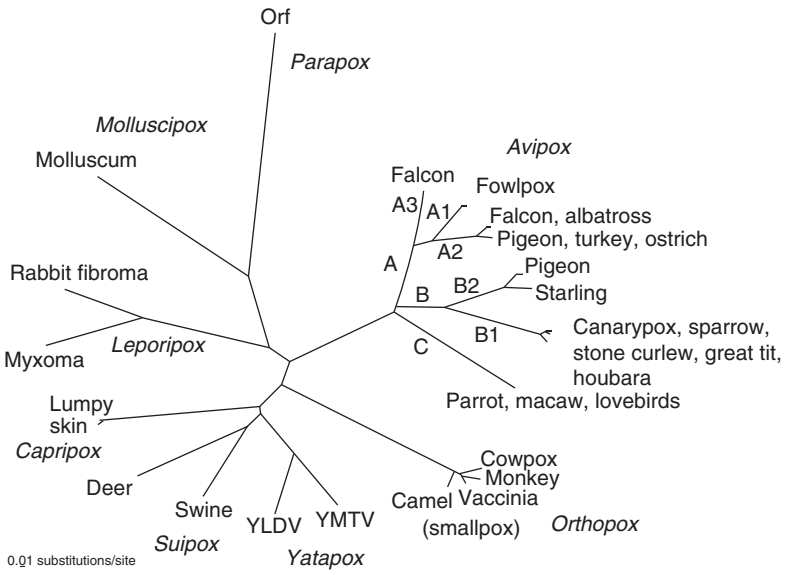

Figure 2 A phylogram showing phylogenetic relationships and evolutionary distances of avipoxvirus clades and mammalian poxvirus genera based on neighbor-joining analysis (supported by bootstrapping) of P4b orthologs.

as chickens, pigeons, turkeys, and quail. Such infectivity studies probably overestimate the degree of similarity between the viruses, as many isolates seem able to cause disease in the test species, possibly due to the inoculation of high doses. *In vivo* analysis of antigenic cross-reactivity allowed the viruses to be grouped or distinguished by their ability or inability to induce protective immunity against each other. Thus, psittacinepox virus offered no protection against FWPV or pigeonpox virus, or vice versa, nor did quailpox virus. Similarly, mynahpox virus showed no cross-protection with fowl, pigeon, psittacine, quail, or turkey poxviruses, and a condor poxvirus induced no protection against FWPV. *In vitro* serological techniques were applied to only a small proportion of the observed isolates because initial propagation in chick embryos or chick embryo fibroblast cells often failed. Possibly as a consequence of the limited characterization of isolates, there are only the ten recognized species of avipoxviruses.

Reintroduction programs appear to be particularly susceptible to problems caused by poxvirus infection. For instance, houbara bustard reintroduced into the Middle East have proved susceptible to uncharacterized avipoxvirus infections from unknown sources. Similar programs, such as that for the closely related great bustard on Salisbury Plain, Wiltshire, in the UK may face similar threats. There are also concerns that avipoxviruses might threaten marginal species such as some species of birds in the Hawaiian Islands and especially the kakapo, the flightless, nocturnal New Zealand owl parrot.

Transmission

Poxviruses produce two types of virion particles that are both infectious: IMV released into the environment only by desquamation of skin lesions and EEV released from the cell to spread to secondary sites of infection. In the wild, the primary route of infection is mechanical transmission of blood-borne EEV by biting insects (mosquitoes and midges). Lesions are therefore characteristically restricted to the featherless areas around the eyes and nares, on the comb, wattle, lower legs, and feet. Fowlpox remains a problem when control of biting insects is difficult but is generally not a problem for intensive production systems in the temperate areas of Northern Europe and the northern USA, even in the absence of vaccination. Problems with epizootics have emerged with free-range flocks, presumably because they are more exposed to biting insects, as well as to pecking by infected birds. In subtropical and tropical climates, fowlpox poses a significant problem requiring vaccination of commercial flocks.

FWPV can also transmit via inhalation or ingestion of dust (or dander, representing virus-infected cells shed from cutaneous lesions), or aerosols, leading to the 'diphtheritic form' of the disease, with lesions on the mucous membranes of the mouth, pharynx, larynx, and sometimes trachea. More likely to occur at high population density, this form of the disease is associated with commercial poultry flocks or collections of captive or domesticated birds (including quarantine facilities). However, such lesions may also form as a consequence of secondary viremia following primary cutaneous lesions, and viral genetic factors may play a role. Avipoxvirus infections of passerine birds (e.g., canaries and finches) can cause significantly higher rates of mortality than those of chickens or turkeys.

Diagnosis

Clinical Signs

FWPV and many other avipoxviruses primarily cause disease in mature birds. The cutaneous form of avipox, including fowlpox in chickens and turkeys, spread mechanically by biting insects or pecking, is normally relatively mild (**Figures 3** and **4**) but the diphtheritic form (**Figure 5**) causes higher mortality by occlusion of the oropharynx. A third form of poxvirus disease causes a pneumonia-like illness in canaries, with high mortality.

Histology

Smears of material scraped from cutaneous lesions or postmortem sections from diphtheritic lesions (or airway epithelium in the case of pneumonia) can be stained with hematoxylin/eosin, or Gimenez stain. The presence of eosinophilic inclusions (A-type inclusions, Bollinger bodies) in the cytoplasm is diagnostic of poxviruses. Basophilic (or B-type) inclusion bodies may also be seen in the cytoplasm (these represent the sites of virus replication, the so-called 'viral factories'), as may Borrel bodies (the virions themselves).

Virus Isolation and Detection

Virus may be passaged and amplified *in vivo* through specific pathogen-free chickens via wing web scarification or through embryonated eggs via chorio-allantoic membrane infection. The method of choice for virus propagation, however, is *in vitro* culture on CEFs for amplification through liquid culture or for plaque purification under semisolid overlay. Not all avipoxvirus isolates will form plaques, or even propagate, on CEFs. Primary cultures of other poultry species (duck, turkey, or quail) may also be used.

Serology

Serological methods such as enzyme-linked immunosorbent assays (ELISAs), available as commercial flock

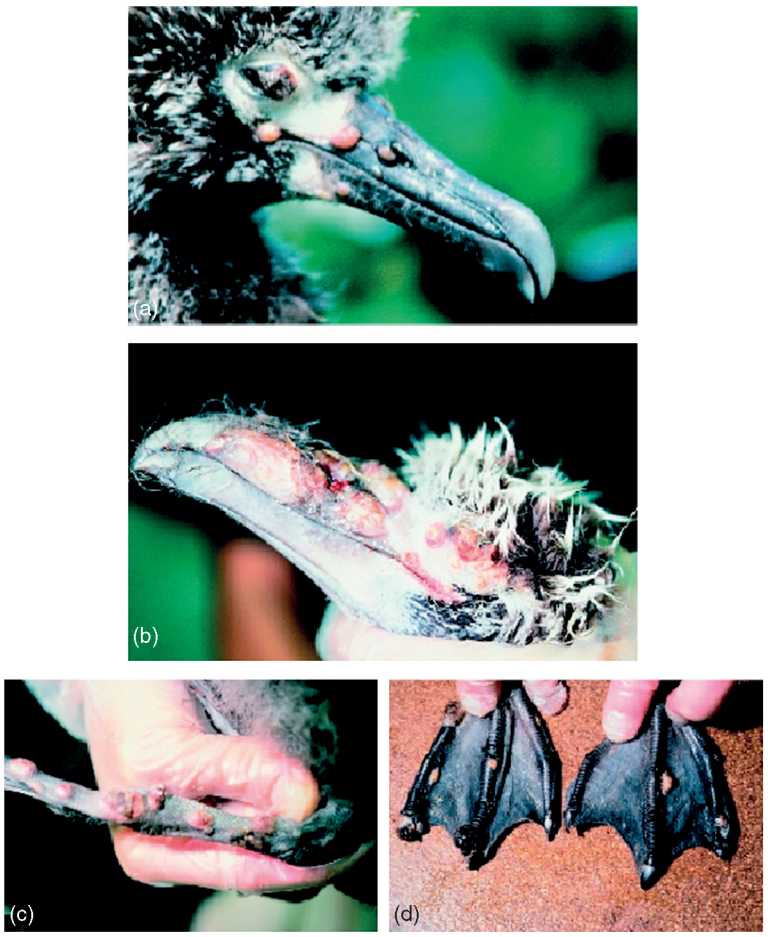

Figure 3 Typical avipoxvirus lesions seen on the head and feet of a Laysan albatross. Reproduced from Hansen W (1999) Avian pox. In: Friend M and Franson JC (eds.) *Field Manual of Wildlife Diseases, General Field Procedures and Diseases of Birds*, pp. 163–169, with permission from USGS.

monitoring kits, can be used to provide evidence for ongoing or prior infection in the flock. Virus neutralization tests are more specific but are technically more demanding and the responsible antigenic epitopes have not been identified.

Monoclonal Antibodies

Monoclonal antibodies against the three major immunodominant structural antigens of FWPV have been isolated and characterized, as described above. None appears to be neutralizing but all can be used in ELISAs and western blotting.

Restriction Enzyme Digestion and Southern Blotting

Before extensive genome sequencing, Southern blotting was the only available molecular diagnostic method, involving examination of restriction enzyme digest profiles. Without the use of radioisotopes, the method was relatively insensitive.

PCR-Based Analysis

With the advent of DNA sequence data for the avipoxviruses, polymerase chain reaction (PCR) amplification became the molecular diagnostic method of choice to identify avipoxvirus infections. This has been based routinely on the sequence of the gene encoding the P4b protein (the A3 ortholog encoded by gene fpv167), with primers for a 578 bp fragment. However, all avipoxviruses produce fragments of the same length, so the avipoxvirus could only be identified either by sequencing the PCR product or by restriction enzyme fragment polymorphism profiling.

A second PCR locus (the H3 locus), which works with most (but not all) avipoxviruses, has the advantage that viruses of the two major groups (CNPV-like and FWPV-like) can be discriminated purely on the basis of the size of the PCR product (**Figure 6**).

The genome sequences of two different FWPV strains, one extensively culture-passaged and attenuated, and of a pathogenic CNPV have been determined. They confirmed

Figure 4 Extensive avipoxvirus lesions seen on the head of a bald eagle. Reproduced from Hansen W (1999) Avian pox. In: Friend M and Franson JC (eds.) *Field Manual of Wildlife Diseases, General Field Procedures and Diseases of Birds*, pp. 163–169, with permission from USGS.

the divergence and differences between the avipoxviruses and the mammalian poxviruses typified by VACV. In fact, phylogenetic analysis showed that avipoxviruses are most closely related to MOCV of humans, a relationship confirmed by other specific aspects of their molecular biology (see **Figure 2**). Despite having sequence information for the prototypic members of the two major groups of avipoxviruses, it has still proved extremely difficult to identify conserved primer sequences that work in PCR reactions for all other members of the genus, further illustrating the extent of sequence divergence and diversity within this group of viruses.

Intraspecies and Interstrain Differentiation

Despite their large genome size, the high level of conservation within species of avipoxviruses makes it difficult to differentiate between different strains or isolates or between vaccines and pathogenic strains. Although numerous loci within FWPV have been surveyed, only one locus (the H9 locus), has been reported to allow clear differentiation. It appears to be an unstable region, with deletions of different lengths found in various FWPV strains, isolates, and vaccines. Three commercial fowlpox vaccines were found to have the same parental sequence found in two clinical isolates, while two other different commercial vaccines shared an identical deletion at the H9 locus (see **Figure 7**).

Control and Prevention

Vaccination

Since its introduction in the 1920s, vaccination against fowlpox using live FWPV or pigeonpox virus (now known to be closely related antigenically to FWPV) has become commonplace and extensive, such that the disease has been nearly eradicated from developed countries in temperate zones. Most currently available commercial vaccines originate from early isolates, though a minority were isolated in the mid-1960s.

Vaccination may be undertaken from 10 days or 4 weeks of age, depending on the residual pathogenicity of the vaccine, which is often related to whether the vaccine

is propagated in cell culture or in embryonated eggs. Inoculation is into the wing web using a bifurcated needle or by scarification of the thigh. The formation of a small lesion at the site of vaccination 6–8 days later indicates a good take, with immunity developing in 8–15 days. Though desirable, alternative routes for vaccination (aerosol, intranasal, or via drinking water) have not generally proved successful.

Treatment

There are no demonstrated effective treatments for avipoxvirus infections other than palliative treatment and to prevent or treat secondary bacterial infections.

Variant FWPVs

Antigenic Variants

Outbreaks of fowlpox have been reported within flocks previously vaccinated with FWPV or pigeonpox virus vaccines. If the vaccination had been effective, which is often not the case, antigenic variation might be suspected, though serotype specificity would be novel among poxviruses. Little is known about protective epitopes for humoral or cellular immune responses in FWPV and there has only been preliminary characterization of the 'variant' isolates.

Tumorigenic Variants

FWPV has also been associated with cases of dermal squamous cell carcinoma in poultry in Brazil. It is not clear whether FWPV is a causative agent and, if so, whether a variant is involved.

The Role of Integrated Reticuloendotheliosis Virus Sequences

FPV-S, a commercial FWPV vaccine known to be contaminated with reticuloendotheliosis virus (REV), was found to carry a near full-length, infectious progenome of REV integrated into the poxvirus genome. The provirus has subsequently been found in most, if not all, pathogenic field isolates of FWPV, but the majority of vaccine strains of FWPV carry only noninfectious, long terminal repeat (LTR) sequences of REV. The provirus and the LTR sequences have only ever been found at the same single locus, although differences exist between the REV LTR sequences retained in different viruses. It appears likely that a single, ancestral event inserted the provirus into the FWPV genome between genes fpv201 and fpv203, in contrast to the multiple REV insertions that have been observed in Marek's disease virus. It is not known whether REV can reintegrate at the site of a retained LTR or whether this would regenerate a pathogenic virus. There are no REV sequences in the completely sequenced genome of CNPV, but they have been detected in a commercial CNPV vaccine as well as in some commercial pigeonpox virus vaccines. Full-length REV sequences have been detected in an isolate from a turkey.

Recombinant Avipoxvirus Vaccines

Recombinant FWPV as a Vaccine Vector in Poultry

Shortly after the development of methods for isolating recombinant VACV in the early 1980s, FWPV was developed as an equivalent recombinant vector for use in poultry. Several commercial vaccine and laboratory attenuated strains were used as vectors against a number of important poultry pathogens, especially avian influenza virus, Newcastle disease virus, infectious bronchitis virus, avian hemorrhagic enteritis virus, Marek's disease virus, turkey rhinotracheitis virus, REV, and infectious bursal disease virus, as well as *Mycoplasma gallisepticum*. Commercial recombinant FWPV vaccines against Newcastle disease virus and avian influenza virus have been licensed for commercial use in the USA. Those against avian influenza have also been licensed for use in Mexico; indeed, between 1997 and 2003, approximately 459 million doses of a recombinant fowlpox-H5 vaccine were used in Mexico as part of a program to control H5N2. The same recombinant and similar viruses developed in China are being used in Southeast Asia to counter the highly virulent avian influenza H5N1 strain.

Recombinant Avipoxviruses as Vaccine Vectors in Mammals

It was demonstrated in the late 1980s that recombinant avipoxviruses (initially FWPV and then CNPV) carrying antigens from mammalian viral pathogens could enter mammalian cells and express the foreign antigens, even though the recombinants could not replicate and spread to neighboring cells. Moreover, vaccination of mammals with the recombinants could elicit immune responses, which could be protective against viral challenge. This discovery, which was surprising because of the low level of antigen expressed from the single-round, abortive infections, offered the prospect of extremely safe recombinant vaccines. Several recombinant avipoxvirus vaccines, mainly based on CNPV, have been developed primarily for veterinary use. However, the more recent focus on T-cell-mediated immunity has seen more use of FWPV-based

vectors. Many clinical trials have been conducted, are underway, or are planned, against viral diseases such as acquired immune deficiency syndrome (AIDS), parasitic diseases including malaria, and various cancers. In many of these trials, the recombinant avipoxviruses are used in combined (so-called 'prime-boost') regimes with the same antigens expressed by different vectors, such as DNA plasmids, the host-restricted MVA variant of VACV, or adenoviruses. These regimes allow immune responses to be boosted by multiple vaccinations without eliciting excessive responses against vector-specific proteins.

Recombinant avipoxvirus vaccines are yet to be licensed for agricultural use in Europe, though recombinant CNPV vaccines against equine influenza and feline leukemia have received European Medicines Agency (EMEA) approval. Both are licensed for use in the USA, besides similar recombinants against canine distemper and West Nile virus (for use in horses).

Glossary

Hyphal anastomosis The union of a hypha with another resulting in cytoplasmic exchange.
Hypovirulence Attenuated fungal virulence mediated by virus infection, mitochondrial defects, or mutations in the fungal genome.
Mycoviruses Viruses that infect and multiply in fungi.
Vegetative incompatibility A genetically controlled self/nonself recognition system in fungi that determines the ability to undergo hyphal anastomosis.

Introduction

Relative to plant virology, animal virology, or bacterial virology, fungal virology is new. In 1948, an economically important disease of the cultivated mushroom, *Agaricus bisporus*, characterized by malformed fruiting bodies and serious yield loss, was first reported in a mushroom house owned by the La France Brothers of Pennsylvania. The disease was called 'La France disease', and similar diseases were reported shortly thereafter from Europe, Japan, and Australia. Different designations, such as 'X-disease', 'watery stripe', 'brown disease', and 'die-back' were given to basically the same disease as the La France. The significance of the 1948 report lies in the fact that it led to the discovery of fungal viruses. In 1962 Hollings noted the presence of at least three types of virus particles in diseased mushroom sporophores. This was the first report of virus particles in association with a fungus and is regarded as the dawn of mycovirology. The subsequent discovery that dsRNA of mycoviral origin was responsible for interferon-inducing activities of cultural filtrates of several species of *Penicillium* spp. greatly stimulated the search for fungal viruses.

Fungi, like other living organisms, can be infected by a number of viruses, and mycoviruses are found in all the major groups of fungi. Although mycoviruses are widely

prevalent, only those infecting a limited number of fungal host species have been studied, for example, the yeast *Saccharomyces cerevisiae*, edible mushroom, and phytopathogenic fungi. Given the predicted vast number of fungal species (approximately 10 000 known species and many more unknown species), it is expected that a greater number of unrecognized mycoviruses occur in nature. Support for this idea comes from recent extensive searches of field fungal isolates that showed relatively high frequencies of virus infection, for example, approximately 65%, 20%, and 2–28% of *Helicobasidium mompa*, *Rosellinia necatrix,* and *Cryphonectria parasitica* isolates were found to be infected, respectively.

Biological Properties

Host Range

The natural host range of mycoviruses is likely to be restricted to the same or closely related vegetative compatibility groups that allow lateral transmission. Until recently, there were no known experimental host ranges for fungal viruses because of lack of suitable infectivity assays. Experimental host ranges for some mycoviruses, however, were recently demonstrated and shown to extend to different vegetative compatibility groups and even to different genera. For example, the prototype mycoreovirus (mycoreovirus 1) can replicate and induce phenotypic alterations in different vegetative compatibility groups of the chestnut blight fungus, *Cryphonectria parasitica*, similar to those exhibited by the original virus-containing strain. Furthermore, CHV1-EP713, the type member of the family *Hypoviridae*, can replicate in and confer hypovirulence onto members of several other fungal genera, for example, *Endothia gyrosa* and *Valsa ceratosperma*, in addition to its natural host, *C. parasitica.*

Symptom Expression

Although the majority of the viruses that infect phytopathogenic fungi have been reported to be avirulent, phenotypic consequences of infections with mycoviruses can vary from symptomless to severely debilitating, and from hypovirulence to hypervirulence. Mycoviruses that attenuate the virulence of plant pathogenic fungi provide excellent model systems for basic studies on development of novel biological control measures and for dissecting the mechanisms underlying fungal pathogenesis. In general, infections due to mycoviruses are both symptomless and persistent. Latency benefits the host for survival, and persistence helps the virus in the absence of extracellular modes of transmission. To ensure their retention, some mycoviruses have evolved to bestow selective advantage to their host (e.g., the killer phenotypes in yeasts and smuts). Because of their ability to secrete killer toxins, yeast killer strains have been utilized by the brewing industry to provide protection against contamination with adventitious sensitive strains. The genes encoding the smut killer toxins have been used for the development of novel transgenic approaches to control the corn smut.

Macroscopic symptoms caused by fungal viruses are a consequence of alterations in complex physiological processes that involve interactions between host and virus factors. Several virally encoded proteins are identified as symptom determinants including the papain-like protease, p29, of some hypoviruses. This protein acts to repress host pigmentation and conidiation regardless of whether it is expressed from host chromosomes or the homologous virus genome. Another interesting example is the proteins encoded by the totivirus *Helminthosporium victoriae* 190S virus. Co-expression of the capsid and RNA-dependent RNA polymerase (RdRp) proteins results in empty capsid production and phenotypic changes similar to those induced in virus-infected isolates, suggesting that viral replication is not required for symptom development. Host factors involved in symptom expression are not well studied except for host genes involved in the killer phenomenon in yeast infected with the totivirus L-A and associated satellite dsRNAs. Transcriptome analysis was performed for only limited virus/natural host combinations. Of the 2200 *C. parasitica* genes, 13.4% are either upregulated or downregulated upon infection with the prototype severe strain of the hypovirus CHV1, while only 7.5% are altered in their transcription levels by infection with a mild strain of CHV1. One-half of the genes responsive to the infection with the latter virus are commonly altered in transcription by the severe strain, which generally causes greater magnitude of transcriptional changes.

Transmission

Mycoviruses lack an extracellular phase to their life cycles. They are transmitted intracellularly during cell division, sporogenesis, and cell fusion. Lateral (horizontal) transmission usually occurs only between individuals within the same species, which belong to the same or closely related vegetative compatibility groups. Vegetative compatibility is governed genetically. Mycoviruses may be eliminated during sexual spore formation. Although the totiviruses and narnaviruses that infect the yeasts are effectively transmitted via ascospores, the mycoviruses infecting the ascomycetous filamentous fungi are eliminated during ascospore formation. Whereas the ssRNA and dsRNA mushroom viruses are transmitted efficiently via basidiospores, the virus-containing strains of the basidiomycete *H. mompa* are cured during the sexual sporulation processes. Therefore, whether a mycovirus is transmitted through sexual spores depends on the host/virus

combination involved. Whereas mycovirus transmission through asexual spores occurs frequently, its rate varies greatly depending on the combination of viral and host strains. It was recently shown that the papain-like protease p29, encoded by CHV1, might play a role in virus transmission since it enhances the transmission of the homologous virus (CHV1) as well as heterologous viruses (mycoreoviruses) in *C. parasitica* conidia.

While rare in nature, interspecies transmission has been reported between members within the same genus including *Cryphonectria*, *Sclerotinia*, and *Ophiostoma* that share the same habitats. It remains unknown whether interspecies barrier is overcome by physical contacts or by vectors. Experimental evidence for vector transmission of fungal viruses, however, is lacking.

Mixed Infections

Mixed infections with two or more unrelated viruses and accumulation of defective dsRNA and/or satellite dsRNA are common features of mycovirus infections. Examples include the sphaeropsis sapinea totiviruses SsRV1 and SsRV2, saccharomyces cerevisiae totiviruses ScV-L-A and ScV-LB/C, and penicillium stoloniferum partitiviruses PsV-S and PsV-F.

There are a number of known examples of mixed infections with plant or animal viruses where one virus either interferes with or enhances the replication of the other one. As a consequence, reduction or increase in symptom severity may arise. Recent extensive searches for fungal viruses confirmed relatively high mixed infection rates in some phytopathogenic fungi like *C. parasitica*, *R. necatrix*, and *H. mompa*. In contrast to mixed virus infections in plants or animals, possible interactions between co-infecting mycoviruses in single hosts is little studied because of the limitation in experimental manipulation of viruses and hosts. Recent studies suggest synergistic interactions between a hypovirus (phylogenetically related to potyviruses and viruses belonging to the picorna-like superfamily) and a mycoreovirus through a hypovirally encoded protein. In this case, one-way synergism is observed in that only hypovirus infection transactivates the replication of a mycoreovirus, which has a replication strategy distinct from that of hypoviruses.

Fungal Virus Taxonomy

A list of the virus families and genera into which mycoviruses are classified is included in **Table 1**. Members of some fungal virus families, for example, the families *Narnaviridae*, *Chrysoviridae*, and *Hypoviridae*, infect only fungi, while members in other families, for example, the families *Metaviridae*, *Pseudoviridae*, *Reoviridae*, *Totiviridae,* and *Partitiviridae*, infect fungi, protozoa, plants, or animals. Except for the rhizidiomyces virus with dsDNA genome (the only member in the genus *Rhizidiovirus*), almost all other mycoviruses have RNA genomes and many have dsRNA genomes. Viruses with (–)-strand RNA or ssDNA genomes have yet to be found in fungi.

dsRNA Mycoviruses

Mycoviruses with dsRNA genomes represent the majority of the fungal viruses so far reported. With the exception of the mycoreviruses (genus *Mycoreovirus,* family *Reoviridae*), which have spherical double-shelled particles 80 nm in diameter, the dsRNA mycoviruses are typically isometric particles 25–50 nm in diameter. They are classified, based on the number of genome segments, into three families, *Totiviridae*, *Partitiviridae,* and *Chrysoviridae*. Viruses in the family *Totiviridae* have nonsegmented dsRNA genomes coding for a CP and an RdRp. At present, three genera have been placed in this family: *Totivirus*, *Giardiavirus*, and *Leishmaniavirus*. Viruses in the genus *Totivirus* infect fungi, whereas those belonging to the latter two genera infect parasitic protozoa. At least two distinct RdRp expression strategies have been reported for totiviruses: (1) those that express their RdRp as a fusion protein (CP-RdRp or Gag-Pol) by ribosomal frameshifting, such as the yeast L-A and the viruses that infect parasitic protozoa and (2) those that synthesize RdRp as a separate nonfused protein by an internal initiation mechanism (e.g., a coupled termination–reinitiation mechanism), as proposed for Hv190SV and others that infect filamentous fungi. Phylogenetic analysis of CP or RdRp sequences of totiviruses reflects these differences, and separate phylogenetic clusters can be generated. Hv190SV and other totiviruses that infect filamentous fungi are closer to each other than to viruses infecting yeast, smut fungi, and protozoa. The fact that independent alignments of CP and RdRp sequences give similar phylogenetic relationships supports the conclusion that totiviruses infecting filamentous fungi should reside in a genus of their own. The genus *Victorivirus* has been proposed to include the totiviruses that infect filamentous fungi with Hv190SV, as the type species (**Table 1**). The genomes of partitiviruses and chrysoviruses consist of two and four segments, respectively.

The unclassified dsRNA mycovirus agaricus bisporus virus 1 (AbV1), also designated La France isometric virus, causes a serious disease of cultivated mushroom (named La France disease). AbV1 is of special interest because of its historical and economic importance. The AbV1 virions, isolated from diseased fruit bodies and mycelia, are isometric 36 nm in diameter and co-purify with nine dsRNA segments (referred to as disease-associated dsRNAs). The size of dsRNA segments varies from 3.6 to 0.78 kbp, three of which are believed to be satellites. It is not clear at present whether the nine dsRNA segments are encapsidated individually, in various combinations, or all nine segments are packaged in single particles. Based on

Table 1 List of viral families and genera into which fungal viruses are classified

Family/genus/virus species[a]	*Virus abbreviation*	*No. of segments*	*Accession number*

[a]The type species of the specified genus are listed. Otherwise, a fungal virus member of the genus is listed and marked with an asterisk.
[b]Proposed new genus in the family *Totiviridae*.
[c]Grouped with dsRNA viruses in the Eighth Report of ICTV.

the size of the particles, cesium sulfate gradient profile, and results of dsRNA and protein analyses of the gradient fractions, it is highly unlikely that all dsRNAs are packaged together in single particles. More realistically, AbV1 represents a multiparticle system in which the various particle classes have similar densities. Interestingly, phylogenetic analysis of the conserved motifs of AbV1 RdRp, encoded by dsRNA segment 1, and other

dsRNA mycoviruses showed that AbV1 is closely related to the multipartite chrysoviruses.

ssRNA Viruses

There are a number of mycoviruses with apparent ssRNA genomes that do not code for capsid proteins and exist more or less predominantly as dsRNA 'replicative' forms in their hosts. Because of lack of true virions, these viruses were easier to isolate and study as their dsRNA forms, and some were grouped with dsRNA viruses (e.g., family *Hypoviridae*). However, there is ample evidence at present that many of these viruses replicate and express their genomes like (+)-strand RNA viruses and that the lineage of their RdRp and helicase genes are within the lineages of (+)-strand RNA viruses. The simplest types of these viruses include members of the genera *Narnavirus* and *Mitovirus* (family *Narnaviridae*), whose RNA genomes code only for RdRp and the viruses exist as RNA/RdRp nucleoprotein complexes. The corresponding dsRNAs can be isolated from infected tissues, usually in lesser molar amounts than the genomic ssRNA. Phylogenetic analysis of RdRps of members of the family *Narnaviridae* along with those of other fungal viruses and related taxa indicate a distant relationship between members of the family *Narnaviridae* and bacteriophages belonging to the family *Leviviridae*.

Lack of true virions is characteristic of two other groups of classified viruses, those belonging to the family *Hypoviridae* and the genus *Endornavirus*. Although these viruses were grouped with dsRNA viruses in the latest ICTV Report, their genome organization and expression strategies are indicative of (+)-strand RNA viruses. Viruses in the family *Hypoviridae* are phylogenetically related to the (+)-strand RNA viruses in the family *Potyviridae* (picorna-like virus supergroup). Comparisons of hypovirus-conserved motifs of RdRp, helicase, and protease with those of members of the family *Potyviridae* suggest that viruses in the genus *Bymovirus* are the closest relatives to hypoviruses. Phytophthora endornavirus (PEV1) is the only nonplant virus in the genus *Endornavirus* of plant viruses. Although *Phytophthora* species and other members of the class Oomycetes have many biological properties in common with fungi, they are currently classified, based on sequence similarities, in a protist group known as the Stramenopiles. Endornaviruses are believed to have evolved from an alpha-like virus that has lost its capsid gene. This is consistent with the recent finding that RdRps of PEV1 and other endornaviruses cluster with those of families and genera in the alpha-like virus superfamily of (+)-strand RNA viruses.

The mushroom bacilliform virus (MBV; genus *Barnavirus*, family *Barnaviridae*) is the only mycovirus known to have bacilliform virions. MBV has a (+)-strand RNA genome that contains seven open reading frames (ORFs), three of which encode a putative chymotrypsin-like serine protease, a putative RdRp, and a CP. The polypeptides encoded by the remaining four ORFs have no homology to known proteins. Amino-acid sequence comparisons of the putative protease and RdRp suggest that MBV is evolutionarily related to sobemoviruses and poleroviruses. Although double infections of cultivated mushrooms with MBV and ABV1 are of common occurrence, the role of MBV in the ensuing dieback disease of cultivated mushroom remains unknown.

Unassigned ssRNA Viruses

It is worth noting that a relatively large number of mycoviruses remain unassigned including some well-characterized ones like botrytis virus F (BVF), sclerotinia sclerotiorum debilitation-associated RNA virus (SsDRV), diaporthe RNA virus (DRV), and sclerophthora macrospora viruses A and B (SmVA and SmV B). BVF has flexuous rod-shaped particles comparable in size and morphology to ssRNA plant 'potex-like' viruses. Amino-acid sequence identities of the conserved helicase and RdRp regions and the coat protein genes are greatest to those of potex-like viruses. The main difference between BVF and these plant viruses is the lack of a movement protein. Although particle morphology along with amino-acid sequence similarities of both the replicase and coat protein genes support the classification of BVF in the family *Flexiviridae*, it is obvious that the mycovirus BVF is distinct enough to belong to a new genus in this family. It is proposed that a new genus tentatively designated '*Mycoflexivirus*' is created to include BVF (**Table 1**). The genome of SsDRV contains a single ORF encoding a protein with significant sequence similarity to the replicases of the 'alphavirus-like' supergroup of (+)-strand RNA viruses. The SsDRV-encoded putative replicase protein contains the conserved methyl transferase, helicase, and RdRp domains characteristic of the replicases of potex-like plant viruses (flexiviruses) and BVF. Although phylogenetic analysis of the conserved RdRp motifs verified that SsDRV is closely related to BVF and to the allexiviruses in the family *Flexiviridae*, SsDRV is distinct enough from these viruses, mainly based on the lack of coat protein and movement protein, to justify the creation of yet another genus in the family *Flexiviridae*.

DRV is another naked RNA mycovirus that is associated with hypovirulence of its fungal host. It has two large ORFs present in the same reading frame, which are most likely translated by readthrough of a UAG stop codon in the central part of the genome. The longest possible translation product has a predicted molecular mass of about 125 kDa, which shows significant homology to the nonstructural proteins of carmoviruses of the (+)-strand RNA virus family *Tombusviridae*. Interestingly, transcripts derived from full-length cDNA clones were

infectious when inoculated to spheroplasts and the transfected isolates exhibited phenotypic traits similar to the naturally infected isolate.

Sclerophthora macrospora virus A (SmV A) found in *S. macrospora,* the pathogenic fungus responsible for downy mildew of gramineous plants, is a small icosahedral virus containing three segments of (+) ssRNAs (RNAs 1, 2, and 3). Whereas RNA 1 contains the RdRp motifs, RNA 2 codes for a capsid protein. RNA 3 is a satellite RNA. Whereas the deduced amino acid sequence of RdRp shows some similarity to RdRps of members of the family *Nodaviridae*, the amino acid sequence of the viral CP shows similarity to those of members in the family *Tombusviridae.* The capsid of SmV A is composed of two capsid proteins, CP 1 and CP 2, both encoded in ORF2. CP 2 is apparently derived from CP 1 via proteolytic cleavage at the N-terminus. The genome organization of SmV A is distinct from those of other known fungal RNA viruses, and suggests that SmV A should be classified into a new genus of mycoviruses.

Sclerophthora macrospora virus B (SmV B), which is also found in *S. macrospora,* has small icosahedral, monopartite virions containing a (+) ssRNA genome. The viral genome has two large ORFs: ORF1 encodes a putative polyprotein containing the motifs of chymotrypsin-related serine protease, and ORF2 encodes a capsid protein. The genome arrangement of SmV B is similar to those belonging to the genera S*obemovirus, Barnavirus,* and *Polerovirus.* The putative domains for the serine protease, VPg, RdRp, and the CP are located in this order from the 5′ terminus to the 3′ terminus. SmV B, however, is distinctive since its genome has only two ORFs. The genome organization of the barnavirus MBV, on the other hand, resembles that of poleroviruses. These results suggest that SmV B, like SmV A, should also be classified into a new genus of mycoviruses.

The mycoviruses belonging to the families *Pseudoviridae*, *Metaviridae*, *Reoviridae* (genus *Mycoreovirus*), *Totiviridae*, *Partitiviridae*, *Chrysoviridae*, *Narnaviridae,* and *Barnaviridae* are discussed in more detail elsewhere in this encyclopaedia.

Replication and Gene Expression Strategy

Replication cycles of fungal viruses are not well studied except for a few cases including the *Saccharomyces cerevisiae* L-A virus. For dsRNA fungal viruses including members of the *Totiviridae*, *Partitiviridae*, *Reoviridae*, and *Chrysoviridae*, virus particles or subviral particles, containing RdRp, are believed to play pivotal roles in RNA transcription and replication. Replication of naked RNA mycoviruses represented by members of the family *Hypoviridae* may occur in infection-specific, lipid-membranous vesicles presumed to contain viral RdRp and RNA helicase. These vesicles are able to synthesize *in vitro* both plus and minus RNA at a ratio of 1:8. The narnavirus RNA, encoding only a single protein (RdRp), is associated with RdRp rather than being encapsidated. These RNA/RdRp complexes seem to play a key role in RNA replication.

Fungal viruses, like many RNA viruses of plants and animals, employ noncanonical translational strategies for expressing their genomes. These include −1 (*Totiviridae*) and +1 frameshifting (*Totiviridae*, *Pseudoviridae*, *Metaviridae*), termination-coupled initiation (*Totiviridae*, *Hypoviridae*), and IRES-mediated initiation (*Totiviridae*). Furthermore, a readthrough of a termination codon strategy is proposed for translation of the 3′ proximal ORF of DRV. A noncanonical mechanism may also be required for efficient translation of mRNA of narnaviruses, which lack poly(A) tails. The (CAA) n repeats found at the 5′ UTR of chrysoviruses are implicated in translation augmentation, as observed for the 5′ UTR sequence of tobacco mosaic virus. Translation of the viral genes that are regulated by these mechanisms is considered critical for virus viability.

Recent Technical Advances in Fungal Virology

Fungal virology has been thwarted by many constraints on manipulation of fungal viruses. Many, if not all, plant and animal viruses can be inoculated into individuals/tissue cultures of plant and animal hosts. Some assays with those hosts allow quantitative detection of biologically active viruses. As for mycoviruses, it is rather rare to be able to inoculate into host fungi because of experimental limitations, which often makes the etiology of mycoviruses difficult to establish. Fungal cells have rigid cell walls and are usually difficult to digest for preparation of cell-wall-free protoplasts ready for transformation or transfection. Even if protoplasts are made, their maintenance like animal cell culturing is not possible. Furthermore, fungal hosts usually have self/nonself recognition systems operating at inter- and intraspecies levels. Intraspecies barriers are based on vegetative incompatibility/compatibility that is governed genetically. This is often regarded as one of the host defense barriers that inhibits virus transfer between individuals. To overcome these barriers, a few methods are available. The prototypic hypovirus cryphonectria parasitica hypovirus 1 (CHV1) is the first for which a reverse genetics is established. Infection with different CHV1 strains can be launched either from cDNA integrated into host chromosomes or *in vitro*-synthesized RNA viral cDNA. It is noteworthy that via bombardment of mycelia, not protoplasts, the infectious CHV1 cDNA clone can be integrated into chromosomes of fungi other than the natural host *C. parasitica.* cDNA-based transfection systems are now available for three other species of RNA viruses: *Diaporthe RNA virus*, *Saccharomyces cerevisiae 20S narnavirus,* and *Saccharomyces cerevisiae 23S narnavirus.*

Mycoviruses in general lack infectivity as purified virions. However, all members of the new genus *Mycoreovirus* including mycoreovirus 1 (MyRV1), MyRV2, and MyRV3 were found to be infectious as purified particles when applied to fungal protoplasts. It is of interest in this regard that treatment of purified virions with trypsin or chymotrypsin was not required for infectivity. Protoplast fusion provides an alternative approach to introduce mycoviruses into vegetatively incompatible fungal strains that are incapable of hyphal anastomosis. Intra- and interspecies virus transfer via protoplast fusion has been reported in *Aspergillus* spp. This method is particularly useful for viruses for which infectious particles or cDNA-derived RNA are unavailable. Another recent revelation is that monokaryotic strains are able to serve as an intermediate virus transmitter between different mycelial incompatibility groups within the same species of *R. necatrix*.

To complete Koch's postulates, virus curing is as important as virus inoculation, because the virus must be back inoculated into an isogenic, virus-free strain with the same genetic background as the original virus-infected strain. Virus-free isolates may be obtained from germlings of asexual spores if virus transmission through spores is less than 100%. Alternatively, virus-free strains may be isolated by hyphal tip culturing, as in the case for *H. mompa* and *R. necatrix*. This technique is applicable to fungi infected with a virus that is transmitted to 100% of the asexual spores or for fungi that produce little or no spores.

Future Perspectives

Yeast as a (Model) Host to Study Viral Replication

S. cerevisiae has provided an excellent system to investigate virus assembly and replication of the dsRNA totivirus L-A and the ssRNA narnaviruses that infect yeast. With the robust yeast genetics, a number of host factors involved in totivirus replication were identified, many of which are related to translation events. Furthermore, the yeast provides an 'artificial' viral host model system to explore host genes affecting viral replication on a genomewide basis. Genetic screens of a collection of 4500–4800 single-gene deletion yeast strains (Yeast Knockout strain collection) have been successfully conducted for identifying host factors involved in replication and recombination with two different plant ssRNA viruses: brome mosaic virus and tomato bushy stunt virus (TBSV). Each screen led to the identification of approximately 100 host genes (approximately 1.8% of the entire yeast genes) that affect virus replication. Interestingly, the replication of the two viruses in yeast is affected by a different set of genes. A similar approach was employed to identify genes affecting the recombination of TBSV. This type of use of the yeast system can be expanded to a (+)-strand RNA animal virus and a (−)-strand RNA vertebrate virus. It may be surprising that the yeast has yet to be used for viruses infecting filamentous fungi. The yeast should be able to serve as a model host for mycoviruses other than those that naturally infect yeast.

Host Defense against Fungal Viruses

Host defense responses against viruses have not been explored intensively. RNA silencing is regarded as one of the host defense strategies of eukaryotes to molecular parasites including viruses, and operates in a number of fungi including important model and phytopathogenic fungi. However, no direct evidence is shown for RNA silencing that target mycoviral RNA. Recently, the hypovirus p29 was shown to be a suppressor of RNA silencing targeting a transgene that functions in both plant and fungal cells. This suggests that RNA silencing may function as an antiviral mechanism in fungal cells. The observation that p29 enhances the replication of a heterologous virus supports this idea. There are genetic elements involved in RNA silencing, for example, that are conserved widely from fungi to vertebrates. Functional roles of these factors in RNA silencing as antiviral reactions will need to be elucidated. Unraveling the mechanism by which the hypovirus p29, or other mycovirus-encoded RNA silencing suppressors, may block the RNA silencing pathway will be an interesting challenge.

Role of Mycoviruses in Plant–Fungal Mutualistic Associations

The question of whether mycoviruses are involved in the mutualistic interactions between endophytic fungi and their host plants is of considerable interest because of the attractive beneficial features of these associations and because of the common occurrences of fungal viruses in all major groups of fungi. This question was recently addressed in an intriguing report that presented evidence for a dsRNA mycovirus being involved in the mutualstic interaction between a fungal endophyte (*Curvularia protuberata*) and a tropical panic grass. This association allows both organisms to grow at high soil temperatures. The virus in question, which was designated curvularia thermal tolerance virus (CThTV), has unusual genome organization with an unknown genome expression strategy. CThTV has apparently a bipartite genome (RNA 1 and RNA 2), but no evidence that these RNAs are packaged in the 27-nm isometric particles isolated from the fungal host. Although many questions pertinent to the fungal endophyte, CThTV, and the veracity of the evidence for viral etiology remain unanswered, this report will undoubtedly stimulate the search for mycoviruses in other mutulastic fungal endophytes. In this regard, it is noteworthy that the well-characterized mutualistic endophyte, *Epichloë festucae*, was found to harbor a totivirus, but no phenotypes were associated with virus infection.

Mycovirus as Biocontrol Agents and as Tools for Fundamental Studies

The hypovirulence phenotype in the chestnut blight fungus (*Cryphonectria parasitica*) is an excellent and well-documented example for a mycoviral-induced phenotype that is currently being exploited for biological control. The debilitating disease of *Helminthosporium victoriae*, the causal agent of Victoria blight of oats, and the disease phenotype of the Dutch elm disease fungus *Ophiostoma novo-ulmi* are examples of pathogenic effects of dsRNA fungal viruses. An understanding of the molecular basis of disease in these fungal-virus systems would provide excellent opportunities for development of novel biocontol strategies of plant pathogenic fungi. Mycoviruses also continue to serve as versatile tools to study the virulence of host fungi, as recognized in studies with the hypovirus/*Cryphonectria parasitica* system, in which substantial advances in our understanding of the molecular basis of hypovirulence have been made.

Glossary

Furovirus Siglum derived from fungus-transmitted rod-shaped virus.

History

Soil-borne wheat mosaic virus (SBWMV) is the type species of the genus *Furovirus*. Originally it was classified as a possible member of the tobamovirus group, because its rod-shaped particles resemble those of the tobamoviruses. In 1991, the fungus-transmitted rod-shaped viruses which all have several genome segments were separated from the tobamoviruses with a monopartite genome to form a new group, named furovirus group, with SBWMV as the type member. Molecular studies performed in the following years revealed that the genome organization of many of these furoviruses greatly differed from that of SBWMV. Eventually four new genera were created, that is, the genus *Furovirus* with SBWMV as the type species, the genus *Benyvirus* with *Beet necrotic yellow vein virus*, the genus *Pomovirus* with *Potato mop-top virus*, and the genus *Pecluvirus* with *Peanut clump virus* as type species, respectively. The genus *Furovirus* presently comprises five species, that is, SBWMV, *Soil-borne cereal mosaic virus* (SBCMV), *Chinese wheat mosaic virus* (CWMV), *Oat golden stripe virus* (OGSV), and *Sorghum*

chlorotic spot virus (SrCSV). SBCMV was simultaneously and independently described by two different working groups who had suggested the names European wheat mosaic virus (EWMV) and soil-borne rye mosaic virus (SBRMV), respectively. These names are no longer in use.

Host Ranges, Diseases, and Geographic Distribution

SBWMV has been known since the early 1920s. It causes mosaic, stunting, and severe losses of yield in winter wheat in the USA where it is widely distributed in the central parts. As with other soil-borne diseases the symptoms often occur in patches in the fields. SBWMV may also naturally infect barley. A deviating strain of SBWMV which differs from the type strain considerably in its nucleic acid sequences, but not in the proteins translated from them has been observed to be rapidly spreading in upper New York State since 1998. Diseases on wheat with symptoms similar to those described for SBWMV are caused by SBCMV in Europe, CWMV in China and by the distantly related Japanese strain (jap) of SBWMV in Japan. A virus closely related to SBWMV jap has recently been isolated from barley in France. SBWMV jap has also been obtained from barley in Japan. SBCMV is now widely distributed in Europe where it infects mainly wheat in Italy, France, and England, but mainly rye in Germany, Denmark, and Poland. SBWMV has been detected on a single field in Germany for the first time in 2002 with apparently no tendency to spread. OGSV has been detected in oats at various sites in Britain, France, and the USA (North Carolina). In oats it induces conspicuous chlorotic striping of leaves, but it fails to infect wheat. SBWMV, SBCMV, CWMV, and OGSV may be transmitted mechanically (sometimes only with difficulty) to some *Chenopodium* and *Nicotiana* species. SrCSV was isolated in 1986 from a single sorghum line from a breeder's plot in Kansas/USA. It is readily mechanically transmissible to maize where it produces a bright yellow mosaic and elongated ringspot symptoms several weeks after inoculation. Local infections are produced on mechanically inoculated *Chenopodium quinoa*, C. *amaranticolor*, and *N. clevelandii*. Attempts to transmit the virus back to *Sorghum bicolor* or to winter wheat either mechanically or by growing plants in soil in which infected sorghum was growing were unsuccessful.

Plants infected naturally by furoviruses are often also infected by bymoviruses, that is, wheat spindle streak mosaic virus in Europe and North America, wheat yellow mosaic virus in East Asia or oat mosaic virus in Europe and the USA. The symptoms caused by these bymoviruses are very similar to those caused by the furoviruses, and both the furoviruses and the bymoviruses are transmitted by *Polymyxa graminis* (see below).

Transmission in Nature and Long-Distance Movement in Infected Plants

Furoviruses, with the possible exception of SrCSV, are soil-borne and transmitted by the zoospores of *Polymyxa graminis,* a ubiquitous plamodiophorid protozoan formerly considered to belong to the fungi. *Polymyxa*-transmitted viruses (or their RNAs?) are taken up by the plasmodia of the vector in infected root cells, but there is no evidence that they multiply in the vector. The multinucleate plasmodia which are separated from the host cytoplasm by distinct cell walls may either develop into zoosporangia from which secondary viruliferous zoospores are released within a few days. Alternatively, the plasmodia may form cystosori which act as resting spores and may survive in the soil for many years even under extreme conditions. They may be distributed on agricultural equipment, by irrigation or even by wind blow. Upon germination they release primary zoospores transmitting the virus. Zoospores inject their contents into the cytoplasm of root cells where new plasmodia are formed. Zoospores treated with antisera to SBWMV or resting spores treated with 0.1 N NaOH or HCl retained their ability to transmit virus into plants indicating that the infectious viral material was carried inside. Immunolabeling and *in situ* RNA hybridization studies have revealed the presence of SBWMV movement protein and RNA but not of SBWMV coat protein in the resting spores of *P. graminis*. This might suggest that the vector does not transmit SBWMV in form of its particles but rather as a ribonucleoprotein complex possibly formed by the movement protein and the viral RNAs. The furovirus movement protein belongs to the '30 K' superfamily of movement proteins which are known to mediate cell-to-cell and vascular transport of viruses by binding viral nucleic acids and carrying them through plasmodesmata and through the vasculature. There is also strong evidence that two transmembrane regions found in the coat protein readthrough proteins of furoviruses are involved in the transmission process.

Immunogold-labeling studies have suggested that SBWMV uses the xylem in order to move from infected roots to the leaves. It may enter primary xylem elements before cell death occurs and then move upward in the plant after the xylem has matured into hollow vessels. There is also evidence for lateral movement between adjacent xylem vessels.

Control

Polymyxa-transmitted plant viruses may survive in soil for decades in the long-living resting spores of the vector. The diseases caused by these soil-borne viruses are, therefore, much more difficult to control than those caused, for

instance, by insect-transmitted viruses. Chemical control, for example, by soil treatment with methyl bromide, is neither efficient nor acceptable for economic and ecological reasons. Growing resistant or tolerant varieties currently represent the only practical and environmentally friendly means to lower the impact of these diseases on yield. Immunity to the wheat-infecting furoviruses has not been found. The tolerant varieties which have been developed contain high virus levels in the root system. The partial resistance in some varieties may be overcome when the plants are grown at temperatures >23 °C. Cereal genotypes with resistance to *P. graminis* have so far not been identified.

Particle Properties

Furovirus particles are nonenveloped hollow rods which have a helical symmetry (**Figure 1**). The diameter of the particles is *c.* 20 nm and in leaves of freshly infected field grown plants in the spring the predominant lengths are *c.* 280–300 and 140–160 nm. Due to internal deletions in the coat protein readthrough protein genes shorter particles arise later in season in naturally infected plants and in laboratory isolates which may outcompete the 140–160 nm particles. The single coat protein species of furoviruses has a molecular mass of *c.* 20 kDa.

Antigenic Properties

Serological relationships exist between all five furoviruses. Monoclonal antibodies (MAb) prepared in several laboratories were either species or even isolate specific or allowed broad-range detection of several or all furoviruses except for SrCSV that was not included in such studies. MAbs to SBWMV have also been used to determine the accessibility of stretches of the coat protein amino acid chain on the virus particles. The C-terminus of the coat protein is apparently exposed along the length of the particles and is readily removed by treatment with trypsin.

Nucleic Acid Properties and Differentiation of Furoviruses

Furovirus genomes consist of two molecules of linear positive-sense ssRNAs. Their complete or almost complete nucleotide sequences have been determined for all five furoviruses described so far. They are 5′ capped and terminate in a functional tRNA-like structure with an anticodon for valine. This tRNA-like structure is preceded in the 3′ untranslated region by an upstream hairpin and an upstream pseudoknot domain (UPD) with two to seven possible pseudoknots. The genome organization is more or less identical for all furoviruses although there are considerable differences in nucleotide sequences (**Figure 2**). The percentages of sequence identities range from *c.* 60% to 75% for RNA1 and from *c.* 50% to 80% for RNA2 of different furovirus species. With strains of CWMV and SBCMV percentages of sequence identities are >94% for RNA1 and >85% for RNA2. Classification on the basis of sequence dissimilarities would suggest that SBWMV jap might be considered to be a separate species rather than a strain of SBWMV. However, the fact that in reassortment experiments a mixture of RNA1 of SBWMV jap and RNA2 of the type strain of SBWMV yielded an infectious progeny and the observation that the biological properties of all wheat-infecting furoviruses are very similar has been taken by some researchers as evidence that the type and the Japanese strains of SBWMV as well as CWMV and SBCMV should all be regarded as distantly related strains of the same species. As with viruses in other genera the decision whether related viruses should be considered as different strains of one virus or as separate species is not always easy, because these categories are men-made and many border-line cases exist in nature.

Organization of the Genome and Properties of the Encoded Proteins

Furoviral RNA1 codes for two N-terminally overlapping, presumably replication-associated proteins and for a *c.* 37 kDa movement protein (**Figure 3**). The shorter of the two replication-associated proteins contains methyltransferase and helicase motifs and the longer one, in addition, the RNA-dependent RNA polymerase motifs (**Figure 3**). The green fluorescent protein (GFP)-labeled 37 kDa protein of SBWMV, as opposed to its GFP-labeled coat protein, was shown to move from cell to cell in leaves of wheat but not in those of tobacco (a nonhost) and, similar to other viral movement proteins, to accumulate in the cell wall of both SBWMV-infected wheat leaves and transgenic wheat plants expressing the 37 kDa protein.

Furoviral RNA2 codes for the *c.* 20 kDa coat protein, a *c.* 84 kDa coat protein readthrough protein and a *c.* 19 kDa

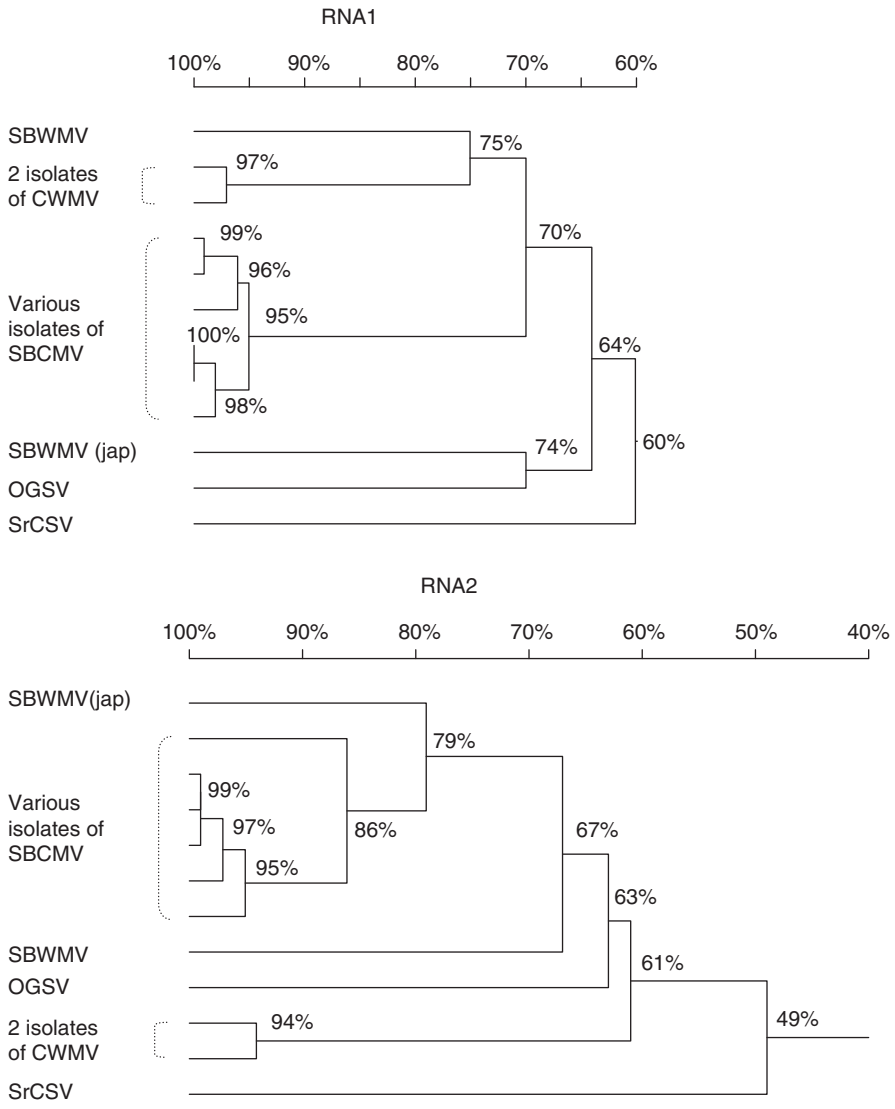

Figure 2 Percentages of nucleotide sequence identities among furoviral RNA1 and furoviral RNA2, respectively.

cysteine-rich protein. A 24 kDa protein found in *in vitro* translation experiments and also *in planta* has been shown to be coat protein with a 40-amino-acid N-terminal extension initiated at a conserved CUG codon 120 nt upstream of the AUG initiation codon for the coat protein gene. Neither the coat protein with this N-terminal extension nor the coat protein readthrough protein are required for SBWMV virion formation and systemic infection. SBWMV with full-sized RNA2 is found in naturally infected wheat in winter or early spring. Prolonged cultivation of field-infected plants, virus propagation by repeated mechanical inoculations or growth at elevated temperatures result in spontaneous deletions in the coat protein readthrough domain which may vary in size from 519 to 1030 nt. Computer analyses have revealed the presence of two complementary transmembrane domains (TM1 and TM2) in the coat protein readthrough proteins of furoviruses and also in those of the likewise *Polymyxa*-transmitted benyviruses and pomoviruses and in the P2 proteins of the *Polymyxa*-transmitted bymoviruses. The TM helices are apparently tightly packaged with ridge/groove arrangements between the two helices and strong electrostatic associations. It has been suggested that they facilitate the movement of the virus across the membrane surrounding the plasmodia in the plant cells. Nontransmissible deletion mutants lack the second transmembrane region partially or completely. The cysteine-rich 19 kDa protein of SBWMV is a suppressor of post-transcriptional gene silencing.

The products of the two 3′ proximal ORFs on RNA1 and RNA2, that is, the movement protein and the cysteine-rich protein, have not been found in *in vitro* translation experiments. It is assumed that they are expressed from subgenomic RNAs.

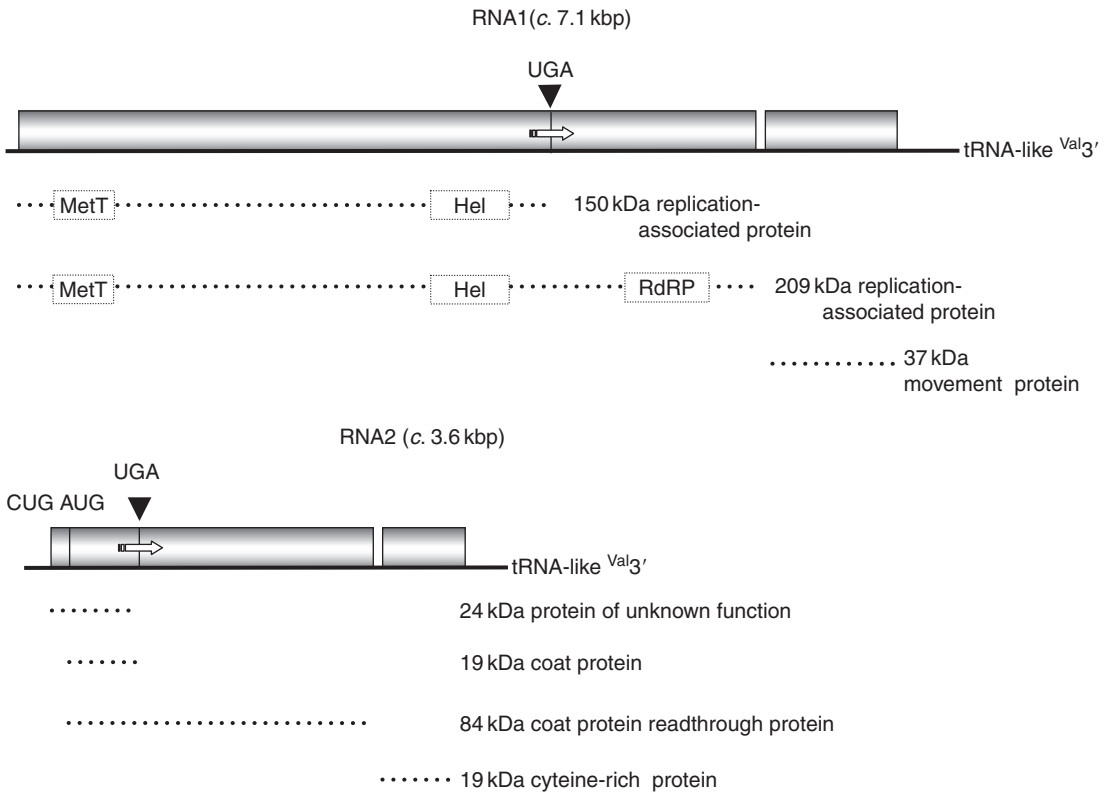

Figure 3 Organization of furoviral genomes (illustrated for SBWMV). The arrows in the open reading frames (boxed) indicate a readthrough translation due to a leaky stop codon.

Diagnosis

Symptoms caused by furoviruses may differ depending on environmental conditions, such as moisture and temperature. Nutrient deficiencies, winter injury or other viruses (especially bymoviruses), may produce symptoms that are easily confused with those caused by wheat-infecting furoviruses. Serological tests such as the enzyme-linked immunosorbent assay (ELISA), tissue print immunoassay, and immunoelectron microscopy as well as polymerase chain reaction (PCR) techniques allow a reliable detection. Real-time reverse transcriptase-PCR (RT-PCR) and PCR assays based on TaqMan chemistry have been developed for the detection and quantitation not only of SBCMV but also of its vector *P. graminis*. Real-time assays were found to be a 1000 times more sensitive than ELISA for the quantitation of SBCMV, and a 100 times more sensitive than conventional PCR for the quantitation of *P. graminis*.

Similarities and Dissimilarities with Other Taxa

The morphology of furoviruses resembles that of other rod-shaped viruses, that is, of benyviruses, pecluviruses, pomoviruses, hordeiviruses, tobraviruses, and tobamoviruses. The CPs of all these viruses have a number of conserved residues, for example, RF and FE in their central and C-terminal parts, respectively, which are presumably involved in the formation of salt bridges. Furoviruses, like pecluviruses and tobraviruses but unlike the other aforementioned viruses, have bipartite genomes. They differ from pecluviruses by having their movement function encoded on a single ORF rather than a triple gene block. They also differ from pecluviruses as well as from tobraviruses by having a coat protein readthrough protein gene. The gene for their cysteine-rich protein is located on RNA2, whereas with pecluviruses and tobraviruses it is located on RNA1. The cysteine-rich proteins of furoviruses, pecluviruses, and tobraviruses act as suppressors of post-transcriptional gene silencing and are phylogenetically interrelated, whereas those of beny- and pomoviruses are surprisingly unrelated to them. Furoviruses have two N-terminally overlapping replication-associated proteins (**Figure 2**) which in their amino acid sequences and structure are related to those of pomoviruses, pecluviruses, tobraviruses, and tobamoviruses. The 37 kDa movement protein of the furoviruses which belongs to the '30 K' superfamily of movement proteins relates them to the dianthoviruses and the tobamoviruses, whereas the valine-accepting tRNA-like structures on the 3′ ends of their RNAs relate them to the tymoviruses.

In other properties, such as particle morphology and mode of transmission, dianthoviruses and tymoviruses are very different from furoviruses. Furoviruses like tobamoviruses have an upper pseudoknot domain in the 3′ untranslated regions of their genomic RNAs.

Glossary

Acidophile An organism whose optimal growth is at acidic pH, often 2 or below.
Archaea One of the three domains of life as defined by Carl Woese, completely microbial and separate from bacteria.
Archaeon Singular of Archaea or Archaebacteria.
Cryptic plasmid Plasmid with no known function.
Cryptic protein Protein with no known function.
Extreme thermophile An organism whose optimal growth temperature is above 80 °C.
Fusiform Having a spindle shape.
Thermoacidophile An organism that is thermophilic and acidophilic.
Thermophile An organism whose optimal growth temperature is above 50 °C.
Tyrosine recombinase One of a family of DNA recombining enzymes with an active site tyrosine.

Introduction

Fuselloviruses are unique spindle-shaped viruses with a short tail at one end that have so far only been observed in archaeal viruses or extreme environments dominated by

Archaea (**Figure 1**). The first fusellovirus to be found and characterized was SSV1, a virus-like particle of *Sulfolobus shibatae*, an extremely thermoacidophilic archaeon (optimal growth at 80 °C and pH 3). Fusellovirus genomes are relatively small double-stranded circular DNA molecules from 15 to 17 kbp. Only one gene, the viral integrase, shows clear similarity to genes outside the fuselloviruses. Their genomes persist in host cells both as episomes and integrated into the host genome. The genome is positively supercoiled when packaged in virus particles. Virus production can be induced by UV-irradiation. Virion production is usually constitutive at a low level and does not impede host growth or lyse the host cells. Viruses appear to be produced by budding at the cellular membrane.

Fuselloviruses have been found throughout the world and five complete genomes have been reported (**Table 1**). Fusellovirus-like DNA sequences have been found in many more locations by culture-independent techniques. Intriguing virus-plasmid hybrids have been discovered along with the SSV1-like viruses. SSV1, or portions thereof, has been used to make the first widely used vectors for genetic manipulation in thermophilic Archaea. Biochemical characterization has focused on the viral integrase with recent results showing that the integrase is similar to eukaryotic recombinases. Interestingly, the integrase gene and integration do not appear to be absolutely necessary for virus function. Nonetheless, the presence of the integrase gene appears to give such viruses a competitive advantage. Two structures of SSV1 encoded proteins have been solved to high resolution, but elucidation of the structure of the entire virion and many of the proteins remains elusive.

A number of archaeal viruses have been described as having a similar morphology to the SSV viruses. However, the spindle-shaped viruses of methanogens that were originally grouped with the fuselloviruses are very pleiomorphic and probably do not belong in this family. Additionally, the haloviruses His1 and His2 have very different genomes and replication and have been placed in the new genus *Salterprovirus*. Other spindle-shaped viruses of Archaea are much larger than the fuselloviruses.

History

The virus SSV1 was originally detected as a UV-inducible plasmid in a *Sulfolobus* isolate from Beppu Onsen in Kyushu, Japan by Wolfram Zillig and his co-workers in the early 1980s. Production of a 60×90 nm spindle-shaped virus-like particle was shown soon thereafter. The term 'virus-like particle' was used because infection of an otherwise uninfected strain could not initially be shown. It appears to be very difficult, if not impossible, to cure a *Sulfolobus* strain of a fusellovirus once infected. This may be due to the integration of the virus genome into a tRNA gene in the host genome by the virus integrase gene. SSV1 integrates into the CCG arginyl tRNA gene, whereas other fuselloviruses integrate into other tRNA genes. SSV1 became a model for the understanding of transcription in Archeaea. It was in the study of SSV1 genes and their promoters that Wolf-Dieter Reiter noticed that they resembled eukaryotic promoters with their canonical TATA-boxes. Together with previous work from the Zillig laboratory that had shown that the DNA-dependent RNA polymerases in Archaea were similar to eukaryotic DNA-dependent RNA polymerases, there was a strong evidence that the archaeal transcription machinery was eukaryote-like. The complete 15 495 bp genome sequence of SSV1 was determined in 1990. Genome analysis showed that other than the previously characterized virus coat protein genes, VP1 and VP3, an apparent DNA-binding protein, VP2, and the viral integrase (see below), none of the other 34 open reading frames (ORFs) showed any similarity to proteins in the known databases (**Figure 2**).

A major breakthrough in the study of SSV1 was made when Christa Schleper showed that SSV1 could infect *Sulfolobus solfataricus*, an uninfected *Sulfolobus* isolated from Pisciarelli, Italy, showing conclusively that SSV1

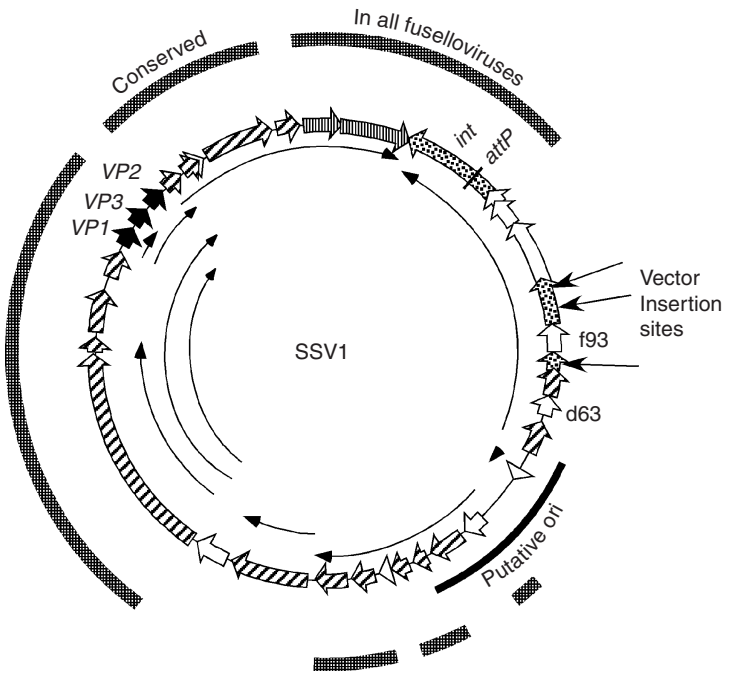

Figure 2 The SSV1 genome with its ORFs is shown, together with mapped transcripts. The attachment site in the viral integrase gene is shown as '*attP*'. Known viral genes are labeled. *VP1*, *VP3*, and *VP2* are virus structural genes. The location of the ORFs whose products have been crystallized, f93 and d63, are labeled. The putative origin of replication is labeled as 'Putative ori'. Insertion points for full-length shuttle vectors are shown with arrows outside the viral genome. Dotted ORFs have been shown to be not essential for virus function. Diagonally striped ORFs appear to be important for virus function. Vertically striped ORFs are conserved in pSSVx. ORFs conserved in all fusellovirus genomes are indicated by a stippled curve, outside of the ORF map.

was a virus. She was also able to transform *Sulfolobus* for the first time using this DNA. With this technique, plaque tests were established, the virus could be characterized, and large quantities could be purified. *Sulfolobus solfataricus* is one of the best studied of the thermophilic Archaea and a complete genome sequence and many other data are available. The development of the plaque test also allowed screening for fuselloviruses (and other viruses) in samples from throughout the world.

Fuselloviruses

Isolates

Using a plaque test and related spot-on-lawn halo techniques, first Wolfram Zillig's group and then others isolated fuselloviruses from Iceland, the USA, and Russia, in addition to SSV1 from Japan. The Zillig group found that approximately 8% of isolates from habitats with $T > 70\,^{\circ}\mathrm{C}$ and $\mathrm{pH}^{+} < 4$ contained SSVs that could be detected by their ability to infect *S. solfataricus*. First characterized was SSV2, from Iceland, followed by SSV-RH from Yellowstone National Park in the USA and SSV-K1 from the Kamchatka peninsula in Russia. All of these viruses had the typical spindle-shape and size of fuselloviruses and all contained *c.* 15 kbp genomes (**Table 1**). Those tested appeared to integrate into the host genome and were also inducible with UV-irradiation. However, the level of induction varied greatly between isolates as did the tRNA gene used as the site of virus integration into the host genome.

The complete genome sequences of all of these new fuselloviruses were determined and it was found that only about 50% of the genome is conserved (**Figure 2**). In some cases there is no sequence similarity whatsoever between parts of the virus genomes. The overall nucleotide identity is only about 55%, but the level of amino acid identity varies from undetectable to about 80%. The genomes have similar organization, with the exception of a large insertion and inversion in the SSV-K1 genome. Strangely, the putative DNA-binding protein, VP2, is missing in all genomes other than SSV1. The question then arose whether these genomic differences were due to geographical isolation of the viruses or to large amounts of local heterogeneity. To address this question the complete genome of a new SSV from Iceland, SSV3, was determined and compared to SSV2. It was found to have about 70% overall nucleotide identity to SSV2 and most of the ORFs were well conserved between the two viruses. However, there were a number of ORFs that were not conserved in SSV2, the other Icelandic virus, but were found in fuselloviruses from other parts of the world.

Culture-Independent Studies

The availability of multiple genome sequences for the fuselloviruses allowed the design of oligonucleotide probes that could be used to amplify conserved parts of fusellovirus genomes using the polymerase chain reaction. This technique was used on DNA samples collected directly from the environment, pioneered by Mark Young and his group. They showed that in a single spring that was known to harbor both *Sulfolobus* and fuselloviruses, the composition and relative abundance of fusellovirus sequences changed on at least a monthly basis. They also showed that a great deal of diversity was present in a single spring, much more diversity than seen in their hosts. Analysis of the sequence data over time indicated that there was a great deal of migration between springs and possibly a very large reservoir of fuselloviruses worldwide. Similar data from Lassen Volcanic National Park in the USA indicate this to be the case. These data contrast with the conservation seen between the whole SSV2 and SSV3 genomes from Iceland mentioned above. This conundrum remains to be resolved.

Plasmid Virus Hybrids

During the investigation of SSV2 from Iceland, a small virus-like particle was observed. This virus-like particle corresponded to a small plasmid, then named pSSVx, that was present in the same culture as SSV2 and appeared to be dependent on it or another complete fusellovirus for propagation. The genome sequence of pSSVx indicated that it was a fusion of a plasmid from the pRN family of cryptic *Sulfolobus* plasmids and two ORFs from a fusellovirus. It is not clear if activity of these ORFs is required for the plasmid to be packaged or if a *cis*-acting DNA sequence is required. At least one more of these virus-plasmid pairs has been reported in viruses from Iceland. This plasmid not only provides insight into virus and plasmid function but also is the basis for new genetic tools for *Sulfolobus*.

Fusellovirus-Based Vectors

One of the major reasons for sequencing the *S. solfataricus* genome and for isolation of viruses and plasmids of thermophilic Archaea was to be able to establish a genetic system for the analysis of these organisms. Many of the first and most successful steps have been taken using SSV1 or other fuselloviruses as the basis for plasmids that replicate in *Sulfolobus* and allow recombinant DNA to be transformed into *Sulfolobus*. A number of repeated sequences near the UV-inducible promoter, Tind, together with divergent promoters, led to the proposition that this region was the origin of replication (**Figure 2**). Pieces of the SSV1 genome containing this region have been incorporated into vectors that appear to replicate in *S. solfataricus* after transformation. However, these vectors have not been widely used. More successful vectors use the whole SSV1 genome with an insertion of an *Escherichia coli* plasmid in a region that was shown not to be critical for virus function to create infectious clones (**Figure 2**). Vectors based on this technique are now in their third generation. They have been successful in complementing mutants, overexpressing homologous and heterologous genes, and for preliminary gene-expression studies.

Fusellovirus Integrases

The only gene in fusellovirus genomes to show clear similarity to other genes is the virus integrase gene. It shows distant but clear similarity to the large family of site-specific tyrosine recombinases. Fusellovirus integrases are, however, unlike most other integrases in that the viral attachment site is within the integrase gene. Thus, integration disrupts the viral integrase gene. The attachment site in all fusellovirus integrases is in the N-terminal domain of the protein, and it is assumed, but not proved, that the remainder of the protein is not active, even though it contains all of the conserved catalytic amino acids responsible for recombination. The host attachment sites are in tRNA genes and proviral insertion preserves most of the tRNA gene so that it should remain functional. Intriguingly, all of the fuselloviruses sequenced to date integrate or are predicted to integrate into different tRNA genes. No additional host or virus genes appear to be required for either integration or excision. No excision of a provirus has been observed to date. Extensive *in vitro* studies with the SSV1 integrase indicate that the integrase itself is necessary and sufficient for both integrative or deletion reactions. Elegant molecular genetic studies have shown that the active site of the integrase is shared between two monomers and performs '*trans*-cleavage', similar to eukaryotic recombinases, but not bacterial ones.

Very recently, it was shown that the virus integrase and integration are not necessary for virus function. This was somewhat surprising due to the conservation of the integrase gene in all fusellovirus genomes sequenced to date. Additionally, a number of partial integrase genes, apparently made by past virus integration events, are present in not only the *S. solfataricus* genome but also in many other extremely thermophilic Archaea where they are thought to be highly involved in horizontal gene transfer.

Viruses lacking the integrase gene appeared not to integrate, but were stably maintained in laboratory cultures and under a number of stress conditions. However in

head-to-head competition experiments between viruses containing and lacking the virus integrase gene respectively, the construct without the integrase was rapidly out-competed.

Structures

A structural genomics program to elucidate all of the structures of the products of all of the ORFs in the SSV1 genome has produced two high-resolution structures to date. The first, the product of ORF f93, is clearly a winged helix-domain containing protein, almost undoubtedly involved in DNA binding. However, its role in virus function is not clear. This ORF is also not conserved in most of the other SSV genomes. A high-resolution structure for the ORF product d63 has been solved. It is a very simple four-helix bundle which may be involved in protein–protein interactions but again its function is not clear. Recently developed genetic tools may help in the elucidation of these functions.

Other 'Fusiform' Viruses

The viruses of extremely halophilic Archaea, His1 and His2, have strikingly similar morphology to the *Sulfolobus* fuselloviruses, but their genomes are linear and their replication is protein primed. Therefore, they have been recently assigned to the new floating genus *Salterprovirus*. The virus-like particle reported from *Methanococcus voltae* strain A3 at first glance appears to be very similar to the *Sulfolobus* fuselloviruses, but it has a much larger genome and many different shapes in transmission electron microscopy. A virus-like particle with a similar shape to the *Sulfolobus* fuselloviruses, PAV1, has been isolated from a deep-sea *Pyrococcus abysii* strain. This virus has not yet been fully characterized and its infectivity has not yet been shown. Its genome has no sequence similarity to the *Sulfolobus* SSVs.

A number of other viruses with a spindle shape with or without projections at one or both ends have been isolated from a number of thermoacidophilic Archaea. Most of them, however, have either been assigned to other virus families or have not yet been classified. Generally, their genomes are very different both in size and sequence from the known fuselloviruses and often their virions have very different sizes.

Biodistribution Tissues infected by a viral vector.
Episomal form Existence of the transgene as an extrachromosomal element.
Gene therapy Introduction of exogenous genes into cells to correct genetic or physiologic defects.
Nonenveloped virus A virus particle in which the viral coat is not surrounded by a lipid membrane.
Nonhomologous recombination Recombination between two unrelated DNA sequences.
Persistent infection An infection in which the viral genome is retained for extended periods, often for life, in host cells.
Replication competent A vector which can self-replicate and potentially spread from cell to cell.
Transgene A gene carried by a vector into a target cell.
Vector The means by which is a transgene is introduced into a target cell.

Introduction

Gene therapy represents the ultimate application of the evolution of molecular genetics from the elucidation of the structure of the double helix to patient treatment. There are only two requirements: the gene or DNA to be used to correct a genetic defect and a vehicle to introduce the DNA into the patient's cells. With the advent of cloning and recombinant DNA technology and the determination of the sequence of the human genome, a large number of genes are available for the therapy of genetic defects. Yet the clinical application of gene therapy remains in its infancy, albeit it has probably moved beyond the neonatal period. The major reason for the lack of more extensive progress has been the challenge of developing effective vectors. Successful vectors must be able to get the transgene (the new gene to be introduced) to the appropriate cell, transport the transgene into the cell, and then into the nucleus. Once present in the nucleus, a successful vector will express the transgene at the desired level and most often for an extended period of time. A major concern is toxicity, which may reflect either a host reaction to the vector itself, a commonly observed problem for early-generation vectors, or to the transgene, if it is perceived as nonself, which could occur in the case of a person with a null mutation. A further consideration is the ability of any DNA molecule introduced into the nucleus to potentially integrate into the host cell genome, most often by nonhomologous recombination. Nonhomologous recombination, which can occur at many sites in the genome, has the potential of disrupting normal gene expression by either altering the gene product or the regulation of the expression of the gene. Thus, important cellular functions may be lost which can impair the normal biology of the cell and in some cases lead to oncogenic transformation. Because of these considerations or hurdles, development of safe, effective vectors has proved to be much more challenging than initially appreciated.

Introduction of the transgene into patients can be done either *in vivo* or *ex vivo*. A variety of routes have been employed for administration *in vivo*; intramuscular, intravenous, via the airway, intraocular (either subretinal or into the vitreous humor), etc. The alternative approach is to remove the target cells from the body, introduce the transgene, and return the cells to the body. This method has been used primarily with the bone marrow. A second consideration is whether the vector will preferentially persist as an extrachromosomal element or will integrate into the host genome, either randomly or at a specific location. If the target consists of cells which divide rarely, if at all, then persistence as an extrachromosomal element may be an advantage. However, if the cell is a stem or progenitor cell which will undergo a sizable number of divisions, the vector is likely to be diluted out if it is not integrated into the genome.

A number of types of vectors have been tried, ranging from purified DNA administered either IV or via a gene gun, to liposomes, to vectors derived from viruses. The latter have been a favorite because viruses have evolved in nature to function by delivering and expressing genetic material within cells. All DNA viruses which replicate in the nucleus (including retroviruses) cause persistent infections which usually last for the life of the host. However, most of the viruses we know about also cause disease and thus the challenge is to engineer the virus so that it can function as a vector without causing disease. Interestingly, two of the viruses to be discussed below are not known to cause human disease. In any event, what has become clear is that to develop safe and effective vectors requires a detailed knowledge of the fundamental biology of the viruses to be used.

Despite the various challenges to be surmounted, gene therapy has developed to the point where there have been numerous clinical trials in which various levels of toxicity have been observed. In the most paradoxical example 12 children in France with severe combined immunodeficiency disease were cured by gene therapy; however, two of the children developed leukemia caused by the vector (happily, they have been successfully treated for this problem, as well). Clearly, much developmental work remains to be done, yet the promise is great. Several of the types of viral vectors which have been developed are described in the sections below.

There are several general considerations in the design of viral vectors. One is the host range or tissue targeting of the vector. A broad host range means that the vector can potentially be used to target many organs; however, if target specificity is desirable, a broad host range is not desirable. In other cases the desired target normally may not be infected by the vector. Thus, in many instances there have been attempts to modify the original host range. This has been achieved naturally by the use of different serotypes with differing host ranges, by modifying the genes encoding the capsid so that new epitopes are present on the surface of the virion, or, in some cases, by chemical linking of ligands to surface proteins. Another approach to altering host range is by creation of pseudotypes, enveloped viruses in which the envelope glycoprotein of a second virus is substituted for the normal constituent, for example, vesicular stomatitis glycoprotein has been substituted for a retrovirus envelope protein. Vector host range may also be affected by the alteration of the regulation of gene expression, so that it can occur or not in specific tissues.

Retrovirus Vectors

Retroviruses have long been considered to be good candidates to be developed as vectors for gene therapy. The viral capsid is surrounded by a lipoprotein envelope and contains two identical copies of a linear, single stranded RNA of plus polarity, in addition to at least two enzymes, reverse transcriptase and an integrase. As a consequence the viral life cycle passes through a double stranded DNA intermediate which integrates at a variety of sites in the cellular genome through the action of the virion integrase. Three different types of retroviruses have been used as vectors; the oncogenic retroviruses, lentiviruses, and spumaviruses. The oncogenic retroviruses have a wide host range (which can be extended by pseudotyping, in which the envelope proteins can be replaced by glycoproteins from other viruses), but can only integrate their genome in dividing cells after the nuclear membrane is removed before mitosis occurs. This property has limited their utility on the one hand; on the other, it has some desirable features because it limits the potential for horizontal spread since most cells in the body do not divide. Since the oncogenic retroviruses cause cancer, it is important that vector preparations not contain replication competent retrovirus (RCR). The viral genome contains three genes, *gag*, *pol*, and *env*. All of these are deleted from vector constructs; the only original sequences that are retained are the long terminal repeats (ltr), the packaging signal, and an ori. Vector production requires the normal gene products and the challenge is to make the probability of recombination to produce RCR very small so that quality checks can be passed. Since the viral genome integrates at a variety of sites, another potential concern is insertional mutagenesis in which either an essential gene is disrupted or a normally silent gene under tight regulation gains the ability to be expressed constitutively. The former seems relatively remote since most genes are present in at least two copies in a diploid genome. However, the latter could be potentially a one-hit phenomenon and lead to cancer. Indeed, this appears to have happened in a clinical trial, which otherwise was one of the great success stories of gene therapy. Twelve French infants with an X-linked form of severe combined immunodeficiency were treated with a vector derived from Moloney murine leukemia virus; nine of the children were 'cured' of this otherwise lethal disease. However, two children developed leukemia; in both cases the disease was clonal and the cells in each case contained the vector inserted next to the LMO gene. The conclusion was that the inserted vector had turned on gene expression, leading to the disease. Fortunately, it has been possible to successfully treat the children for this additional problem. Interestingly, the French government decided to continue the trial since the disease was otherwise lethal; that is, the benefit outweighed the proven risk.

Lentivirus vectors are derived from human immunodeficiency virus (HIV) and, thus, there is the real and psychological challenge of using a vector based upon a dangerous human pathogen. In addition to the three genes contained in the genomes of all retroviruses, the

lentivirus genome contains six additional genes which are the products of splicing and function in a variety of regulatory roles. Again the approach has been to generate vectors from which all the viral genes have been deleted in producer cells where the helper genes required have a minimal amount of sequence homology so that there is very little chance of recombination to generate RCR. Lentivirus vectors are easier to produce in higher titers than the oncogenic retrovirus vectors and have the great potential advantage that they can successfully infect both dividing and nondividing cells and integrate the genome in both cases to establish persistence. Whether the psychological question can be successfully overcome remains to be seen. An alternative possibility is the development of spumavirus vectors. These have many of the same desirable features as lentivirus vectors without the problem of being derived from a serious pathogen. Spumavirus is a common human infection but has never been convincingly associated with human disease. They have been used successfully in a variety of animal models and indeed seem promising.

Adenovirus Vectors

Certain DNA viruses offer the potential to transduce both dividing and nondividing cells, with a much lower risk of integration-related carcinogenesis. Recombinant adenovirus (rAd) and recombinant adeno-associated virus (rAAV) have both been used in clinical gene therapy trials, as have recombinant herpes simplex virus (rHSV). Adenoviruses are nonenveloped, double stranded DNA viruses with a 36 kb genome that contains both early genes (encoding regulatory proteins expressed prior to DNA replication during a lytic life cycle) and late genes (encoding structural proteins expressed after DNA replication). Adenoviruses are present in over 60 serotypes in humans, and they commonly cause acute, self-limited infections of the respiratory and gastrointestinal tracts of humans. rAd vectors based on the group C adenoviruses, Ad2 and Ad5, were initially developed by deleting portions of the early genes E1a and E3 and inserting a therapeutic gene of interest. These first-generation rAd vectors are relatively easy to propagate and mediate robust short-term expression in a wide range of cell types, *in vitro* and *in vivo*. rAd vectors also trigger innate and adaptive immune responses in the host under most circumstances, which can limit both the duration of expression and the safety of *in vivo* gene therapy. An acute inflammatory response to a first-generation rAd vector resulted in the death of one patient with partial ornithine transcarbamylase (OTC) deficiency in a well-publicized incident. Nonetheless, clinical trials of rAd vectors continue in cancer patients and as recombinant vaccines.

Recognition of the immunogenicity of rAd vectors has led to the generation of later-generation versions of the vector, in which more viral coding sequences have been deleted. Second-generation vectors were produced by deletion of other early genes such as E2a and E4, in addition to the E1a and E3 deletions described above. The second-generation vectors mediate less expression of viral proteins, especially the late proteins, and trigger less adaptive immunity than first-generation vectors. The latest version of the rAd technology, known as the high-capacity or helper-dependent adenoviral (HD-Ad) vector, has a greater payload for therapeutic genes and expression elements, a lower risk of adaptive immune responses, and a longer duration of effect. HD-Ad vectors are currently beginning early-stage clinical trials.

Adeno-Associated Virus Vectors

Adeno-associated viruses (AAVs) are nonpathogenic, and include among others, human and primate parvoviruses, with a nonenveloped icosahedral capsid and a 4.7 kbp single stranded DNA genome. The genome contains genes required for replication (*rep*) and for the capsid components (*cap*). The use of internal promoters and alternate splicing allows for the production of a total of four Rep proteins (Rep78, Rep68, Rep52, and Rep40) and three capsid proteins (VP1, VP2, and VP3). These two genes are flanked by two palindromic inverted terminal repeats (ITRs), which contain all of the *cis*-acting elements required for replication and packing of the AAV genome.

AAVs are not adenoviruses, but were originally discovered as contaminants of adenovirus cultures. Wild-type AAV requires a helper virus (usually an adenovirus or herpesvirus) for efficient replication. In the absence of helper virus co-infection, AAV enters into the latent stage of its life cycle, either by maintaining itself as a stable episome or by integrating its DNA into the host genome, often into a specific site on human chromosome 19, the AAVS1 site. This site-specific integration is dependent upon the AAV Rep protein, which is deleted from rAAV vectors. Thus, the vectors have been found to persist primarily as episomal form, with a low frequency of non-site-specific integration. rAAV vectors are also capable of transducing nondividing cells and have been shown to persist long term *in vivo* in nondividing cells in animal models. One of the major limitations of the rAAV system is the small packaging capacity of the virion, with a payload of approximately 4.5 kb of exogenous DNA. This may be overcome in certain instances by taking advantage of the propensity of rAAV vector genomes to form heteromultimers, thus allowing for *trans*-splicing between two different vector genomes within a single target cell.

rAAV vectors have been used in clinical trials in cystic fibrosis, hemophilia B, limb-girdle muscular dystrophy, Parkinson's disease, Batten's disease, and alpha-1 antitrypsin (AAT) deficiency. Results of these early phase trials

confirm the fact that rAAV is safe over a wide dose range when administered to the airways, muscle, and central nervous system. Delivery to the liver in patients with hemophilia B resulted in transient elevations of liver enzymes that appeared to be associated with cell-mediated immune responses to rAAV capsid proteins retained in hepatocytes. While these immune responses may have limited the duration of therapeutic effect of the vector, no clinically important toxicity was observed.

All of the previous clinical trials experienced with rAAV have been using the type strain, AAV serotype 2. In recent years, over 100 new serotypes and genomic variants of AAV have been identified. Many other serotypes have been developed as rAAV vectors and some have substantially higher efficiency for transduction of specific tissues than rAAV2. One trial of an alternative serotype has just been initiated in AAT deficient patients with AAV serotype 1 capsids. The preclinical rAAV1 experience demonstrates that switching to a different AAV serotype capsid can still retain the basic property of long-term persistence of vector DNA, yet capsid–receptor interactions may lead to a distinct pattern of vector biodistribution to distant organs and to increased innate immunity as the distinct capsids interact with pattern recognition receptor proteins. Altered biodistribution could be advantageous if it leads to increased transduction of a target cell population. However, it could also lead to an increased risk of inadvertent germ line transmission of vector DNA, a phenomenon that is generally to be avoided. The clinical utility of alternative rAAV serotype vectors may become clearer in the near future as more clinical trials with these vectors are undertaken.

Both rAd and rAAV vector capsids have also been genetically engineered to create receptor-targeted versions of their respective vectors. Essentially, this approach involves insertion of specific peptides that may serve as ligands for specific cell-surface receptors. These 'designer' vectors have the potential for highly efficient and specific cell targeting. One key to the use of targeting technology is the identification of sites within the capsid which can be modified without a loss of the integrity of the capsid. Another important factor is the size of the peptide insert that may be tolerated within the insertion site. In the case of rAAV, one of the three capsid proteins, VP2, can either be completely deleted from the vector without loss of infectivity (and with a modest increase in packaging capacity), or can be modified at its N-terminus to include very large inserts, including single-chain antibodies. This form of rationally designed vector appears to hold much promise for future vector development, as does another variant of rAAV capsid alteration, an *in vitro* evolution, or DNA shuffling approach. In these types of approaches libraries of rAAV capsid variants are developed by mutagenesis and/or recombination of domains between distinct AAV serotypes. Serial passage on relatively nonpermissive cell types allows for positive selection for novel AAV variants capable of transducing those cell types, thus further expanding the repertoire of AAV capsids available as vehicles for therapeutic gene transfer.

Herpesvirus Vectors

Human herpesviruses are large double stranded DNA viruses with a complex structure. An envelope is separated from the nucleocapsid by the tegument which is composed of a large number of proteins which subserve various functions during viral infection, including turning off cell protein synthesis and initiating viral transcription. The herpes simplex virus (HSV) genome is composed of two parts, a long unique sequence and a short unique sequence, both bounded by terminal repeats. There are three classes of cellular genes: (1) immediate early, which control gene expression; (2) early, involved in DNA replication; and (3) late, which encode structural proteins. HSV preferentially infects cells of the central nervous system; after initial entry through epithelial cells of the skin or mucosa the virions travel retrograde through axons to cell bodies, particularly in sensory ganglia, where the virus most commonly establishes a latent infection. The viral genome is maintained as an extrachromosomal circle. Because the neurons which are persistently infected do not divide, the latent state is maintained unless a variety of environmental stimuli which can stress the cell activate viral replication. HSV vectors of two types have been developed and most often are intended to be lytic and cidal for tumors of the brain. The first type of vector has had several viral genes which are normally associated with virulence removed (immediate early genes and the gene for the tegument protein which shuts off cell protein synthesis) and replaced with genes specifically toxic to tumor cells. The second type is termed an amplicon, which consists of a cassette containing the transgene with its regulatory sequences, the HSV origin of replication and the packaging signal. The former type has a transgene capacity of almost 30 kbp while the latter can accommodate almost the full 160 kbp in the full genome. Since the latter expresses no viral genes, toxicity associated with wild-type virus and an inflammatory immune response can be avoided (unless caused by the transgene). HSV vectors of the first type have been used in several clinical trials and in phase I trials have been found to be nontoxic and to indicate the possibility of beneficial effects on the target tumors, although the number of patients in completed trials has been too small for definitive results.

Clinical Trials

The future of clinical gene therapy may lie with the appropriate matching of vector properties with the properties

of the cell target and the desired timing of transgene expression. Situations in which transient, high-level expression is needed may be best addressed with rAd or liposomal vectors. First-generation rAd vectors may be particularly well suited for recombinant vaccine approaches since the innate responses to Ad may serve as an adjuvant for adaptive immune responses to the transgene product. Longer-term expression in nondividing cells might be better addressed with lentivirus or rAAV vectors. Finally, long-term expression in rapidly dividing cells might be best addressed with onco-retrovirus or lentivirus vectors since episomal rAAV vector genomes may be lost in such cells. The choice of vector and route of administration is often dictated by the disease process itself. While many applications of gene therapy have been for recessive genetic disorders, which usually require long-term gene expression within a particular organ, others have aimed to induce immune responses to malignant tumors, to stimulate a new vascular supply to ischemic limbs or segments of myocardium, to augment wound healing, or to relieve inflammatory diseases, such as rheumatoid arthritis. Each of these examples would require a different route of administration, as well as different timing and level of gene expression in order to achieve the desired therapeutic effect.

As more gene therapy vectors are developed into clinical products for specific diseases, a regulatory pathway to the clinic has emerged in USA and in other industrialized countries. The paradigms established for biological agents by the US Food and Drug Administration (FDA) provide the model for such regulatory approval. The pathway begins with proof-of-principle studies in which an appropriate vector is chosen to transfer the therapeutic gene into a cell culture or animal model. These studies generally address the efficiency and duration of gene expression, the biological effects of the transgene product, and functional correction of the defect. The gene transfer approach used in the proof-of-principle study generally mimics the ultimate clinical use of the vector, in terms of whether the vector is injected directly *in vivo* into a target organ, or is used for *ex vivo* transduction of a cell population that is amenable to reimplantation.

If the proof-of-principle studies demonstrate a potentially therapeutic effect, additional preclinical safety testing is usually undertaken in animals. These studies often are done in a larger number of animals, so that important potential toxicities can be understood and their frequency predicted. In some cases, both small animal (usually rodent) models and larger animal (occasionally nonhuman primate) models will be used. Formal safety studies should cover a fairly broad dose range and should include evaluations at both early and late time points. Safety studies in gene therapy have special considerations, including studies of the biodistribution of vector genomes to distant organs, particularly to germ cells within the gonads, studies of the immune responses to vector components and transgene products, and possibly a survey for vector-related tumorigenesis. The complete toxicology package should address potential toxicity of the vector over a specific dose range, and thus guide both the dosing and the safety studies within the early-phase clinical trials.

Traditionally, clinical trials have included phase I safety studies, phase II studies that focus on safety and biological effects, and phase III studies to prove efficacy and document lower frequency toxicities. In recent years, there has been a growing emphasis on phase IV studies, which occur after licensure of a drug or biological product for distribution and sale. In addition, there is a new concept of phase 0 studies in gene transfer, which are used as an experimental context to learn about properties of a given vector or vector class, without necessarily being part of the regulatory process for a specific gene therapy product. Once again, clinical gene therapy studies have certain special considerations, including sampling of semen (as an indicator of potential for inadvertent germ line transmission in males), studies of the immune responses to the vector and transgene product, and long-term follow-up of gene therapy study participants. The latter is designed to monitor the long-term effects of vector-mediated mutagenesis, that might result in secondary malignant changes in target cells at a later time. There are also special regulatory processes for gene therapy trials, particularly those that receive federal funding in USA. These include the involvement of the Office of Biotechnology Activities at the National Institutes of Health, and its Recombinant DNA Advisory Committee, as well as the use of Data and Safety Monitoring Boards by sponsoring NIH institutes for ongoing monitoring of clinical trials.

Given the fairly broad range of available vectors and the rapidly developing systems for clinical testing of vector candidates, it seems likely that a growing number of gene therapy agents will reach clinical application in the coming years. However, the long-term impact of gene therapy will likely take much longer to be fully realized. It remains to be seen just how broad that impact will be.

Glossary

Chromosome Encapsidated nucleic acid polymer that is the genomic component of the phage virion.
Concatamer A long nucleic acid polymer made up of tandemly linked genomes.
Packaging ATPase Enzyme complex that binds to, or is part of, the procapsid and translocates the chromosome from the outside to the inside of the capsid.
Procapsid The preformed, precursor capsid into which the genome is packaged.
Prohead See procapsid.
Virion The mature, infectious phage particle.

Introduction

The parasitic phase of the virus life cycle begins with the delivery of a viral genome into the host cell. Therefore, the bringing together of the virus chromosome with the viral capsid can be considered the culmination of the process of virus assembly that yields the infectious particles that will continue the next round of host-dependent replication. Bacteriophages have evolved complex mechanisms by which they ensure that this process is both effective and efficient.

As in other virus types, the encapsidation of the bacteriophage chromosome occurs by one of two distinct pathways. The first is the co-assembly of the components of the proteinaceous capsid with the chromosome at the terminus of viral replication. By this mechanism, capsid components assemble around the phage chromosome via the principles of self-directed assembly, with large classes of single-stranded DNA (ssDNA) and single-stranded RNA (ssRNA) phages being general examples. The ssDNA filamentous phages of the family *Inoviridae*, such as M13, achieve co-assembly of chromosome and capsid via an extrusion process by which ssDNA chromosome, coated with binding protein, is translocated through the cell membrane. The chromosome picks up external protein components of the capsid at membrane associated assembly sites. This extrusion/co-assembly is ATP dependent. In contrast, ssRNA phages of the family *Leviviridae*, such as MS2, present a co-assembly of an icosahedral capsid around a highly structured ssRNA chromosome.

In the second general pathway of genome encapsidation, the focus of this article, capsid assembly and genome replication remain separated until they converge in an event during which the phage chromosome is packaged into a preformed capsid using a process distinct from those that drive co-assembly. Unlike co-assembly, genome packaging is often mediated by mechanisms that energetically drive the chromosome from the outside to the inside of the capsid. In many phage systems, this event requires the assembly of specialized molecular machinery and the input of energy to push the nucleic acid chromosome into a confined space against a concentration gradient that result in the compaction of the nucleic acid polymer by several orders of magnitude.

There are three types of genome packaging that represent three large groups of phages and are distinguished by the type of nucleic acid substrate that is packaged. These consist of (1) the double-stranded DNA (dsDNA) phages of the order *Caudovirales*, which includes the families *Podo-*, *Sipho-*, and *Myoviridae*, and others groups including the family *Tectiviridae*; (2) the ssDNA phages of the family *Microviridae*; and (3) the double-stranded RNA (dsRNA) phages of the family *Cystoviridae*. All three of these groups of phages have evolved complex and highly efficient strategies to select and translocate viral chromosomes from the cytosol of the host cell into a preformed capsid.

General Considerations

One of the most crucial aspects of genome packaging in bacteriophage, as in other viruses, is the appropriate selection of virus chromosomal nucleic acid polymer from the milieu of nucleic acid inside the host cell. This selectivity is achieved by the binding and recognition of precursor viral chromosomes by components of the genome packaging apparatus and targeting them to the preassembled precursor capsid. This targeting event can be coupled to other events such as genome replication, as in the family *Microviridae*, be part of the chromosomal maturation process, as in the dsDNA phages, or precede the final replicative stages of the chromosome as found in the family *Cystoviridae*. Nomenclature can be diverse throughout the literature, with precursor capsids being referred to as procapsids, proheads, or preheads, depending on the system. This article refers to the precursor capsid targeted for packaging as the prohead or procapsid as is the convention for each system.

Additionally, distinction must be made between the bacteriophage genome and the packaged chromosome that becomes part of the infectious progeny virion. In some cases, these two terms are synonymous, as in the family *Microviridae* and the dsDNA phages lambda, ø29, and PRD1, since the chromosome is limited to a single copy of the genome. Exceptions arise for two reasons: (1) the genome is segmented into multiple chromosomes, as in the family *Cystoviridae*; and (2) the chromosome is terminally redundant as a result of a headful packaging mechanism using a concatamer as a substrate, as in caudoviruses such as the T-phages, P22, SPP1, etc. A singular exception is the Mu-like bacteriophage, in which the chromosome is comprised of a complete copy of the phage genome flanked by host-derived DNA sequences, a result of excision of the phage DNA from the host chromosome.

Finally, the inclusion of the packaging motor complex into the mature virion is variable, depending on the phage. In general, the enzyme complex responsible for chromosome translocation detaches from the packaged capsid in the dsDNA phages and is replaced by tail organelles. In the family *Microviridae*, the packaging complex is part of the DNA replication complex that is similarly not retained on the capsid surface. In contrast, the packaging complex of the family *Cystoviridae* remains attached to the capsid and is part of the mature virion. A summary of the key components and processes involved in packaging is presented in **Table 1**.

dsDNA Packaging

Since dsDNA phages are the most prevalent biological pathogens in the biosphere, the dominant type of genome packaging is the dsDNA packaging seen in the families *Podo-*, *Sipho-*, *Tecti-*, and *Myoviridae* (**Figure 1**). As with other packaging motifs, dsDNA phages pre-assemble an empty, immature capsid that docks with the phage chromosome for packaging. Universally, DNA packaging in dsDNA phages involves three viral components: (1) the preassembled prohead or procapsid, (2) the matured DNA chromosome, and (3) the ATP-dependent DNA-translocating enzymes.

The dsDNA phage chromosome is packaged into an immature, icosahedral prohead. The architecture of the capsid in these dsDNA phages is different from other icosahedral phages. At a unique fivefold vertex of the prohead, a portal structure is embedded, replacing one of the 12 pentamers of the icosahedron. This portal is a

Table 1 Packaging facts

Phage family	*Genome type*	*Point of entry into procapsid*	*Enzymes involved*	*Nucleic acid polymer translocated*	*Completion events*
Sipho-, Podo-, Myo-, Tectiviridae	dsDNA	Unique fivefold vertex via portal	Large and small packaging enzyme complex	Concatameric dsDNA (lambda, P22, SPP1, T-phages) Unit-length genome inserted into host chromosome (Mu) Unit-length chromosome with terminal proteins (phi29, PRD1)	Cleavage of concatamer, motor detachment, and tailing Cleavage of chromosome from host genome, motor detachment, and tailing Motor detachment and tailing
Microviridae	ssDNA	Twofold axis	Replication complex, J protein	ssDNA	
Cystoviridae	dsRNA	Fivefold vertex	Translocating NTPase complex	ssRNA	Replication of ssRNA to dsRNA

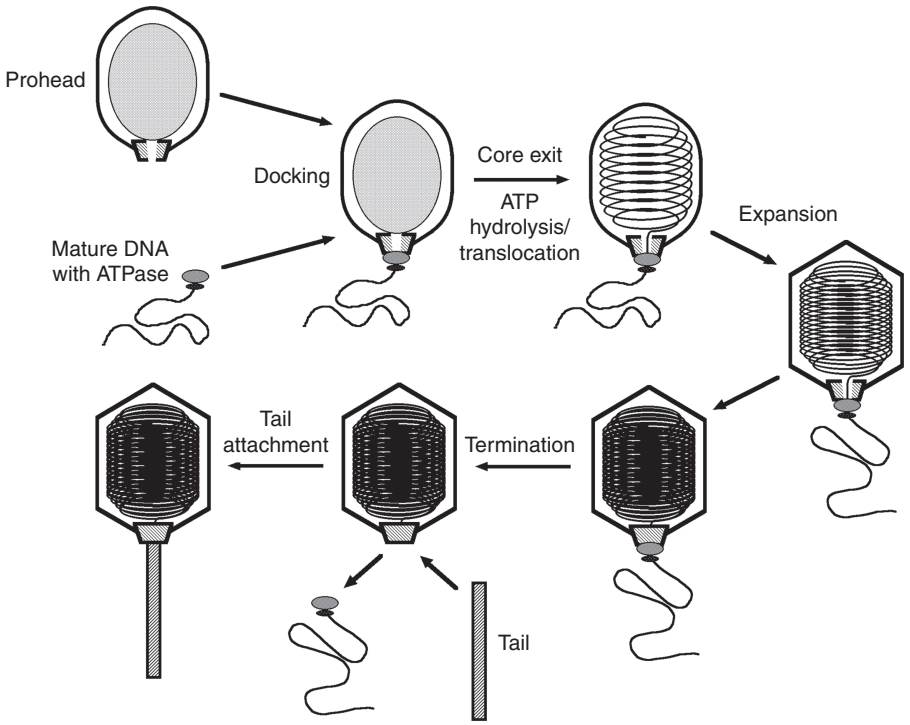

Figure 1 Schematic of generalized dsDNA phage assembly. A prohead interacts with the packaging ATPase holoenzyme–DNA complex via its head–tail connector. ATP hydrolysis powers translocation of the mature DNA, and at some point the scaffold core is ejected, either whole or following proteolysis. After an amount of DNA enters the head the shell capsomeres rearrange, making the head more angular and, in most phages, increasing the head volume. DNA translocation continues until a full complement of DNA enters the head, determined by either the unit length of the DNA, sequence recognition of the DNA length, or a headful mechanism. The ATPase–DNA complex detaches from the connector and is replaced by neck, tail, and/or tail fiber components, yielding a mature, infectious virion. Reproduced from Calendar R (ed.) (2006) *The Bacteriophages*. New York: Oxford University Press, with permission from Oxford University Press.

12-fold homo-oligomer of the phage-encoded portal protein forming a channel through the capsid wall. In phages with prolate heads, the portal vertex is always at one end of the long axis of the prohead. In most cases, it is believed that the portal is responsible for initiation of capsid polymerization in conjunction with an associated scaffold structure. The portal provides the binding site for the rest of the DNA packaging machinery and is the channel through which the DNA passes into, and ultimately out of, the capsid. After packaging, it is the axis around which the neck and tail components assemble, hence the designation connector for this structure in some systems.

The dsDNA phage prohead lattice is in an immature form prior to genome packaging. The immature prohead lattice is often physically less stable than in the mature virion. In some cases, accessory domains of the major capsid protein required for lattice assembly are proteolytically cleaved prior to packaging. In most phages, the conformational switch of the capsid lattice to the mature form occurs during packaging. This rearrangement of the capsid lattice is accompanied by an increase in the sixfold symmetry of the capsid hexons, and an overall increase, or expansion, of the head shell volume and consequent thinning of the shell thickness. Expansion ranges from the unperceivable, as in ø29, to the dramatic, as in HK97 where the capsid volume doubles.

Considerable diversity in the structural organization and maturation pathway of the DNA chromosome exists in these phages. DNA maturation converges at the point of chromosome translocation in that all dsDNA phages studied employ a common mechanism for genome translocation. The differences in DNA chromosome structure in the dsDNA phages arise as a result of differing strategies that have evolved to replicate phage dsDNA inside the cell. The central challenge, not faced by RNA phages, is the inability to initiate DNA-dependent DNA replication from a linear dsDNA without loss of information from the 5′ ends of the replicated DNA polymer. This 'riddle-of-the-ends' is solved by dsDNA phages by using one of four strategies: (1) replication of a circular form of the genome (P1); (2) producing multiple, tandemly linked copies of the genome, termed concatamers, in a single replicating molecule such that complete chromosomes can be produced by cleavage (P22, T-phages, SPP1); (3) replication of the genome as part of integrated segment imbedded in the host cell DNA genome (Mu); and (4) initiate replication of linear DNA using a priming mechanism dependent on a covalently linked terminal

protein that does not lead to degeneracy of the chromosome (ø29, PRD1). The first three replication strategies require a DNA cleavage reaction as part of the packaging initiation process, since only linear dsDNA of a certain size can be packaged. Bacteriophage lambda combines the first two replication strategies in that early replication is by theta replication of its circular genome that switches to the lambda rolling circle mechanism to produce long, multigenome concatamers which serve as the packaging substrate. The fourth replication mechanism above does not require a cleavage event since the DNA substrate is present in the cell in unit length form.

The DNA substrate is recruited from the cytosol by the enzymatic components of the packaging apparatus. In general, there are two proteins involved, one large and one small, that form a holoenzyme complex. Their stochiometry, relative to each other and to the procapsid, is still unclear, with reports from various systems ranging from four complexes per motor up to six. The 'small' subunit is a DNA binding and recognition protein, while the 'large' component is an ATPase. These proteins assemble on the DNA substrate, with the small subunit recognizing a specific sequence in the DNA termed the pac site. This process has been particularly well described in phage lambda (**Figure 2**). It is believed that initial DNA-binding step is mediated by other factors of cellular origin (integration host factor (IHF) in the case of lambda). (In phages with terminal proteins at the DNA ends, the terminal protein is analogous to the small subunit.) The specificity of this recognition ensures that only phage chromosomes will be packaged into the receptive phage prohead. In the case of phages with either circular- or concatameric-replicated DNA, the large subunit of these enzymes cut the DNA to produce a free end. This endonuclease activity is also responsible for production of a second endonuclease cut of the DNA at the end of packaging in phages that package segments of concatameric DNA, thus the designation 'terminase' for this enzyme ensemble in many phages (P22, lambda, T-even, T-odd, SPP1, Mu, etc). The designation terminase is not relevant to phages with unit length chromosomes such as ø29 and PRD1 since no cleavage is required; thus, these enzymes are more accurately termed packaging ATPases.

Once formed, the packaging ATPase–DNA complex docks with the prohead via the portal complex. The initial events that mediate the insertion of the DNA into the portal are unclear. Once initiated, DNA translocation occurs via an ATP hydrolysis-mediated process. The energy requirement for this process is clear when one considers the forces against which this molecular machine is working. First, entropy dictates that the concentration of DNA outside and inside the prohead should be equal. Thus, entropy works against dsDNA packaging throughout the process. Second, dsDNA is a relatively stiff polymer, with a persistence length (the minimum curvature of relaxed dsDNA) on the same scale as the capsid into which the DNA is being packaged in most phages. Therefore, energy is required to bend the DNA within the confines of the prohead. Finally, DNA has a net negative surface charge owing to the phosphate backbone of the polymer. As the DNA becomes compacted into the prohead, DNA strands are forced into close contact and electrostatic repulsion builds. Once again, energy must be invested into the DNA to achieve this end state. The end result is that the compacted DNA is pressurized inside the capsid to several atmospheres, requiring that the packaging motor complex must exert a translocating force on the order of 100 pN, making these molecular motors some of the strongest described in any biological systems. It is not clear how the DNA is organized to accommodate the degree of packing density, which approaches that of crystalline DNA. It is clear that the DNA must be

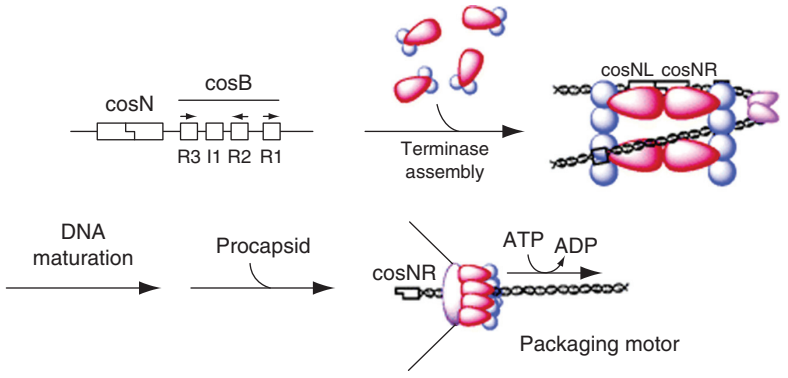

Figure 2 Model for terminase assembly at the cos site. The terminase protomer is a heterotrimer composed of one gpA subunit (red lobes) tightly associated with a gpNu1 dimer (blue spheres). Four protomers assemble at cos, resulting in bending of the duplex into a 'packasome' complex. Duplex bending by a gpNu1 dimer (purple lobes) bound to the R3 and R2 elements is central to the assembly of the packaging machinery. DNA maturation includes duplex nicking and separation of the DNA strands. Reproduced from Ortega M and Catalano CE (2006) Bacteriophage lamda gpNu1 and *E. coli* proteins cooperatively bind and bend viral DNA: Implications for the assembly of a genome packaging motor. *Biochemistry* 45: 5180–5189, with permission from ACS Publications.

pressed together in some form of hexagonal array that follows the contour of the capsid (**Figure 3**), which is the most energy-efficient conformation. Several models, including solenoids, liquid crystals, and folded toroids, have been suggested, but to date no structural study has been able to clearly resolve the structure of the packaged chromosome.

Packaging is terminated either by simply reaching the end of the unit-length chromosome (ø29, PRD1), or by a second DNA cleavage event necessitated by the translocation of a concatameric packaging substrate. In the latter, this cleavage event relies on the signaling from the packaged DNA density inside the capsid to the translocating complex on the outside of the capsid. In some cases, the near filling of the capsid permits the recognition and cleavage of the next approaching pac sequence, as with the lambda cos sequence, such that all progeny have identical genomes. In other instances, the second cleavage event is strictly 'headful', meaning the restriction of the DNA being packaged is sequence independent and relies on the detection of packaged DNA density inside the head. In this case, the capsid volume has evolved to exceed the capacity required to package a chromosome the length of the genome; thus the packaged DNAs are terminally redundant. This terminal redundancy is crucial to the progeny in that it will buffer the genome against loss during the next replicative infection. How this signal is transmitted from the portal to the packaging enzymes is unclear.

As described above, prohead assembly often involves the assembly of a precursor capsid that is structurally distinct from the mature capsid. In many cases, the prohead is yet to undergo ejection of the core-scaffold components that mediate head shell polymerization into the size and shape required by the virus. Similarly, final conformational rearrangements that stabilize the capsid shell allow the binding of accessory stabilizing proteins to the head surface, or release of the packaging motor and assembly of neck and tail components required to make

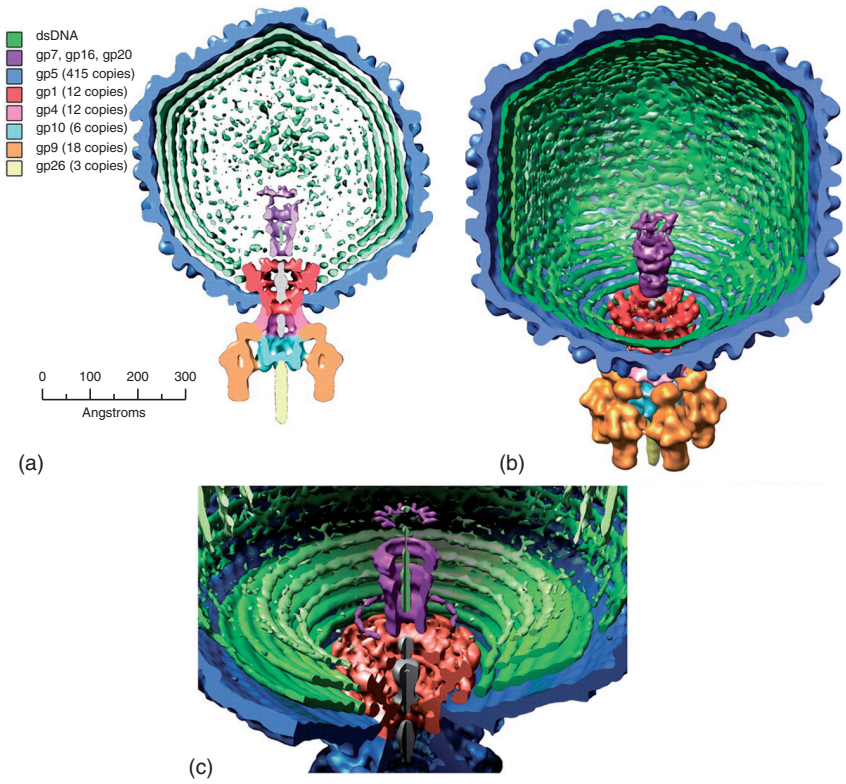

Figure 3 The interior features of the P22 virion. (a) The locations, deduced from many previous molecular biological studies, of the assembled gene products within a cutaway view of the reconstructed density of the P22 virion. Gene products 1, 4, 9, 10, and 26 make up the tail machine. Layers of dsDNA (green) are clearly visible as concentric shells within the capsid; they break into distinct rings of density near the portal vertex. Density (green) in the center of the channel formed by the ejection proteins (purple) could be the end of the P22 chromosome; however, density on this axis within the portal protein ring (red) does not appear to be consistent with DNA. (b) A cutaway view of the internal portion of the asymmetrically reconstructed particle contoured at 3, showing the 12-fold symmetry of the portal (red), the putative ejection proteins (purple), and individual strands of dsDNA (green). (c) Close-up view of the packaged interior upon 12-fold averaging along the tail tube axis. Although the E-proteins (purple) themselves in reality may or may not exhibit 12-fold symmetry, this view demonstrates the channel-like nature of the structure they form in the virion, as well as the dsDNA (green) that may be seated within their channel. Three concentric shells of spooled DNA are clearly visible. Reproduced from Lander GC, Tang L, Casjens SR, *et al*. (2006) The structure of an infections P22 vision shows the signal for headful DNA packaging. *Science* 312(5781): 1791–1795, with permission from American Association for the Advancement of Science.

the completed virion infectious. The end result of the separation of these final events in assembly permits the specific targeting of immature proheads by the DNA packaging machinery and completion of assembly (i.e., packaging motor detachment and neck/tail assembly) only after packaging has been completed. Upon completion of packaging, the ATPase complex detaches from the packaged head and neck and tail components assemble. This generally involves the assembly of several neck proteins, followed by the assembly of the tail in completed form (e.g., T4, lambda) or by the stepwise addition of tail components to the packaged head (P22, ø29).

The mechanism of DNA translocations in these motors remains unresolved, owing mostly to the complex nature of the portal motor complex. The role of the ATPases is clear in that they bind and hydrolyze ATP, transferring the energy of this reaction to the physical movement of the DNA substrate. It is widely held that the ATPases therefore have an active role in translocation, and function in a manner similar to the helicases, as is clear in the dsRNA phage packaging complex. What is unclear is whether the portal protein actively participates in this process. Regardless of a direct role in translocation, the portal protein ring does appear to play a role in signaling the end of translocation, as illustrated by mutants in the portal proteins of SPP1 and P22 phages which package altered chromosome lengths. This suggests the head-full sensor for these phages lies in the portal protein, and that the signal for the cleavage of the DNA upon completion of packaging is transmitted to the ATPase by the portal ring.

ssDNA Packaging

The archetype ssDNA phage assembly system is øX174 due to its extensive genetic and structural characterization over recent decades. Unlike the dsDNA phages, genome packaging in ssDNA phages is coupled to genome replication. The substrate genome for replication is a closed, circular dsDNA that is copied using a complex of host cell enzymes. This replicating complex switches to rolling circle replication upon interaction with viral proteins A and C, a host helicase (the *rep* protein), and the procapsid. As the positive polarity DNA is extruded from the rolling circle, it is transferred into the procapsid through a depression in the twofold axis of the preformed icosahedral shell. Unlike dsDNA phages, this point of entry is not structurally unique like a portal, but the replication/packaging complex binding confers exclusion to the other twofold axis on the capsid surface. Packaging in øX174 is dependent on an ssDNA binding protein J, which enters the capsid during packaging, and binds the DNA via charge interaction. J protein also mediates interaction of the packaged DNA with the inner surface of the capsid. Changes in capsid size and stability also occur during packaging, as with the dsDNA phages. In contrast to the dsDNA phages, phages of the family *Microviridae* do not require the high chromosome density inside the capsid that requires extensive input of energy for packaging. Thus, the energy of translocation harnessed from coupled DNA replication and DNA binding is sufficient in generating the required packaging force to efficiently produce infectious progeny.

ssRNA Packaging

A large class of dsRNA phages, the family *Cystoviridae*, translocate their genome into preformed capsids. These phages are analogous in their replication and structure to the eukaryotic reoviruses, and are best characterized in the ø6 group. Unlike the dsDNA phages, the cystoviruses translocate a single-stranded nucleic acid polymer into the procapsid. This circumstance is the product of the replication strategy of the virus, during which positive-strand RNA synthesized during infection serves as both template for translation and substrate for genome packaging. Conversion of the ssRNA to dsRNA occurs inside the capsid after translocation at the end of the assembly pathway. Also, unlike the dsDNA or ssDNA phages, the dsRNA genome is segmented into three chromosomes of different lengths (S, M, and L for small, medium, and large, respectively). This requires the translocation apparatus to not only select chromosomal nucleic acid polymer as in the dsDNA phages, but to select and process multiple ssRNAs in sequence (designated s, m, and l in the ssRNA form prior to conversion to S, M, and L) to allow for fidelity in the assembly of the mature virion.

The translocating NTPase of this class of viruses, the P4 enzyme, has been extensively characterized by biochemical and structural analysis. (Unlike the ATPases in the dsDNA phages, the packaging enzymes in the family *Cystoviridae* are not limited to ATP, but can use other NTPs depending on the phage.) A hexameric complex of this enzyme is assembled at each fivefold vertex of the precursor procapsid. The mechanism by which only one of the 12 vertices is selected to translocate a bound ssRNA substrate is unclear. The complex is believed to function in a manner analogous to helicases, translocating ssRNA through the hexamer and into the capsid. The P4 prohead complex recognizes stem loop structures at the 5′ end of the ssRNAs to be packaged, presumably through binding sites on the capsid surface adjacent to the ATPase. The order of binding, and thus packaging, is controlled by the alteration of the capsid binding site that occurs as RNA is packaged. Thus, a naive procapsid binds the s fragment specifically, packages it, and in doing so undergoes a conformational change that alters the procapsid RNA binding domain such that it now binds the m fragment,

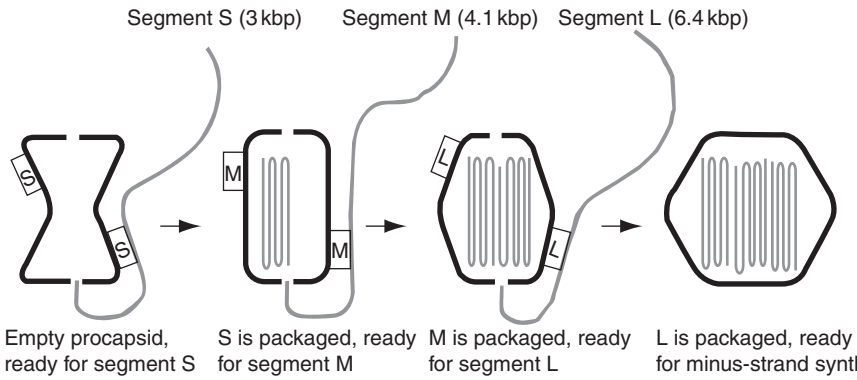

Figure 4 The packaging model of ø6. The empty procapsid shows only binding sites for S. After a full-size S is packaged, the S sites disappear and M sites appear. After a full-size M is packaged, the M sites disappear and L sites appear. After a full-size L is packaged, minus-strand synthesis commences. Reproduced from Calendar R (ed.) (2006) *The Bacteriophages*. New York: Oxford University Press, with permission from Oxford University Press.

which is then packaged, followed by the l fragment (**Figure 4**). The determinate of these conformational changes in the capsid to allow recognition of the variant 5′ ends of the chromosomes is the length of packaged RNA, rather than sequence.

Concluding Remarks

The phenomenon of genome packaging remains one of the most intensively studied processes of virion assembly, bringing together diverse but complementary fields of biochemistry, molecular genetics, structural biology, and biophysics. Since many of the phage studied have evolved mechanism analogous to eukaryotic viruses, efforts to resolve the mechanisms involved in genome packaging in phage promise to be reflected in their eukaryotic counterparts. Since genome translocation has no direct link to most cellular processes, inhibition of genome packaging has been long held to serve as a future target for antiviral therapy once the mechanisms of chromosome and capsid maturation and chromosome translocation are resolved. Regardless of this practical consideration, the efficiency, complexity, and power of this process will remain a target of investigation for its own sake.

History

In 1986, a 6.3 kbp linear double-stranded (ds) RNA molecule was observed in nucleic acid extracts of *Giardia lamblia* Portland I trophozoites. *Giardia lamblia* is an anaerobic parasitic flagellate that inhabits the upper gastrointestinal tracts of humans as well as many other mammals. When infecting humans, the parasitic protozoan causes giardiasis, an acute diarrhea that often progresses to chronic, carrier-stage for adults and severe malnutrition for children. Further examination of this 6.3 kbp dsRNA isolated from the extract of *G. lamblia* revealed it to be the genome of a small isometric virus, hence named giardiavirus (GLV), that specifically infects this protozoan.

It is interesting to note that although GLV was first detected in an isolate of *G. lamblia* Portland I (P1) obtained

from Dr. D. G. Lindmark of Cleveland State University, the same P1 isolate from the American Type Culture Center is virus free. It therefore remains a mystery as to how the Cleveland P1 became exposed to the virus. All the information included here has been derived from studies of the virus originally isolated from this Cleveland P1 strain.

Taxonomy and Classification

GLV belongs to the family *Totiviridae*, genus *Giardiavirus*, of RNA viruses. This family is characterized by the non-segmented dsRNA genome and simple virion structure. Members of *Totiviridae* include the yeast dsRNA virus (ScV-L). Many of the viruses recently discovered from protozoa, such as the trichomonas vaginalis virus (TVV), leishmania RNA virus (LRV), and eimeria stiedae virus (ESV), also belong to this family.

Host Range and Geographic Distribution

Purified GLV readily infects many virus-free isolates of *G. lamblia* trophozoites, but not any other parasitic protozoa tested, including *Tritrichomonas foetus, Trichomonas vaginalis, Trypanosoma brucei brucei, Entamoeba histolytica*, and *Eimeria stiedae*. The virus has also been shown not to infect two transformed human intestinal cell lines. It is therefore believed that giardiavirus has a rather narrow host range. It probably infects only *G. lamblia* in nature. On the other hand, the cellular host for this virus, *G. lamblia*, parasitizes many mammals other than humans. Viruses that are identical in shape and size of genomic dsRNA and share dsRNA sequence homology with one another have been detected from many *G. lamblia* strains and isolates obtained from humans, guinea pigs, cats, beavers, llamas, and sheep. The human isolates were collected from Belgium, Poland, England, Israel, Ecuador, Puerto Rico, and various states in the USA. Since *G. lamblia* is found in almost all parts of the world, affecting developing as well as developed countries, it is expected that GLV follows its host and is distributed worldwide.

Physical and Biochemical Characteristics

Under the electron microscope, GLV appears as an icosahedron of 36 nm diameter, consisting of an electron-dense core encapsidated in a shell 5–6 nm thick (**Figure 1**). In addition to the 6.3 kbp linear dsRNA genome, the virion contains a major polypeptide of 100 kDa (p100) which is most likely the viral capsid. Purified virions are good antigens in mice. Polyclonal antibodies raised against whole virions react with p100 in Western blots and

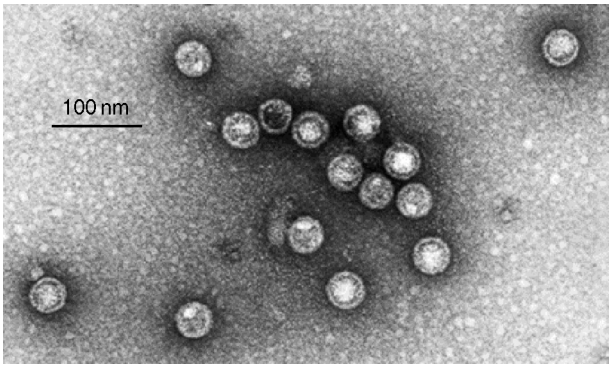

Figure 1 Giardiavirus.

can effectively block viral infection in the *in vitro* culture of *G. lamblia* trophozoites. The same antiserum also reacts positively with a minor component of the virion, a polypeptide of 190 kDa, which is believed to be the viral RNA-dependent RNA polymerase (RDRP). Indeed, GLV-encoded RDRP activity has been detected in the infected cell extract as well as the purified GLV fractions.

Antisera raised against synthetic dsRNA cross-react only with the viral dsRNA and are not protective against viral infection of *G. lamblia* trophozoites *in vitro*. Giardiavirus does not contain any lipids nor is the p100 polypeptide glycosylated.

The entire nucleotide sequence of the linear GLV dsRNA genome has been determined. It consists of 6277 bp and is flush at either end. As the dsRNA can be readily radiolabeled by [^{32}P]pCp and RNA ligase, this molecule must have a free 3′-OH group at one or both of its 3′ termini. The exact structure at the 5′ termini of the dsRNA has not yet been elucidated. It is known that the dsRNA molecule cannot be phosphorylated by T4 polynucleotide kinase, and that the denatured dsRNA molecule can be circularized with T4 RNA ligase. Therefore, the 5′ termini of the GLV genomic dsRNA are probably phosphorylated. Additionally, no covalently linked protein is found at these termini such as in the case of poliovirus.

Organization and Molecular Biology of the GLV dsRNA Genome

The 6277 nt GLV dsRNA genome contains only two large open reading frames (ORFs), both on the same strand of RNA (**Figure 2**). The first ORF (nts 368–3015) encodes the precursor polypeptide for the GLV capsid protein. Thirty-two amino acid residues from the N-terminus of this precursor protein are apparently removed by a cellular cysteine protease before the processed capsid protein is assembled into the virion.

The second ORF (nts 2806–5976) is –1 relative to ORF 1, and the two ORFs overlap by 220 nts. Amino acid

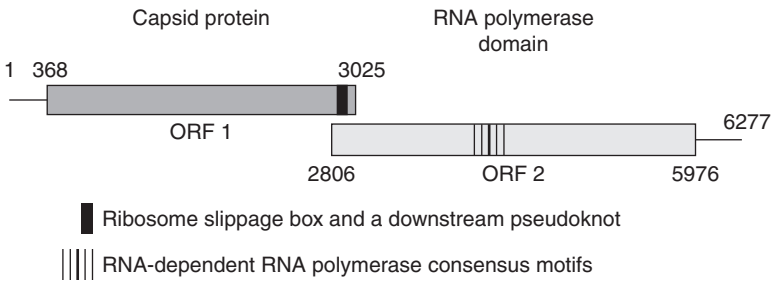

Figure 2 Organization of the giardiavirus dsRNA genome.

sequence motifs conserved for all RDRPs have all been found in ORF 2. It is now known that the 190 kDa GLV RNA polymerase is synthesized as a fusion protein of ORFs 1 and 2 at a level that is 2–5% of p100. Apparently, ribosomes carrying the growing nascent polypeptide chain are stalled when they encounter the pseudoknot structure residing within the 220 nt overlap of these two ORFs. At a 2–5% frequency, the ribosomes slip back one reading frame and proceed to translate ORF 2 as the C-terminus of a fusion protein. The ability of this GLV overlap fragment to induce −1 ribosomal frameshifting has been demonstrated in a reporter system in yeast.

Flanking the two ORFs, there are 367 and 301 nt untranslated regions respectively on the 5′ and 3′ sides. These two regions contain sequence elements that are critical for initiation of transcription and replication of GLV RNA. For example, deletion of a single nucleotide from the 5′ terminus of the (+)-strand GLV RNA totally abolishes transcription of GLV mRNA. Similarly, deletion or alteration of sequences in these two regions drastically reduces the level of progeny viral RNA.

In recent years, GLV has been successfully used as a vector for the introduction of foreign genes into *G. lamblia*. When a portion of the GLV genome is replaced with the firefly luciferase gene in a cDNA construct downstream from a T7 promoter, chimeric RNA can be synthesized *in vitro* using T7 polymerase. *Giardia* cells that are infected with wild-type GLV and electroporated with the chimeric RNA show luciferase activity of a millionfold above background. The chimeric RNA is replicated as dsRNA and packaged into recombinant virions that are shed into the culture supernatant. These recombinant viruses, together with wild-type GLV, can in turn infect naive *Giardia* trophozoites to produce luciferase activity. The list of foreign genes tested in this system include genes encoding neomycin phosphotransferase, hygromycin phosphotransferase, and green fluorescence protein. All can be delivered and expressed at high levels. Inclusion of a fragment, nts 368–631 in the coding region of p100, as the N-terminus of a fusion protein with the foreign gene product has been shown to enhance translation level by 5000-fold. This region therefore may contain elements that can promote interaction between GLV mRNA and ribosomes of *G. lamblia*.

Giardiavirus mRNA is uncapped and not adenylated. Translation is initiated at an internal ribosomal entry site (IRES) in the mRNA consisting of a 253 nt segment in the 5′ untranslated region (5′ UTR) and a 264 nt stretch in the ORF immediately downstream from the 5′ UTR. The initiation codon is localized at the center of an unstructured 31 nt segment flanked by complex secondary structures in the 5′ UTR and the ORF of the IRES. The precise position of the initiation codon is critical for translation initiation. It suggests a direct recruitment of the 40 S small ribosomal subunit to the initiation codon without ribosomal scanning, which is known to be absent from the translation machinery in *Giardia*.

Infection and Replication

GLV infects susceptible isolates of *G. lamblia* very efficiently. It has been estimated that demonstrable infection can be achieved at a multiplicity of infection as low as 10 GLV particles per cell. The exact mode of viral entry into the cell has not been elucidated. However, a number of virus-free *G. lamblia* strains have been found resistant to GLV infection. When trophozoites of these strains are electroporated with the single-stranded (ss) GLV RNA (see below), they become infected by GLV and can support and complete the cycle of replication, producing progeny virions that are fully infective to sensitive strains. It is therefore probable that certain cellular component(s) such as viral receptors are involved in the initial interaction between GLV and susceptible strains.

Using purified GLV to infect virus-free *G. lamblia* WB strain, it was shown by *in situ* hybridization that dsRNA replication was first detected in the cytoplasm. Toward the late stage of infection, viral dsRNA was found to spread into the twin nuclei of the infected flagellate. Transmission electron microscopic examination of thin sections of infected cells at stationary phase also reveals paracrystals of virus-like particles in the nuclei (**Figure 3**). It has been estimated that an infected cell may harbor as many as 10^5 GLV particles without lysis. Meanwhile, mature and infectious GLV particles begin to appear in the supernatant of *Giardia* culture medium 42 h after infection. It is not known whether a specific cellular

process is involved in the release of giardiavirus into the culture supernatant, although cell lysis has not been observed as a consequence of viral infection.

The growth rate of newly infected cells decreases with increasing multiplicity of infection. As the ratio of the infecting virus to cell increases, the percentage of the nonadhering (nondividing) trophozoites also increases. However, in established infected cell lines or at moderate multiplicity of infection (<1000), the infected cell assumes normal appearance and maintains the same growth rate as its uninfected counterpart. Furthermore, GLV infection persists indefinitely throughout repeated subculturings.

In addition to the 6.3 kbp genomic dsRNA, an ssRNA (SS) of identical length that is homologous to only one of the two strands of GLV dsRNA is also found in the GLV-infected cellular extract. Studies of the infection time course showed that, in contrast to GLV dsRNA which increases steadily from 23 to 141 h after infection, SS becomes detectable at about the same time, peaks at 42–50 h after infection, then gradually declines. Electroporation of gel-purified SS into the uninfected WB cells resulted in the recovery of dsRNA from the cell extract and infectious GLV particles in culture supernatant, demonstrating that SS is the viral messenger RNA as well as the full-length replicative form of the viral genome. Recent nucleotide sequence analysis of GLV cDNA clones also verifies that it is the SS strand that encodes the large ORFs. There is no subgenomic viral RNA detected inside the infected cell.

The RNA products synthesized *in vitro* by the virion-associated RDRP are homologous to SS and complementary to the negative strand. Transcription of viral message therefore must proceed conservatively by utilizing the dsRNA as its template.

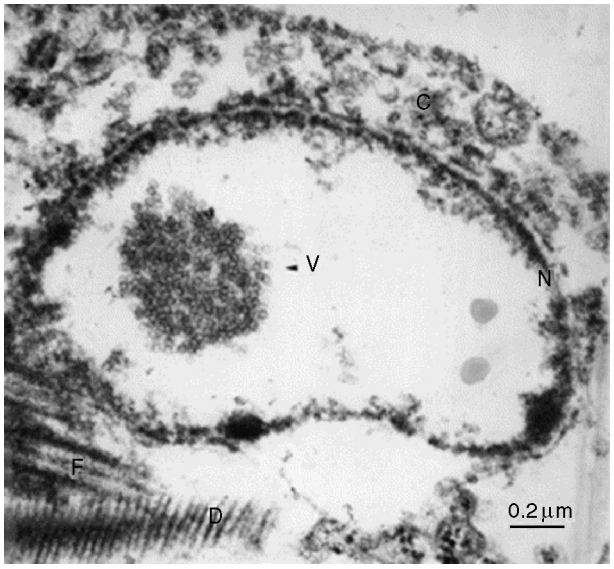

Figure 3 Thin section of a giardiavirus-infected cell. C, cytoplasm; N, nuclear envelope; F, flagella; D, ventral disk; V, aggregates of virus particles.

Evolution

The extent to which a person is affected by giardiasis varies widely. The outcome of the severity of parasitic infection depends on many variables derived not only from the parasite but also from the human host. Attempts at correlating the presence or absence of GLV with the severity of giardiasis have been inconclusive, and we still do not know the role GLV might play in the delicate balance of the host–parasite interaction, if any.

Some of the characteristics of GLV are listed with those of other dsRNA viruses of *Totiviridae* in **Table 1**. When compared with ScV-L, the best-known virus of this group, GLV and ScV are similar in many ways: (1) single molecules of genomic dsRNAs of similar sizes; (2) single major capsid polypeptides of similar sizes; (3) virion-associated RDRP with similar amino acid sequence motifs deduced from the genomic sequence, (4) ability to synthesize viral messages from intact virions *in vitro*; and (5) use of ribosomal frameshifting for the synthesis of viral polymerase. However, the two viruses do not cross-infect and the two dsRNAs do not cross-hybridize in Northern blots. GLV dsRNA has also been shown not to cross-hybridize with dsRNAs of TVV or LRV. Comparison of the nucleotide sequence from GLV

Table 1 Physical properties of some small dsRNA viruses

Virus	*Shape*	*Diameter (nm)*	*Density (gm/ml^{-1})*	*dsRNA (μm)*	*dsRNA (kbp)*	*Capsid protein (kDa)*
GLV	Isometric	33	1.368	1.50	6.277	100

Glossary

Coevolution Evolution of a virus together with its rodent/insectivore host.
Hantavirus A virus in the genus *Hantavirus*.
Reassortant A virus having genome segments of two different viruses.
Robovirus A virus transmitted from rodents to other vertebrates without arthropods.
Sympatric Occupying the same or overlapping geographic areas without interbreeding.

Historical Introduction

Hantavirus infections are not new to humankind. The first description of a hemorrhagic fever with renal syndrome (HFRS)-like disease can be found in a Chinese medical account written in about AD 960 and the earliest definite description of HFRS comes from Far East Russian clinical records dating back to 1913. During World Wars I and II, HFRS became an important military problem; for example, 'field nephritis' in Flanders during World War I may well have been caused by a hantavirus. In Manchuria in the mid-1930s, 12 000 Japanese soldiers caught the disease and military researchers were investigating the cause of the disease, sometimes using prisoners of war in infection experiments. Finnish and German soldiers encountered an HFRS-like epidemic in Finnish Lapland in 1943–44. During the Korean conflict in 1950–53, the disease again gained much attention when about 3000 United Nations troops contracted it – since then known as Korean hemorrhagic fever – with a 5–10% case–fatality rate. The milder form of HFRS, nephropathia epidemica (NE), common in Fennoscandia (Scandinavia and Finland), was first described by Swedish authors in 1934. However, the infecting agent of HFRS remained unknown until 1976, when the Korean researcher Ho Wang Lee discovered that cryostat-sectioned lungs of striped field mice (*Apodemus agrarius*), trapped near the Hantaan river, contained virus-specific antigen reactive with HFRS-patient sera. By a similar approach, the causative agent of NE was demonstrated in 1980 in bank voles, *Clethryonomys glareolus*, trapped in Puumala, Finland. Another agent, this one from urban rats in Seoul, Korea, was also found to cause HFRS. In the early 1990s, a further distinct European human-pathogenic hantavirus was isolated from the yellow-necked mouse, *Apodemus flavicollis*, near the village of Dobrava in Slovenia, and a few years later, the related, less pathogenic, Saaremaa virus from striped field mice on Saaremaa Island, Estonia. Thottapalayam virus from an insectivore (*Suncus murinus*, a shrew) in India, Prospect Hill virus from a meadow vole (Microtus *pennsylvanicus*) in USA, and Thailand virus from a bandicoot rat (*Bandicota indica*) already had been isolated in the early 1970s to the 1980s – they all apparently are nonpathogenic for humans.

Human disease had not been known to be caused by a hantavirus in the Americas until a cluster of acute respiratory distress syndrome cases with a high (60%) case–fatality rate in the Four Corners area of the American Southwest (where Arizona, Utah, Colorado, and New Mexico are contiguous) was recognized in May 1993. Subsequent studies led to the discovery of Sin Nombre virus and other hantaviruses that cause hantavirus pulmonary syndrome (HPS), all transmitted from sigmodontine rodents indigenous to the New World. An increasing number of pathogenic hantaviruses have been reported in South America, including Andes virus, which can be transmitted person to person, and which have high case–fatality rates. While only about 2000 HPS cases have been reported so far, approximately 150 000 HFRS cases are estimated to occur worldwide annually.

Virology

Hantaviruses are enveloped viruses with a tripartite negative-stranded RNA genome and belong to the genus

Hantavirus of the large virus family *Bunyaviridae*. The 6.4 kb L (large) genome segment encodes the ~250 kDa RNA polymerase, the ~3.6 kb M (medium) segment, the two glycoproteins 68–76 kDa Gn and 52–58 kDa Gc (formerly known as G1 and G2), and the ~1.7 kb S (small) segment the 50–54 kDa nucleocapsid protein (N). In addition, the S segment of hantaviruses carried by arvicolid and sigmodontine rodents has another overlapping (+1) open reading frame (ORF) named NSs, which has been shown to inhibit the interferon response. Viral messenger RNAs of the members of the *Bunyaviridae* are not polyadenylated and are truncated relative to the genomic RNAs at the 3′ termini. Messenger RNAs have 5′-methylated caps and 10–18 nontemplated nucleotides derived from host cell mRNAs. The termini of all three segments are highly conserved and complementary to each other, a feature that has assisted in cloning and discovery of new hantaviruses.

Unlike most other bunyaviruses, hantaviruses are not arthropod borne (arboviruses), but are rodent borne (roboviruses). Each hantavirus is primarily carried by a distinct rodent/insectivore species, although several host switches seem to have occurred during the tens of millions of years of their co-evolution with their carrier hosts. We now know that the genetic diversity of hantaviruses is generated by (1) genetic drift (accumulation of point mutations and insertions/deletions) leading to mixtures of closely related genetic variants, quasispecies; (2) genetic shift (reassortment of genome fragments within a given virus genotype/species); and (3) according to recent findings, also by homologous recombination, a mechanism not previously observed for negative-strand RNA viruses.

Ecology and Epidemiology

Hantavirus infections are prime examples of emerging and reemerging infections. As are most of these infections, hantaviral diseases are zoonoses. With the exception of the South American Andes virus, hantavirus infections are thought to be transmitted to humans primarily from aerosols of rodent excreta (feces, urine, saliva). Only some hantaviruses cause disease in humans. In Asia, Hantaan and Amur viruses, carried by *Apodemus* spp. mice, cause severe HFRS, and Seoul virus, carried by rats, a milder disease. In Europe, there are three major hantaviral pathogens: Puumala virus carried by bank voles causes NE; Dobrava virus, carried by yellow-necked mice, causes severe HFRS; and the genetically and antigenically closely related Saaremaa virus carried by striped field mice causes mild NE-like disease. There also are reports that Seoul virus, carried by rats (*Rattus norvegicus* and *Rattus rattus*), causes HFRS of moderate severity both in Europe and North America. In addition, European common voles (*Microtus arvalis* and *Microtus rossiaemeridionalis*) carry Tula hantavirus, which can asymptomatically infect humans. Topografov hantavirus isolated from Siberian lemmings (*Lemmus sibiricus*) has not been detected in North European lemmings (*Lemmus lemmus*), although it can replicate in them. Infections of hantaviruses in rodents are asymptomatic and, often, persistent.

Hantavirus infections are quite common in Europe. Puumala virus occurs in Northern Europe, European Russia, and parts of central-western Europe. Dobrava virus is found mainly in the Balkans and the neighboring Central European areas. Saaremaa virus has been detected in Eastern and Central Europe, and in Slovenia the two viruses Dobrava and Saaremaa occur sympatrically. Apart from infections of laboratory rats, Seoul virus has been detected in wild rats in France and in several city harbors. It is apparent that many parts of Europe, such as Britain, Poland, and Byelorussia, and most of Africa, remain completely or relatively unstudied with regard to hantaviruses. This suggests either that HFRS is rare or nonexistent in these regions or is not generally recognized and is not diagnosed by local biomedical communities.

In Northern Europe, HFRS as well as the carrier rodents exhibit peaks in 3–4 year cycles, while in Central Europe the HFRS incidence follows the fluctuations of 'mast years', that is, the abundance of beech and oak seeds for the hantavirus-carrying rodents. In Central Europe, HFRS peaks in the summer whereas in Northern Europe most cases occur in late autumn and early winter, from November to January. Risk factors for acquiring hantavirus infections and HFRS include professions such as forestry, farming, and military, or activities such as camping, and the use of summer cottages. Cigarette smokers and males are more likely to be infected than are females. In the Americas, the increased precipitation during El Niño/Southern Oscillation in South and North America has been suggested as the main reason for the peaks in rodent population densities and for the consequent increased number of HPS cases.

Sigmodontine-borne hantaviruses circulating in North America (**Table 1**) form three phylogenetically distinct groups: those associated with *Peromyscus* spp. and *Reithrodontomys* spp. rodents, and the third carried by *Sigmodon* spp. and *Oryzomys* spp. rats. The first group carries both human pathogens (Sin Nombre virus, New York virus) and viruses not thus far associated with human disease (e.g., Blue River virus, Limestone Canyon virus). *Reithrodontomys*-borne viruses have not been shown to cause human disease. Hantaviruses discovered in South America are associated with several tribes of Sigmodontinae, mostly Oryzomyini-associated viruses, several of which are important human pathogens, including Andes, Lechiguanas, and Laguna Negra viruses. Results of phylogenetic analyses of South American hantaviruses suggest that several host-switching events have occurred during coevolution with their

Table 1 Hantavirus types

Virus	*Host*	*Distribution (origin)*	*Disease*
Murid-borne viruses	Mice and rats		
Hantaan (HTNV)[a]	Striped field mouse (*Apodemus agrarius*)	Asia (Korea)	HFRS
Da Bie Shan	Chinese white-bellied rat (*Niviventer confucianus)*	Asia (China)	NR
Seoul (SEOV)	Rat (*Rattus rattus, R. norvegicus*)	Worldwide (Korea)	HFRS
Dobrava (DOBV)	Yellow-necked mouse (*A. flavicollis*)	Europe (Slovenia)	HFRS
Saaremaa (SAAV)	Striped field mouse; western (*A. agrarius)*	Europe (Estonia)	HFRS
Thailand (THAIV)	Bandicoot rat (*Bandicota indica*)	Thailand (Thailand)	NR
Amur (AMRV)	Korean field mouse (*A. peninsulae*)	Asia (Far East Russia, China)	HFRS
Arvicolid-borne viruses	Voles and lemmings		
Puumala (PUUV)	Bank vole (*Clethrionomys glareolus*)	Europe (Finland)	HFRS
Hokkaido (HOKV)	Red bank vole (*C. rufocanus*)	Asia (Japan)	NR
Tula (TULV)	European common vole (*Microtus arvalis*)	Europe (Russia)	NR
Prospect Hill (PHV)	Meadow vole (*M. pennsylvanicus*)	North America (USA)	NR
Bloodland Lake (BLLV)	Prairie vole (*M. ochrogaster*)	North America (USA)	NR
Isla Vista (ISLAV)	Californian vole (*M. californicus*)	North America (USA)	NR
Khabarovsk (KHAV)	Reed vole (*M. fortis*)	Asia (Far East Russia)	NR
Topografov (TOPV)	Lemming (*Lemmus sibiricus*)	Siberia (Russia)	NR
Vladivostok (VLAV)	Reed vole (*M. fortis*)	Asia (Far East Russia)	NR
Sigmodontine borne	New World sigmodontine rodents		
Sin Nombre (SNV)	Deer mouse (*Peromyscus maniculatus*)	North America (USA)	HPS
Monongahela (MGLV)	Deer mouse (*P. maniculatus nubiterrae*)	North America (USA)	HPS
New York (NYV)	White-footed mouse (*P. leucopus*)	North America (USA)	HPS
Blue River (BRV)	White-footed mouse (*P. leucopus*)	North America (USA)	NR
Limestone Canyon (LCV)	Brush mouse (*P. boylii)*	North America (USA)	NR
Bayou (BAYV)	Rice rat (*Oryzomys palustris*)	North America (USA)	HPS
Black Creek Canal (BCCV)	Hispid cotton rat (*Sigmodon hispidus*)	North America (USA)	HPS
Muleshoe (MULV)	Hispid cotton rat (*S. hispidus*)	North America (USA)	NR
Andes (ANDV)	Long-tailed pygmy rice rat (*Oligoryzomys longicaudatus*)	South America (Argentina)	HPS
Lechiguanas (LECV)	Rice rat (*O. flavescence*)	South America (Argentina)	HPS
Oran (ORNV)	*O. longicaudatus*	South America (Argentina)	NR
Bermejo (BERV)	*O. chacoensis*	South America (Argentina)	NR
HU39694	Unknown	South America (Argentina)	HPS
Choclo (CHOV)	Pygmy rice rat (*O. fulvescens*)	Central America (Panama)	HPS
Calabazo	*Zygodontomys brevicauda*	Central America (Panama)	NR
Laguna Negra (LANV)	Vesper mouse (*Calomys laucha*)	South America (Paraguay)	HPS
Rio Mamore (RIOMV)	Small-eared pygmy rice rat (*O. microtis*)	South America (Bolivia)	NR
Caño Delgadito (CADV)	Cane mouse (*S. alstoni*)	South America (Venezuela)	NR
El Moro Canyon (ELMCV)	Western harvest mouse (*Reithrodontomys megalotis*)	North America (USA)	NR
Rio Segundo (RIOSV)	Mexican harvest mouse (*R. mexicanus*)	Central America (Costa Rica)	NR
Maciel (MACV)	Dark field mouse (*Necromys benefactus*)	South America (Argentina)	NR
Pergamino (PERV)	Grass field mouse (*Akodon azarae*)	South America (Argentina)	NR
Juquitiba	Unknown	South America (Brazil)	HPS
Araraquara	Unknown	South America (Brazil)	HPS
Castelo dos Sonhos	Unknown	South America (Brazil)	HPS
Insectivore-borne	Insectivores		
Thottapalayam (TPMV)	Asian house shrew (*Suncus murinus*)	Asia (India)	NR

Distinct hantavirus species listed in the 8th ICTV Report are shown in bold.
HFRS, hemorrhagic fever with renal syndrome; HPS, hantavirus pulmonary syndrome; NR, disease not recorded.
[a]Type species.

rodent hosts. The phylogenetic split between murine and sigmodontine rodents presumably dates to a divergence that occurred between subfamilies 30 million years ago, when the precursors of the sigmodontine rodents crossed the Bering Strait into the Americas. Notably, sigmodontine rodents are found only in the Americas and thus it is unlikely that HPS would occur in Eurasia, unless imported.

Clinical Picture and Pathogenesis

Amur, Dobrava, Hantaan, Seoul, Puumala, and Saaremaa viruses all cause HFRS but the infections differ considerably in severity. All are characterized by acute-onset, fever, headache, abdominal pains, backache, temporary renal insufficiency (first oliguria, proteinuria,

and increase in serum creatinine, and then polyuria), and thrombocytopenia, but the extent of hemorrhages (hematuria, petechiae, internal hemorrhages), requirement for dialysis treatment, hypotension, and case–fatality rates are much higher in HFRS caused by Amur, Dobrava, or Hantaan viruses than in NE caused by Puumala or Saaremaa viruses. About a third of NE patients experience temporary visual disturbances (myopia), which is a very characteristic if not pathognomonic sign of the disease. Notably, the clinical consequences of all of the hantaviral pathogens in humans vary from none to fatal. Severe NE is associated with a certain haplotype, HLA-B8, DR3, DQ2 alleles, severe HPS with HLA-B35, and mild NE with HLA-B27. Yet, although Puumala virus infection is generally associated with mild HFRS, NE may have significant long-term consequences. A 5-year followup study demonstrated that 20% of NE patients had a somewhat increased systolic blood pressure and proteinuria. This is important, since the infection is so common in many areas of Europe. In addition, in some patients, Puumala virus infection may infect the pituitary gland and lead to mortality or at least to hypophyseal insufficiency requiring hormone-replacement therapy.

The pathogeneses of HFRS and HPS are poorly understood. However, it is known that β3 integrins can mediate the entry of pathogenic hantaviruses and that hantaviruses can regulate apoptosis. Also, there is evidence that increased capillary permeability is an essential component in the pathogenesis of both HFRS and HPS, although different target tissues, kidneys and lungs, respectively, are affected in the two diseases. HFRS and HPS patients show activation of tumor necrosis factor α (TNF-α) in the plasma and tissues and high levels of urinary secretion of the pro-inflammatory cytokine interleukin 6 (IL-6) are seen in NE. Studies with a monkey model mimicking human Puumala virus infection and HPS-like disease in Andes virus-infected Syrian hamsters may assist in elucidating the mechanism of pathogenesis.

HPS is characterized by pulmonary edema but death often results from cardiac failure; thus the term hantavirus cardiopulmonary syndrome (HCPS) has been proposed for the disease. HFRS and HPS, although primarily targeted at kidneys and lungs, respectively, share a number of clinical features, such as capillary leakage, TNF-α, and thrombocytopenia; notably, hemorrhages and alterations in renal function occur also in HPS and pulmonary involvement is not rare in HFRS.

Of the four structural proteins, both in humoral and cellular immunity, the nucleocapsid protein appears to be the principal immunogen. Cytotoxic T-lymphocyte responses are seen in both HFRS and HPS and may be important for both protective immunity and pathogenesis in hantavirus infections.

Diagnostics and Prevention

The diagnosis of acute hantavirus infection is primarily based on serology. Both immunofluorescence tests and enzyme immunoassays are widely used for detection of specific IgM or low-avidity IgG antibodies, characteristics of acute infection. In addition, immunochromatographic 5 min IgM-antibody tests have been developed. Hantaviruses show extensive serological cross-reactivity, especially within each of the three virus subgroups (murid, arvicolid, and sigmodontine borne; **Table 1**), but for accurate typing, neutralization tests are needed. For example, in Paraguay, a considerable seroprevalence of hantavirus antibodies, as high as 40%, is noted in people without a history of HPS. Average seroprevalences in Finland and Sweden suggest that only 10–25% of Puumala virus infections are diagnosed; thus, most infections either are subclinical or are mild or atypical and remain undiagnosed.

Viral RNA usually can be detected in the blood of HPS patients using polymerase chain reaction with samples collected during the first week of illness, which is useful because it also identifies the infecting virus genotype. The same is true for severe forms of HFRS but in the case of Puumala virus infections, viral RNA cannot be regularly detected in the blood or urine of NE patients.

Vaccines against hantaviral infections have been used for years in China and Korea, but not in Europe or the Americas. No specific therapy is used in Europe, but both ribavirin and interferon-α have been administered in trials in China. A major problem is that at the time the patients are hospitalized, the rate of virus replication is declining, so that reduction of virus replication no longer is necessary for the patient. Thus, prevention of hantaviral infections continues to rely on reduced contact with excreta from infected rodents.

Henipaviruses

B T Eaton and L-F Wang, Australian Animal Health Laboratory, Geelong, VIC, Australia

© 2008 Elsevier Ltd. All rights reserved.

History

The first henipavirus was isolated in 1994 following an outbreak of acute respiratory disease in a stable in Brisbane, Australia. In less than 3 weeks, 21 of 30 horses became infected and 14 either died or were euthanized. Two people who worked at the stable also became infected and one died. The virus responsible was a previously undescribed paramyxovirus, subsequently called Hendra virus (HeV) after the suburb where the outbreak occurred. In the subsequent decade, HeV was identified as the cause of equine deaths at four separate locations in Queensland, spilling over on two occasions to cause single human infections, one of which was fatal. In the latter instance, the patient succumbed to encephalitis over a year after infection during the necropsy of HeV-infected horses. Initial serological evidence suggested that fruit bats (flying foxes) in the genus *Pteropus* were reservoir hosts and in 1996, HeV was isolated from several Australian flying fox species.

The second member of the genus, Nipah virus (NiV), emerged in 1998–99 in Perak State, Peninsular Malaysia, as the cause of an outbreak of respiratory and encephalitic disease of low morbidity and mortality in pigs. The virus spread to humans causing febrile encephalitis among pig farmers and those who had direct contact with pigs. The epidemic moved south to the intensive pig-farming areas of Negeri Sembilan in December 1998 and was only brought under control by the imposition of movement restrictions and the culling of over 1 million pigs. Two hundred and sixty-five human cases of encephalitis were documented with 105 deaths. A cluster of 11 cases with one death occurred among abattoir workers in Singapore. NiV was subsequently isolated from the urine of Malaysian flying foxes in 2002. NiV re-emerged in Bangladesh and an adjoining area of India (West Bengal) in 2001, and since then outbreaks of encephalitis caused by the virus have re-occurred in Bangladesh almost every year, with case–fatality rates approaching 75%.

Taxonomy and Classification

The full-length genome sequence of HeV revealed it to be a member of the family *Paramyxoviridae*, subfamily *Paramyxovirinae*, but one with unique genetic features that precluded its classification in the genera *Morbillivirus, Respirovirus*, or *Rubulavirus*, the three genera established in the subfamily at that time. Complete genome sequencing of NiV revealed a high degree of similarity to HeV and, in 2002, the genus *Henipavirus* was created to accommodate these novel paramyxoviruses. The genus *Henipavirus* is now one of five genera in the subfamily *Paramyxovirinae* (**Figure 1**).

Several molecular features distinguish henipaviruses from other paramyxoviruses. First, the genome length of NiV and HeV at 18 246 and 18 234 nt, respectively, is approximately 15% larger than most other paramyxoviruses. It is not the extra length *per se* that is unique to henipaviruses. The unclassified paramyxoviruses J virus and Beilong virus have genomes over 19 000 nt in length. The novel henipavirus genomic feature is the length of the noncoding regions at the 3′ end of five of the six genes, which in most cases are 3–13 times longer than their *Paramyxovirinae* counterparts. The function of these regions is unknown. A second unique feature of henipaviruses

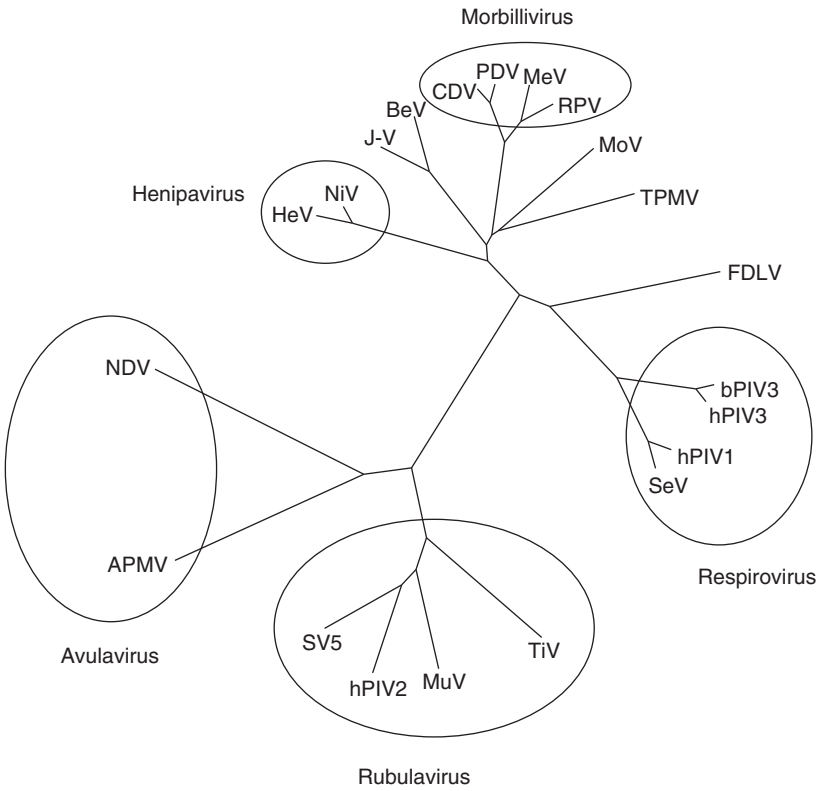

Figure 1 Classification of henipaviruses. The number of genera in the subfamily *Paramyxovirinae* was raised in 2002 from three (*Respirovirus*, *Morbillivirus*, and *Rubulavirus*) to five by the addition of two new genera, *Avulavirus* and *Henipavirus*. The phylogenetic tree shown here is based on an alignment of the deduced amino acid sequence of the L gene of selected family members using the neigbor-joining method. Viruses are grouped according to genus and abbreviated as follows. *Avulavirus* genus: APMV (avian paramyxovirus), NDV (Newcastle disease virus); *Respirovirus* genus: SeV (Sendai virus), hPIV1 (human parainfluenzavirus 1), hPIV3 (human parainfluenzavirus 3), bPIV3 (bovine parainfluenzavirus 3); *Morbillivirus* genus: MeV (measles virus), CDV (canine distemper virus), RPV (rinderpest virus), PDV (phocine distemper virus); *Henipavirus* genus: HeV (Hendra virus), NiV (Nipah virus); *Rubulavirus* genus: hPIV2 (human parainfluenzavirus 2), MuV (mumps virus), SV5 (simian parainfluenzavirus 5), TiV (Tioman virus); and unclassified viruses: MoV (Mossman virus), BeV (Beilong virus), FDLV (Fer-de-lance virus), TPMV (Tupaia paramyxovirus), and J-V (J virus).

commensurate with their status in a separate genus within the family *Paramyxoviridae* is the presence of 3′ and 5′ genomic terminal sequences 12 nt in length, that differ from all other paramyxoviruses and contain the genus-specific promoter elements for replication and transcription.

Molecular Biology

Although the genomes of henipaviruses, respiroviruses, and morbilliviruses are organized in an identical manner and, with the exception of the P protein, virus-encoded proteins in each genus are similar in size, analyses have revealed striking differences between some henipavirus proteins and their respirovirus and morbillivirus counterparts.

The attachment glycoproteins of paramyxoviruses are designated as hemagglutin-neuraminidase (HN), hemagglutinin (H), or glycoprotein (G) on the basis of their capacity to agglutinate red blood cells and remove sialic acid from carbohydrate moieties. The HN-positive status of respiroviruses, avulaviruses, and the vast majority of rubulaviruses reflects their use of sialic acids as cell surface receptors. In contrast, morbilliviruses and henipaviruses bind to cells using sialic acid-independent mechanisms. SLAM (signaling lymphocyte-activation molecule) is regarded as a universal morbillivirus receptor and ephrin B2 has been identified as a functional receptor for both HeV and NiV. Ephrin B2 is a member of a family of cell surface glycoprotein ligands that bind to surface-expressed tyrosine kinases known as Eph receptors. Binding of ephrins to Eph receptors leads to bidirectional signaling and cell-to-cell communication. The widespread distribution of ephrin B2 among mammals may help explain the extensive host range of henipaviruses (see below). Like the fusion protein of all other paramyxoviruses, the henipavirus F protein is activated by proteolytic cleavage of a precursor F_0 protein. Henipaviruses invariably generate systemic infections and most paramyxoviruses which do so synthesize F proteins

which are cleaved at a multibasic cleavage site by furin, a cellular protease located in the *trans*-Golgi network. Surprisingly, the cleavage site of both HeV and NiV is a single basic amino acid, arginine and lysine, respectively. What is more, that basic residue and the amino acids in the vicinity of it are not required for proteolytic cleavage. A second unique feature of henipavirus F proteins is the presence of an endocytosis consensus motif YXXϕ (where Y is tyrosine, X is any amino acid, and ϕ is an amino acid with a bulky hydrophobic group) in the cytoplasmic tail of the protein. Endocytosis is required for F protein cleavage activation, an observation consistent with the fact that cathepsin L, a lysosomal cysteine protease that lacks a distinctive cleavage recognition site, is responsible for cleavage of the HeV F protein.

In paramyxoviruses, mechanisms to inhibit the antiviral effects of interferon are encoded by the P gene, which generates multiple proteins (P, V, W, and C in henipaviruses) by means of internal translation initiation sites, overlapping reading frames, and a transcription process in which nontemplated G nucleotides are inserted at a conserved editing site, resulting in a reading frameshift during translation. Insertions of one and two G residues generate transcripts which encode the V and W proteins, respectively. Whereas the henipavirus V protein resembles that of other paramyxoviruses in having a conserved cysteine-rich C-terminal domain, the henipavirus W protein is unusual because the C-terminal domain is significantly longer than that of most *Paramyxovirinae*, where translation of the encoding P gene transcript terminates soon after the editing site.

Host Range and Viral Propagation

HeV and NiV replicate in a variety of mammalian cell lines. The rate of replication, the size of syncytia generated, and the location of nuclei in syncytia vary depending on cell type and virus species. Infected Vero cell monolayers yield titers in excess of 10^8 infectious virions per milliliter. The broad host range of henipaviruses has been corroborated by experiments in which cells infected with vaccinia virus recombinants and expressing henipavirus cell attachment (G) and fusion (F) proteins on the surface fuse with cells from a gamut of vertebrate sources. Susceptibility to virus infection and virus glycoprotein-mediated fusion *in vitro* are reflected in the wide range of mammalian hosts sensitive to virus infection *in vivo*. The host range of henipaviruses is considered uncommon for paramyxoviruses, which usually adopt a narrow host range. In addition to bats, NiV has been shown to infect animals in six other mammalian orders. Although the widespread distribution of ephrin B2 in vertebrates provides an explanation for the diverse host range of henipaviruses, there are mammalian species such as mice which express functional ephrin B2, shown to bind henipaviruses, but remain resistant to infection with HeV and NiV.

Serologic Relationships

NiV was initially described as Hendra-like on the basis of its reactivity with anti-HeV antibodies, a similarity corroborated by complete genome sequencing. No serological relationship between henipaviruses and other paramyxoviruses has been confirmed. The close serological relationship of HeV and NiV makes it difficult to identify antibodies to each virus and determine the virus species circulating in specific geographical areas. A four- to eightfold difference between homologous and heterologous neutralization titers is the basis upon which antibody specificity has been determined.

Four neutralizing epitopes have been mapped on the globular head of the HeV G protein. Two discontinuous epitopes are located on the base of the head and two on the top, in locations resembling those identified as neutralizing sites in other paramyxoviruses. The amino acid homology between HeV and NiV is relatively high at one of the discontinuous epitopes but decreases significantly at the other three sites.

Geographical Distribution

HeV has been isolated from horses, humans, and flying foxes in Australia and NiV from humans, pigs, and flying foxes in Malaysia, Bangladesh, and Cambodia. NiV has also been isolated from fruit partially eaten by flying foxes in Malaysia, and NiV RNA has been detected in human patients and bats in India and Thailand, respectively. Comparative neutralization studies using Australian bat sera confirm that HeV populates the southern domain of the henipavirus distribution. Conversely, Malaysian and Indonesian sera preferentially neutralize NiV, rather than HeV. Equivalent neutralization titers to both HeV and NiV suggest that a related virus may be circulating in the Cambodian bat population. The geographic distribution of *Pteropus* species which range from the east coast of Africa, through the Indian subcontinent and Southeast Asia, north to Okinawa and south to Australia, suggests that henipaviruses may also be found in flying fox populations in geographically more diverse locations.

Evolution and Genetics

Genetically diverse populations of NiV circulate in Southeast Asia. In Malaysia, three closely related lineages of NiV have been identified. A number of identical isolates from humans and pigs during the major outbreak in

the pig-farming communities in central Malaysia in 1999 constitute the first lineage. A 1999 isolate from the initial focus of infection in northern Malaysia is the sole representative of a second lineage and NiV isolated from the urine of flying foxes on Tioman Island off the east coast of peninsular Malaysia constitutes the third lineage, one that is genetically closer to viruses isolated during the major outbreak. It has been suggested that there may have been two bat-to-pig spillover events in Malaysia, only one of which caused significant transmission to humans. However, the role played by virus evolution in pigs, particularly during the period following introduction into the pig population in 1998 and prior to the major outbreak in 1999, remains uncertain.

Unlike the Malaysian isolates which displayed an overall sequence divergence of less than 1%, regardless of source, NiV isolates from human patients in Bangladesh in 2004 differed from the Malaysian isolates by approximately 7% in the protein-coding regions and up to 25% in the non-coding regions. The heterogeneity of Bangladesh isolates suggested multiple spillovers of NiV from flying foxes into the human population. A further evolutionary lineage situated between the NiV-Malaysia isolates and NiV-Bangladesh isolates appears to exist in Cambodia.

The paucity of HeV isolates has restricted speculation on the evolution of this henipavirus in Australia. Partial sequencing suggests that viruses isolated from equine and human sources during the initial outbreak in Brisbane in 1994 and from flying foxes two years later were identical.

Epidemiology and Transmission

Human henipavirus infections in Australia and Malaysia occurred as a result of transmission of the viruses from flying foxes via horses and pigs, respectively. In contrast, NiV may have been directly transmitted to humans in Bangladesh, where it is believed that date palm juice contaminated with bat secretions constituted a potential transmission route. The mode of transmission from bats to spillover hosts in Australia and Malaysia is not known. It has been suggested that horses and pigs may have been infected by HeV and NiV through masticated fruit pulp spat out by flying foxes or by flying fox urine which contaminated pastures or pig sties. Alternatively, the source of virus may have been infected fetal tissues or fluids, a suggestion based on the fact that HeV outbreaks occurred during the birthing period of some species of flying fox, the isolation of HeV from a pregnant flying fox and its fetus, and the transplacental transmission of HeV in experimental infections.

HeV has been transmitted from horse to man on four occasions. The source of the virus may have been the saliva of infected horses, the nasal discharge commonly found at the terminal stages of the disease, or a wide range of infected tissues made accessible by necropsy. The paucity of virus in the bronchi or bronchioles of infected horses suggests transmission of HeV to either man or horse by aerosol is highly unlikely and experimental infection has confirmed the poor transmissibility of HeV in horses.

Risk factors for human infection by NiV in Malaysia were contact with pigs or fresh pig products and because the virus was present in a wide range of organs, the greatest likelihood arose for those in direct contact with sick or dying pigs on farms during farrowing or slaughtering or in abattoirs. NiV is readily observed in the respiratory epithelium of naturally and experimentally infected pigs, a feature suggesting that the virus probably spread to humans and within the pig population by aerosol or by direct contact with oropharyngeal or nasal secretions. Although NiV was present in the urine and respiratory secretions of patients, human-to-human transmission in Malaysia was extremely rare. In contrast, in Bangladesh, epidemiologic evidence indicates spread of the virus from person to person.

Tissue Tropism

Henipaviruses cause systemic infections displaying a predilection for vascular endothelial cells. The identification of ephrin B2 as a henipavirus receptor not only provides an explanation for the diverse host range of these viruses, but also helps to explain the observed systemic distribution of viral antigen particularly in arterial endothelial cells and smooth muscle. Ephrin B2 is found in arteries, arterioles, and capillaries in multiple tissues and organs but is absent from venous components of the vasculature. It is also found in arterial smooth muscle. Ephrins play critical roles in axonal guidance during vertebrate embryonic development and ephrin B2 is expressed on neurons. The availability of ephrin B2 or other receptors, the requirement for co-receptors, or the differing capacities of cells to support the production of infectious virus may determine whether henipaviruses act as respiratory or neurological pathogens.

Pathogenicity

The outcome of henipavirus infections can range from high mortality, as seen with HeV in horses and NiV in humans, through low mortality and morbidity, best exemplified by NiV in pigs, to asymptomatic as observed in flying foxes. The highly virulent nature of henipaviruses in humans and the lack of therapeutic modalities have led to the classification of HeV and NiV as Biosafety Level 4 (BSL4) pathogens. Experimental infections reveal that

henipaviruses are infectious following either oronasal or parenteral administration. Figures for the minimum lethal dose of henipaviruses are known only for NiV in golden hamsters (*Mesocricetus auratus*) where the LD_{50} was 270 plaque-forming units (pfu) and 47 000 pfu following intraperitoneal and intranasal administration, respectively.

Clinical Features of Infection

Henipaviruses display either predominantly respiratory or neurological tropisms depending on the host. In natural infections of horses and young pigs with HeV and NiV, respectively, and in experimental infections of cats with either virus, respiratory symptoms predominate. Neurological symptoms were also observed in a proportion of HeV-infected horses. Experimental infection of horses and cats is usually fatal, with death or euthanasia occurring 5–10 days post infection. Following natural infection of horses, however, the observations during the initial outbreak indicated that some animals displayed respiratory symptoms but survived and others responded to infection asymptomatically. HeV-induced respiratory disease in horses may be accompanied by facial swelling and ataxia and *in extremis*, a copious frothy nasal discharge. Natural infection of pigs with NiV is usually asymptomatic, an outcome also observed after experimental administration of NiV by the ocular and oronasal route. When symptoms are present, they vary according to the age of the pig. Young animals present primarily with respiratory symptoms. Older animals display increased salivation and nasal discharge and on occasion develop neurological signs such as trembling, muscle spasms, and an uncoordinated gait. In Malaysia, pigs displaying symptoms of NiV infection, such as nasal discharge and rapid and labored respiration, had a harsh and nonproductive cough, which gave rise to the name 'barking-pig-disease'.

In contrast, NiV infection in humans is usually associated with severe acute encephalitis and although a proportion of cases presented with respiratory disease, particularly in Bangladesh, the majority displayed fever, headache, drowsiness, dizziness, myalgia, vomiting, and a reduced level of consciousness. Clinical signs such as the absence of reflexes and the irregular twitching of muscles or parts of muscles and an abnormal doll's eye reflex are indicative of brainstem and upper cervical spinal cord dysfunction. In the Malaysian outbreak, 105 of 256 patients died, a mortality rate of 41%. However, this figure reduces to *c.* 30% when individuals who experienced either a mild or asymptomatic infection are taken into account. In Bangladesh, 66 of 90 patients died in outbreaks in 2001, 2003, and 2004, giving a combined case–fatality rate of approximately 70%. Whereas HeV or NiV infection of cats presents a model of respiratory infection, the clinical and pathological features observed in NiV-infected hamsters resemble those found in human cases of encephalitis.

Both HeV and NiV can cause prolonged infection in humans before manifesting as causes of severe neurological disease. In Malaysia, NiV persisted in a proportion of patients (*c.* 10%) who either recovered from encephalitis or who had experienced an asymptomatic infection. Such cases of relapsed and late-onset encephalitis respectively presented from months to years after the initial infection. Only four cases of human HeV infection have been recorded. Two displayed influenza-like symptoms and one died. A third, fatal case of encephalitis occurred over a year after a self-limiting episode of meningitis, attributed to HeV infection.

Pathology and Histopathology

The respiratory disease caused by HeV in horses is characterized by pulmonary edema and congestion. Viral antigen is found in endothelial cells in a range of organs including lungs, lymph nodes, kidneys, spleen, bladder, and meninges, and virus can be recovered from a number of internal organs, including lung, and from saliva and urine. Young pigs infected with NiV present primarily with respiratory symptoms caused by tracheitis and bronchial and interstitial pneumonia. After experimental infection by the ocular and oronasal routes, virus replication occurs in the oropharnyx and spreads to the respiratory tract and lymphoid tissues before appearing in the trigeminal ganglion and neural tissue. Viral antigen is found, particularly in clinically affected animals, in both lungs and meninges and virus is recovered from a range of tissues including tonsil, nasal, and throat swabs and lung. Detection of NiV in the urine of infected pigs is uncommon.

The primary site of replication and dynamics of henipavirus spread in humans are unknown but the distribution and time of appearance of lesions throughout the vasculature and in the brain in NiV encephalitis suggest that hematogenous spread delivers the virus from primary to secondary sites of replication in widely dispersed vascular endothelial cells. Inflammation of blood vessels, particularly small arteries, arterioles, and capillaries, occurs in most organs but is prominent in brain, lung, heart, and kidney. The interval between maximum vasculitis in the brain and parenchymal infection in NiV encephalitis suggests that infection of neurons occurs as a result of vascular damage and that neurological impairment may be due, not only to the effects of ischemia and infarction, but also viral infection of neurons. Although NiV antigen is found infrequently in epithelial cells of the bronchi and kidney, replication in such locations may play a role in virus dissemination. Recent outbreaks of NiV in Bangladesh strongly suggest human to human transmission.

No disease syndromes associated with henipaviruses have been documented in wild flying fox populations. Nor does HeV cause clinical disease in experimentally infected flying foxes and only a proportion of infected bats respond with sporadic vasculitis in the lung, spleen, meninges, kidney, and gastrointestinal tract. The mode of henipavirus transmission between flying foxes is unknown but the presence of virus in the placenta and transmission without apparent harm to the fetus in experimentally infected bats suggests that horizontal transmission is feasible.

Immune Response

Adaptive

In susceptible nonpteropid species, henipaviruses elicit strong humoral immune responses. No studies have been made of cellular responses to henipavirus infection. Antibodies to P, N, and M proteins are evident in Western blots and anti-F and anti-G antibodies are readily detected by enzyme-linked immunosorbent assay (ELISA), using both traditional and bead-based formats, and by immune precipitation. In contrast to the consistent antibody response in susceptible, nonvolant species, in flying foxes there appears to be little direct correlation between detectable virus replication and the appearance of antiviral antibody. Antibody production is irregular and of uncertain longevity.

Anti-NiV antibodies were present in a majority of patients with clinical NiV encephalitis and IgM antibodies occurred more frequently than IgG antibodies in both serum and cerebrospinal fluid (CSF). The appearance of specific IgM antibodies in serum preceded their appearance in the CSF, a sequence consistent with viremia preceding central nervous system infection.

Innate

Henipaviruses inhibit both interferon (IFN) induction and IFN signaling. In the induction phase, the detection of viral double-stranded (ds)RNA by both RNA helicase enzymes and Toll-like receptor 3 (TLR3) leads to the transcription of IFN. Henipaviruses inhibit this process in a number of ways. The V protein, like that of other paramyxoviruses, blocks the activity of the helicase sensor in the cytoplasm but does not inhibit the TLR3 pathway. In contrast, in a process unique to paramyxoviruses and by virtue of the nuclear localization signal in its C-terminal domain, the W protein inhibits IFN induction by blocking a late nuclear step in the activation process which is shared by both helicase and TLR3 pathways.

In the IFN signaling pathway, IFN binds to cell surface receptors in a paracrine manner and initiates a sequence of reactions that leads to activation of members of a family of proteins called signal transducers and activators of transcription (STAT). STAT proteins activate transcription of hundreds of genes some of whose products inhibit virus replication. In a strategy unique to paramyxoviruses, henipaviruses inhibit IFN signaling by sequestering STAT proteins in high molecular weight complexes. The V and P proteins bind STAT proteins in the cytoplasm, whereas the W protein co-localizes with STAT in the nucleus. The extra length of the henipavirus P gene compared with that of other *Paramyxovirinae* results in the encoded P, V, and W proteins having an N-terminal extension of *c.* 100 amino acids compared with their morbillivirus and respirovirus counterparts. This domain appears to provide henipaviruses with a multifaceted anti-IFN signaling activity.

Prevention and Control

Therapeutic options for treatment of infections caused by henipaviruses are limited and currently use of ribavirin appears to be the only recourse. The drug inhibits replication of HeV in cells in culture, and in an open-label study of 194 patients during the NiV outbreak in Malaysia, its use resulted in a 35% reduction in mortality. Duration of ventilation and total hospital stay were both significantly shorter in those receiving ribavirin. Human monoclonal antibodies to the henipavirus G protein also appear to have therapeutic potential. Antibodies which react with the soluble G protein of HeV have been generated from naive recombinant human antibody libraries and they neutralize both HeV and NiV *in vitro*.

A number of promising strategies to develop henipavirus vaccines are being explored. NiV F and G glycoproteins expressed from vaccinia virus elicit neutralizing antibodies in both mice and hamsters and in the latter both anti-F and anti-G antibodies protected from a lethal NiV challenge, although they did not prevent virus replication. Murine anti-F and anti-G antisera also inhibited membrane fusion mediated by F and G glycoproteins expressed in cell culture. More importantly, because of the attractiveness of a subunit compared with a recombinant vaccine, purified soluble HeV and NiV G proteins elicit potent neutralizing antibody responses in rabbits. Antibodies neutralized both HeV and NiV in cell culture and displayed a slightly higher titer against the homologous virus.

A further therapeutic option relies on the fact that henipavirus F_1 glycoproteins have α-helical heptad repeat (HR) domains proximal to the fusion peptide and transmembrane domain at the N- and C-terminal of the protein, respectively. HR domains form a trimer-of-hairpins structure during the fusion of virus and cell membranes. Peptides corresponding to the N- and C-terminal HR domains of HeV and NiV form trimer-of-hairpins structures *in vitro*. Addition of exogenous peptide from either HR domain blocks formation of the trimer-of-hairpins, inhibits cell

fusion mediated by vaccinia virus-expressed F and G proteins, and prevents virus infection of cells in culture.

Future Perspectives

The presence of HeV or NiV in flying foxes throughout Australia, Southeast Asia, and part of the Indian subcontinent suggests that the distribution of henipaviruses may parallel that of pteropid species, which range from Madagascar to the South Pacific. Although the factors responsible for the emergence of henipaviruses have not been clearly elucidated, the destruction of native habitats, a process which is unlikely to abate, forces flying foxes into contact with man as they seek food in areas frequented by humans. Although documented outbreaks of disease caused by henipaviruses are relatively infrequent, lack of knowledge of the modes of transmission between fruit bats and from fruit bats to spillover hosts, the high infectivity of the viruses for certain species, their broad species tropism, and their zoonotic potential will ensure that further work on henipaviruses remains a priority.

Introduction

The avian hepadnaviruses belong to the genus *Avihepadnavirus* in the family *Hepadnaviridae*. Within this genus, duck hepatitis B virus (DHBV) and heron hepatitis B virus (HHBV) are assigned to the species *Duck hepatitis B virus* and *Heron hepatitis B* virus, respectively. These avian viruses are related phylogenetically through similarities in genome sequence and organization of open reading frames (ORFs) to human hepatitis B virus (HBV) and other hepadnaviruses that infect mammals (genus *Orthohepadnavirus*). The major site of hepadnavirus infection and replication is the hepatocyte, the predominant cell type of the liver, constituting about 60–70% of liver cell mass. There are $\sim 5 \times 10^{10}$ hepatocytes in the liver of an adult duck.

Hepadnaviruses contain a relaxed circular double-stranded DNA (rcDNA) genome which is converted in the nucleus to covalently closed circular DNA (cccDNA). cccDNA acts as the virus transcriptional template and is used by host RNA polymerase II to produce a greater than genome length, 'pregenomic' RNA, referred to as the pregenome, and a number of other mRNA species. Hepadnaviruses have a unique method of replication that involves reverse transcription of pregenomic RNA into DNA. Virus replication and release are generally considered to be noncytopathic and disease activity is attributed to the host immune response to infected hepatocytes.

The avian hepadnaviruses are naturally transmitted *in ovo* via vertical transmission of virus from an infected female duck to the egg, with virus replication occurring in the yolk sac and liver of the developing embryo. Ducks infected *in ovo* develop widespread and persistent DHBV infection of the liver but have minimal or no liver disease as they are immune tolerant to the virus. Although experimental infection of newly hatched ducks also leads to widespread and persistent DHBV infection of the liver, DHBV-infected ducks, unlike HBV-infected humans, do not develop severe liver disease, cirrhosis, or liver cancer. However, they provide a reproducible experimental system for studying virus kinetics and immune clearance, and much of what we know of the hepadnavirus replication

strategy has been discovered from studies of DHBV *in vitro* and *in vivo*. DHBV-infected ducks are also used to evaluate new antiviral therapies and vaccines with the ultimate aim of applying the same strategies to the treatment of HBV infections in humans.

Virion and Particle Structure

Like the mammalian hepadnaviruses, avian hepadnaviruses are enveloped viruses possessing an icosahedral nucleocapsid and ~3000 nt rcDNA genome (**Figure 1**). DHBV, the prototypic avian hepadnavirus, has a diameter of 40–45 nm, and different isolates contain genomes ranging in length from 3021 to 3027 nt. In infected ducks, mature enveloped DHBV virions are released from hepatocytes directly into the bloodstream. Virus titers in chronically infected ducks are up to 1×10^{10} virions per ml of serum.

The envelope of DHBV is composed of a lipid bilayer containing multiple copies of two transmembrane virus proteins, Pre-S/S and S (36 and 17 kDa, respectively). These two proteins are synthesized from the same virus ORF, with initiation of Pre-S/S occurring upstream of S. The two proteins share a common carboxy terminus. An additional 28 kDa protein antigenically related to Pre-S/S and S has been detected in DHBV-infected liver but it is unclear whether this is a degradation product of Pre-S/S or is translated from an AUG codon mapping between the start sites of Pre-S/S and S. As for HBV, the envelope proteins not only participate in virion formation but also self-assemble into noninfectious virus-like DHBV surface antigen particles (DHBsAg particles). This process occurs in the endoplasmic reticulum and results in the release from infected hepatocytes of a 500- to 1000-fold excess of DHBsAg particles over infectious virions. DHBsAg particles do not contain a virus nucleocapsid and lack virus nucleic acids. DHBsAg particles are pleomorphic and spherical, with a diameter of ~35–60 nm, and the larger particles are almost indistinguishable from DHBV virions by electron microscopy (EM). In contrast, during HBV infection, filamentous forms of surface antigen-containing particles (HBsAg) are produced as well as 22 nm spherical HBsAg particles, both of which are readily distinguished from those of HBV by EM.

The nucleocapsid of DHBV is icosahedral, as observed by cryoelectron microscopy, and is comprised of dimers of 30 kDa nonglycosylated DHBV core antigen (DHBcAg). In mature virions, the rcDNA genome and a virus-encoded DNA polymerase are contained in the virus nucleocapsid (**Figure 1**), which also contains cellular chaperones.

The DHBV polymerase is a 90 kDa molecule that functions as both an RNA-dependent DNA polymerase and a DNA-dependent DNA polymerase. The polymerase also has an RNase H activity that digests the RNA pregenome during virus replication. The protein sequence of the DHBV polymerase has four separate domains listed from the N terminal end, that include a terminal protein (TP), 'spacer', reverse transcriptase (RT), and RNase H domain. Each of these domains has one or more key roles during virus replication, as described below.

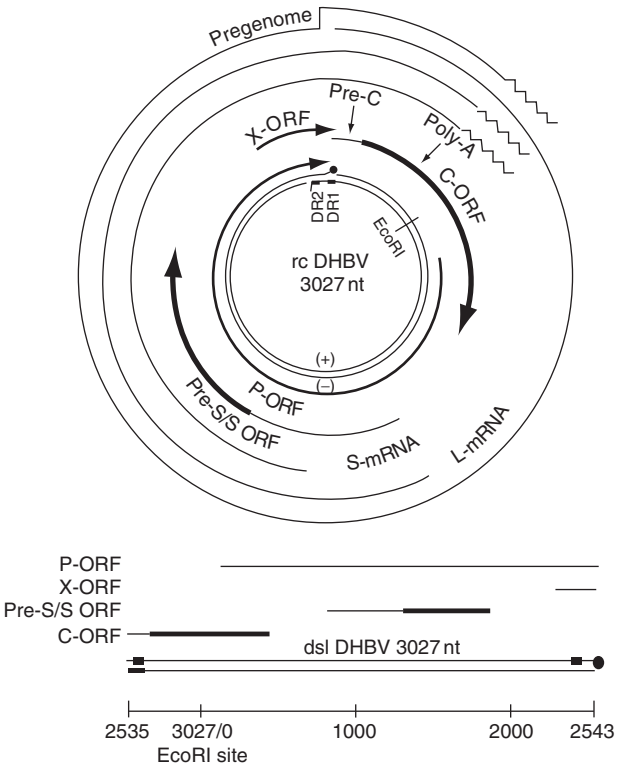

Figure 1 Organization of the DHBV genome. The rcDNA genome is shown at the top center, with the virus polymerase covalently attached to the 5′ end of the negative strand and an 18 nt RNA bound to the 5′ end of the positive strand. The DHBV genome contains two direct repeat (DR) sequences (DR1 and DR2). The locations of the virus ORFs, DR1 and DR2 and maps of the virus mRNAs are also shown. None of the major mRNAs is spliced. Thus, each has its own promoter. However, they share a common polyadenylation (poly-A) signal in the virus C-ORF. The pregenome RNA is terminally redundant and serves as the mRNA for both the C-ORF and, less frequently, the downstream P (polymerase) ORF. The pregenome lacks the AUG of the Pre-C/C-ORF, which instead is translated from an mRNA a few nt longer at the 5′ end than the pregenome (not shown). The L and S mRNAs encode the Pre-S/S and S envelope proteins, respectively. The more rarely synthesized double-stranded linear (dsl) virus genome is shown at the bottom. The common nucleotide numbering system is also displayed, proceeding in a clockwise direction from a conserved EcoRI restriction site.

Also released from hepatocytes and circulating in the blood of infected ducks is the so called DHBV e antigen (DHBeAg), a proteolytically processed form of the 35 kDa Pre-C/C protein. Different forms of DHBeAg range in size from a nonglycosylated 27 kDa to 30–33 kDa glycosylated forms. DHBeAg is thought to play an important

role in either the initiation or maintenance of persistent infection by delaying or diverting the host immune response to DHBcAg. Both DHBsAg and DHBcAg are highly immunogenic. Anti-DHBc antibodies can be detected by ELISA in the serum of ducks during acute and persistent DHBV infections. Anti-DHBs antibodies are produced during the resolution phase of acute DHBV infection and are generally not detected in ducks with persistent infection except in complexes with circulating DHBsAg. Anti-DHBs antibodies bind virus particles and are able to block DHBV infection of cells. For this reason, ducks that have recovered from acute DHBV infection are immune to challenge with DHBV.

Genome Organization

As noted above, all hepadnaviruses have a similar genome organization, despite the low DNA sequence identity between the mammalian and avian hepadnaviruses (40%). The negative strand of the DHBV genome contains S-ORF, C-ORF, and P-ORF encoding the surface or envelope proteins, core and e antigen proteins, and polymerase protein, respectively (**Figure 1**). The DHBV genome was originally thought to contain only these three ORFs and to lack an ORF encoding a protein analogous to the X protein of the mammalian hepadnaviruses. It was subsequently discovered that avian hepadnaviruses, including HHBV and DHBV, have a fourth ORF, the X-ORF, which directs synthesis of a candidate X protein that is translated using an unconventional start codon. The significance of this observation is still unclear. Using woodchuck hepatitis virus (WHV), a close relative of HBV, the X gene was shown to be essential for successful WHV infections *in vivo*. In contrast, knockout of the X gene of DHBV did not alter the time course of DHBV infection. As with wild-type DHBV, the X gene knockout of DHBV spread rapidly through the liver of newly hatched ducks and caused persistent DHBV infection.

The positive strand of the DHBV genome does not contain any functional ORFs. All virus mRNA species are produced from the negative strand of the virus genome.

The difference in size between the genomes of the avian (e.g., DHBV with a genome of 3027 nt) and the mammalian hepadnaviruses (e.g., HBV with a genome of 3200–3300 nt), is due in part to deletion of a 150 nt stretch in S-ORF. This region in the HBV genome encodes the so-called 'a' determinant, a highly immunodominant region to which most of the neutralizing anti-HBV antibodies are directed. This region in HBV is present on the small form of HBsAg, the S protein. The absence of this region in DHBV results in a lack of immunodominance, and both DHBV Pre-S/S and S domains have been shown to induce high titer, neutralizing, anti-DHBs antibodies.

Replication Cycle

Hepatocytes, the major parenchymal cell of the liver, are the primary site of DHBV infection. The cell specificity of infection is determined by the presence of specific receptors required for virus binding and entry into hepatocytes. In early studies, DHBsAg particles, which appear to have the same envelope structure as DHBV virions, were shown to bind cell surface receptors on primary duck hepatocytes in a species-specific manner. Receptor binding occurs via the Pre-S/S region of DHBV and is followed by cell entry via receptor-mediated endocytosis. Recent studies have determined that the cellular protein carboxypeptidase D (180 kDa) binds DHBsAg particles and DHBV with high affinity and is found on both internal and external membranes of the cell. However, whereas DHBV has a narrow host range, carboxypeptidase D is expressed on many cell types that are not susceptible to DHBV infection. In addition, despite the observed binding of DHBsAg to carboxypeptidase D, transfection of cells with carboxypeptidase D cDNA does not confer susceptibility to DHBV, suggesting that other co-receptors or mechanisms may be operating. An additional DHBV-binding protein, glycine decarboxylase (120 kDa) has been identified. Its cellular expression is restricted to the liver, kidney, and pancreas. Interestingly, DHBV infection and replication has been detected in a few percent of cells in both the kidney and pancreas (see below and **Figure 5**). Thus, these proteins are potential components of a DHBV receptor complex and probably have a role in determining DHBV organ tropism. However, definite proof that these are the receptors that lead to DHBV binding, receptor-mediated endocytosis, and infection is still lacking.

Whatever the receptor, the immediate sequel to virus uptake is transport of the rcDNA genome to the nucleus to form cccDNA (**Figure 2**). The negative strand of the rcDNA DHBV genome is nicked, with a 9 nt terminal redundancy and with the virus polymerase molecule covalently attached to its 5′ end. Covalent attachment of the virus polymerase occurs during priming of reverse transcription through a tyrosine located in the TP domain of the polymerase. Similarly, the positive strand of the DHBV genome has an 18 nt RNA primer attached to its 5′ end (**Figure 1**). In addition, the positive strand is incomplete, with a minimum gap of 12 nt. Thus, following transport to the nucleus, the covalently linked polymerase protein, the RNA primer, and the terminal redundancy in the negative strand are removed, the positive strand is completed, and ligation of the ends of each strand takes place. As noted above and discussed in detail below, ~10% of circulating DHBV virions contain double-stranded linear (dsl) genomes that result from a defect that occurs during synthesis of positive-strand DNA. Following infection these dsl genomes can also enter the nucleus to form cccDNA, which in this case is formed

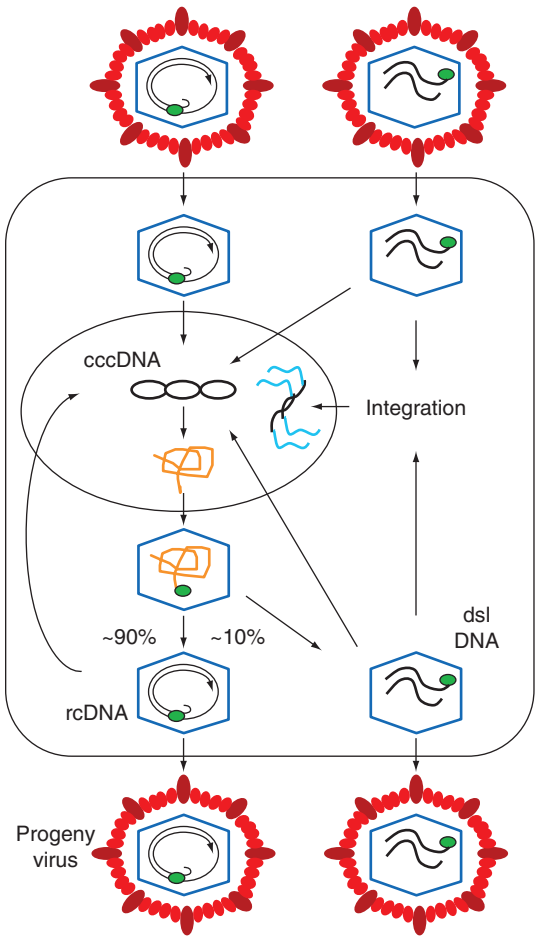

Figure 2 DHBV infection of hepatocytes. Virions, shown at the top, may have either an rcDNA or, more rarely, a dsl DNA genome. Upon infection virus nucleocapsids are uncoated and move to the nucleus. Virus DNA is released from nucleocapsids and probably enters the nucleus at nuclear pores. Both rcDNA and dsl DNA give rise to cccDNA, the virus transcriptional template. cccDNA is used by host-cell RNA polymerase II to produce pregenomic RNA that is reverse transcribed to rcDNA or dsl DNA. dsl DNA also has a propensity to integrate into host-cell DNA (see text). Early in infection, cccDNA copy number increases by intracellular amplification from rcDNA and dsl DNA made in the cytoplasm via reverse transcription. Later, this pathway is shut down and nucleocapsids containing rcDNA and dsl DNA bud into the endoplasmic reticulum and are released as progeny virus.

by illegitimate recombination between the ends of the dsl DNA. This recombination event typically involves some loss of sequences, and cccDNA formed from dsl genomes is generally defective.

DHBV cccDNA molecules exist within the nucleus of each infected hepatocyte as a population of virus minichromosomes that bind up to 20 nucleosomes per 3000 nt molecule. cccDNA does not undergo semiconservative replication. New copies are therefore formed from rcDNA and dsl DNA synthesized in the cytoplasm of infected hepatocytes. Once formed, cccDNA is transcribed by host RNA polymerase II to produce pregenomic and other virus mRNAs (**Figures 1** and **2**), followed by protein production, assembly of nucleocapsids from the viral core protein and packaging of pregenomic RNA. Each virus mRNA is produced from its own promoter and virus RNA molecules including the pregenome have a 5′ cap and are polyadenylated at a common site (nt 2778–2783) on the DHBV genome numbered according to the sequence of the Australian strain of DHBV (GenBank AJ006350) where the unique EcoRI site is nucleotide 1.

Packaging of pregenomic RNA is facilitated by the presence of an encapsidation signal, epsilon (ε), located at the 5′ end (nt 2566–2622) and at the 3′ end of the pregenome, within the terminal redundancy (**Figure 3(a)**). Pregenome packaging is dependent upon binding of the virus polymerase to the 5′ ε sequence. In fact, the pregenome is able to serve as the mRNA for both core and polymerase proteins (**Figure 1**). However, once polymerase is translated, it may bind to its own message and block its further translation. Once packaging into nucleocapsids has occurred, virus DNA synthesis takes place via reverse transcription of the pregenomic RNA, with production of replicative intermediate DNA (RI DNA) to produce rcDNA and dsl DNA genomes in a ~10:1 ratio (**Figures 3(f)** and **3(h)**).

DNA synthesis begins with reverse transcription of 4 nt (5′ UUAC 3′) in the bulge in the stem–loop structure of ε, leading to synthesis of 4 nt of DNA (5′ GTAA 3′) (**Figure 3(b)**). As noted above, a tyrosine residue in the TP domain of the polymerase serves as the primer of reverse transcription. Following synthesis by reverse transcription of the first 4 nt, the complex is translocated to DR1, in particular the 3′ copy of DR1, DR1* (**Figure 3(c)**).

DR1 is a 12 nt sequence located 6 nt from the 5′ end of the pregenome at nt 2541–2552. It is therefore also present in the terminal redundancy of the pregenome. The same sequence known as DR2 is located about 50 nt upstream of the terminal redundancy at nt 2483–2494. Once transferred to DR1*, where the 4 nt can base pair due to sequence homology, reverse transcription reinitiates and continues to the 5′ end of the pregenome, to produce a full-length negative strand with a 9 nt terminal redundancy (**Figures 3(d)** and **3(e)**). Most of the pregenome is degraded during negative-strand elongation by the RNase H activity of the virus polymerase. However, the 5′ ~18 nt of the pregenome, including the cap and all of the 5′ copy of DR1, escapes RNase H degradation and serves as the positive DNA strand primer. Positive-strand synthesis leading to rcDNA formation initiates near the 5′ end of the negative strand. The primer is first translocated from its original location at the 3′ end of the template to DR2 where it can hybridize due to the sequence identity of DR1 and DR2 (**Figure 3(e)**). Following positive-strand elongation to the 5′ end of the negative strand, circularization occurs to facilitate continuation

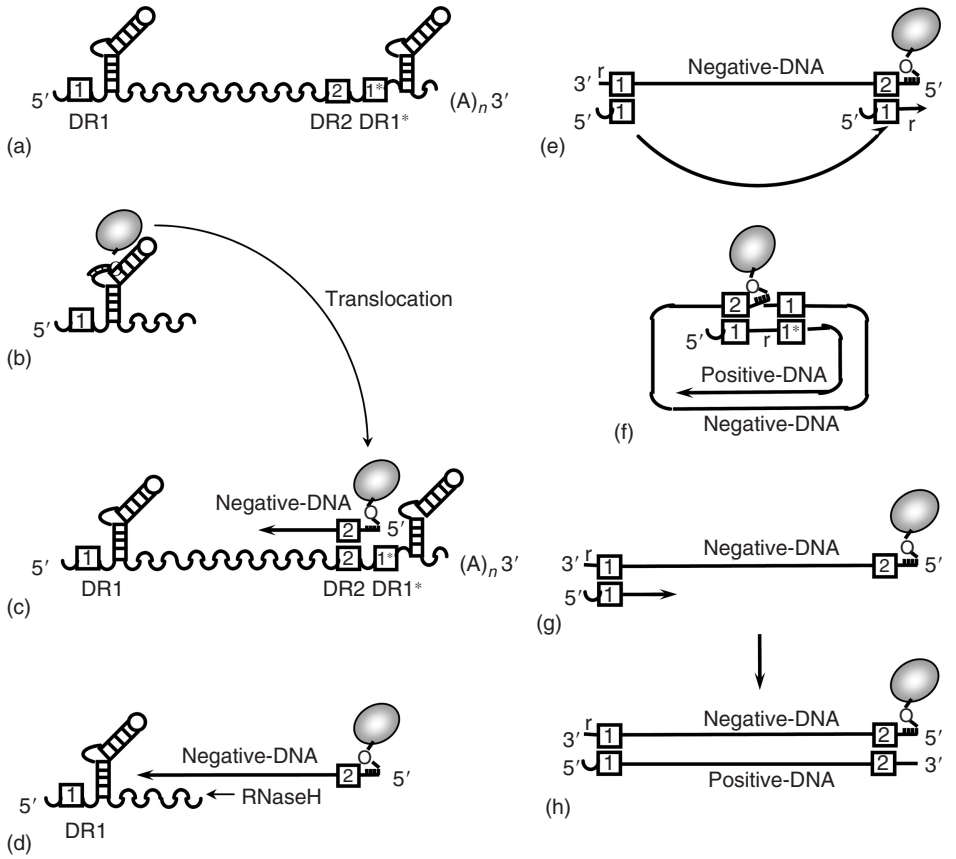

Figure 3 Mechanism of DHBV DNA synthesis. Virus DNA synthesis begins with reverse transcription of 4 nt (5′ UUAC3′) of the bulge in the stem–loop structure, ε, and leads to synthesis of the first 4 nt (5′ GTAA3′) of negative-strand DNA, as shown in (b). Polymerase with the nascent transcript then translocates to the right-hand copy of DR1, DR1*, and reverse transcription of the negative strand and degradation of the pregenomic RNA template by RNase H proceeds as shown in (c) and (d). Following completion of the negative strand, the 5′ 18 nt of the pregenome, including the cap, are typically translocated to DR2 and positive-strand DNA synthesis then initiates from this RNA primer. In this case, rcDNA formation is of necessity an early step in positive-strand synthesis ((e) and (f)). About 10% of the time, positive-strand synthesis initiates without translocation of the primer (g), leading to the formation of dsl DNA (h). The details of DNA synthesis are described in greater detail in the text.

of positive-strand synthesis to produce mature rcDNA (**Figure 3**(**f**)). Circularization is facilitated by the 9 nt terminal redundancy on the negative-strand template.

dsl DNA genomes reflect a failure of positive-strand primer translocation from DR1 to DR2, resulting in a phenomenon known as *in situ* priming to produce a DNA that is collinear with pregenomic RNA up to DR1* (**Figure 3**(**h**)). Interestingly, both the polymerase, the protein primer of negative-strand synthesis and the RNA primer of positive-strand synthesis remain associated with virus DNA throughout virion assembly. Biochemical evidence suggests that each nucleocapsid contains only a single copy of polymerase protein, implying that a single protein is simultaneously the primer of DNA synthesis and the polymerase for both RNA- and DNA-dependent DNA synthesis.

Newly made rcDNA and dsl DNA are enveloped by budding into the endoplasmic reticulum and exported as progeny virus via the Golgi apparatus, or are transported to the nucleus to make additional copies of cccDNA, typically found at 10–30 copies per hepatocyte. Nuclear transport is negatively regulated by the virus envelope proteins, which direct nucleocapsids into the pathway of virus assembly. This negative regulation is essential because excessive accumulation of cccDNA will kill the host cell. Strong negative regulation may also be important because of the stability of cccDNA, and new synthesis of cccDNA may only be necessary to restore cccDNA levels in the progeny following division of infected hepatocytes. Negative regulation of cccDNA synthesis also appears to occur during HBV infection, but it is still not known whether the viral envelope proteins have an essential role in this process.

dsl DNA also integrates randomly into chromosomal DNA and has been detected in ~0.01–0.1% of hepatocytes during acute infections by both DHBV and the mammalian hepadnaviruses. Higher levels of integrated virus DNA accumulate during chronic infections. This

probably reflects ongoing import of rcDNA and dsl DNA into the nucleus to restore cccDNA copy number as infected hepatocytes divide to replace those killed by the host immune response, thereby providing new dsl DNA genomes for integration. Integrated forms of hepadnavirus DNA are usually unable to act as templates for transcription of pregenomic RNA since the promoter for this virus RNA is located at the 3′ end of the integrant, not the 5′ end, and integrated DNA is therefore not able to direct virus replication (see **Figure 1**). In addition, virus sequences may be lost during the integration process, particularly from the ends of the dsl molecule.

Since each integrated virus–cell DNA junction is unique, and will be present only once in the liver unless the infected hepatocyte divides, integration sites can be used to identify and track the fate of individual hepatocyte lineages. In particular, assays for integrated DNA were used to show that hepatocytes present in the liver following recovery from an acute WHV infection were derived from previously infected hepatocytes, indicating the existence of mechanisms for removal of cccDNA from infected hepatocytes.

Phylogenetic Information

Assigned species within the genus *Avihepadnavirus* include DHBV isolated from Pekin ducks (*Anas domesticus*) and HHBV from grey herons (*Ardea cinerea*). Many DHBV isolates have been found in domesticated ducks and, in the wild, in the mallard, the species from which most domesticated ducks are derived. Viruses less closely related to DHBV have been isolated from geese and other duck species and include the Ross's goose hepatitis B virus (RGHBV) from Ross's geese (*Anser rossii*), Mandarin duck hepatitis B virus (MDHBV) from Mandarin ducks (*Aix galericulata*), and the snow goose hepatitis B virus (SGHBV) from snow geese (*Anser caerulescens*). The stork hepatitis B virus (STHBV) has been isolated from white storks (*Ciconia ciconia*), with additional viruses isolated from demoiselle (*Anthropoides virgo*) and grey crowned cranes (*Balearica regulorum*) (**Figure 4**). By genome sequencing, HHBV and STHBV are the most distant from DHBV (**Figure 4**). HHBV was assigned as a species based both on genome divergence and a host range difference from DHBV. Current information does not provide clear evidence for designation of additional new species among the isolates shown in **Figure 4**.

Thus, the avihepadnaviruses are currently classified phylogenetically into 'Chinese' and 'Western Country' isolates as well as four highly distinct lineages that include SGHBV, RGHBV, plus MDHBV, STHBV, and HHBV. Sequence divergence within the 'Chinese' and 'Western Country' DHBV strains is 5.99% and 3.35%, respectively, while divergence between the strains is 9.8%. SGHBV diverges from DHBV by 11–13%, RGHBV and MDHBV by 17–19% and STHBV and HHBV by 22–24%. Additional closely related viruses have been isolated from the puna teal (*Anas puna*), ashy-headed sheldgoose (*Chloephaga poliocephala*), Orinoco sheldgoose (*Neochen jubata*), and Chiloe wigeon (*Anas sibilatrix*) (**Figure 4**).

Pathogenesis and Control of Diseases

In persistently DHBV-infected ducks, the natural route of virus transmission is from the bloodstream to the egg. Virus replication then occurs in the yolk sac and developing liver and pancreas of the embryo (**Figures 5(a)–5(c)**) and results in congenital DHBV infection. Congenitally DHBV-infected ducks remain persistently infected for life, with infection in >95% of hepatocytes (**Figure 5(e)**). Bile duct cells are also infected with DHBV and express high levels of DHBcAg and DHBsAg (**Figure 5(e)**). Virus replication also occurs in acinar and islet cells in the pancreas (**Figure 5(f)**), and in glomeruli (**Figure 5(d)**) and tubular epithelial cells in the kidney. Cells located in the germinal centers of the spleen contain nonreplicating DHBV DNA, which is thought to be associated with follicular dendritic cells. In ducks with congenital infection, levels of DHBV DNA and DHBsAg in the bloodstream gradually decrease over 800 days and anticore antibodies can be detected from ~90 days post hatch, consistent with a high degree of immune tolerance.

Persistent DHBV infection also results following experimental inoculation of newly hatched ducks, and inoculation of infected serum containing the equivalent of one virion is sufficient to initiate DHBV infection. Infection of newly hatched ducks with DHBV has allowed detailed studies of the kinetics and tissue specificity of DHBV infection. Inoculation of 2- to 4-week-old ducks with DHBV results in either acute or persistent infection depending on the age of the duck at the time of inoculation and the dose of DHBV administered. Ducks from this age group that develop persistent infection have histological changes in the liver with mild mononuclear cell infiltration of portal tracts but no evidence of lobular hepatitis or extensive liver damage. Experimental inoculation of 4-month-old ducks with high doses of DHBV leads to either persistent infections with mild to marked liver disease or to transient infections that are rapidly cleared.

Since hepadnavirus infection is noncytopathic, the liver damage seen during DHBV infection has been attributed to the immune response directed against infected hepatocytes. Although cirrhosis and primary hepatocellular carcinoma (HCC) are not reported to occur in DHBV infection, the clinical and serological events, hepatocyte specificity, and ability of the host to rapidly resolve an infection involving the entire hepatocyte population are similar for DHBV, WHV, and HBV.

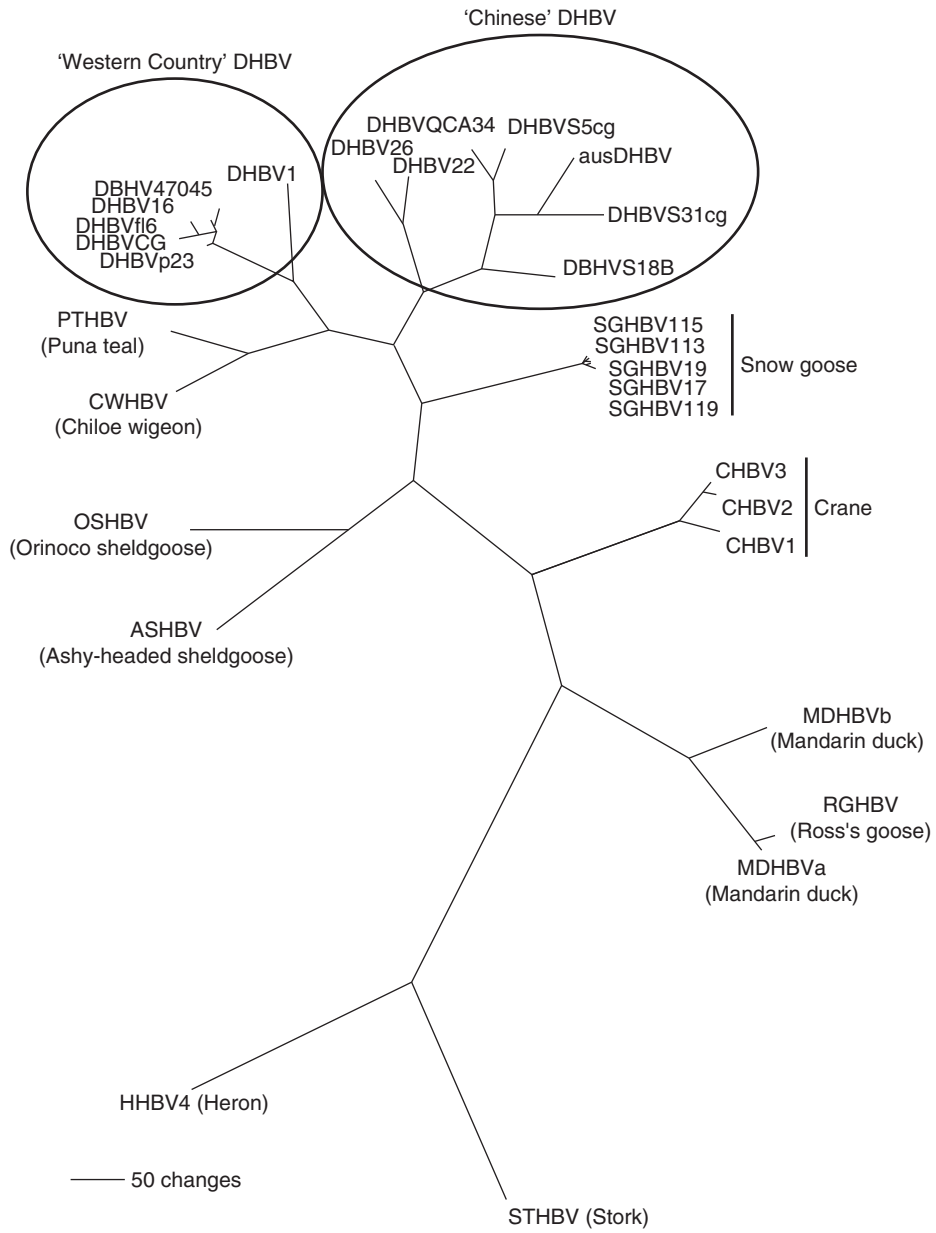

Figure 4 Phylogenetic relationships of avian hepadnaviruses. A dendrogram file was constructed using Clustal X and full-length virus sequences and displayed using Treeview. The following sequences were included: 'Chinese' DHBV isolates, accession numbers M32990, M32991, X60213, AJ006350, M21953, X58568, X58569; 'Western Country' DHBV isolates, K01834, M60677, X12798, X74623, AF047045, X58567; snow goose hepatitis B virus isolates: AF110996, AF110997, AF110998, AF110999, AF11000; Ross's goose hepatitis B virus: M95589; grey heron hepatitis B virus: M22056; stork hepatitis B virus: AJ251937; crane hepatitis B virus isolates: AJ441111, AJ441112, AJ441113; Mandarin duck hepatitis B virus isolates: AY494848, AY494849; Chiloe wigeon hepatitis B virus: AY494850; puna teal hepatitis B virus: AY494851; Orinoco sheldgoose hepatitis B virus: AY494852; and ashy-headed sheldgoose hepatitis B virus: AY49485.

Humans infected with HBV, especially when less than a year of age, often develop a healthy carrier state which can last for several decades without clinically evident liver disease. Similarly, persistent infection with avian hepadnaviruses, resulting either from *in ovo* infection or experimental inoculation after hatching, generally results in only mild hepatitis similar to the 'healthy' carrier state in humans. The failure to detect liver disease, cirrhosis and HCC in persistently DHBV-infected ducks may to be linked to the timing and mode of transmission of these viruses, since they are usually transmitted vertically by *in ovo* transmission resulting in congenital infection with immune tolerance and an absence of, or only mild, liver disease. The inability of DHBV-infected ducks to progress to HCC may also be affected by their limited life span in captivity, which is generally less than 5 years.

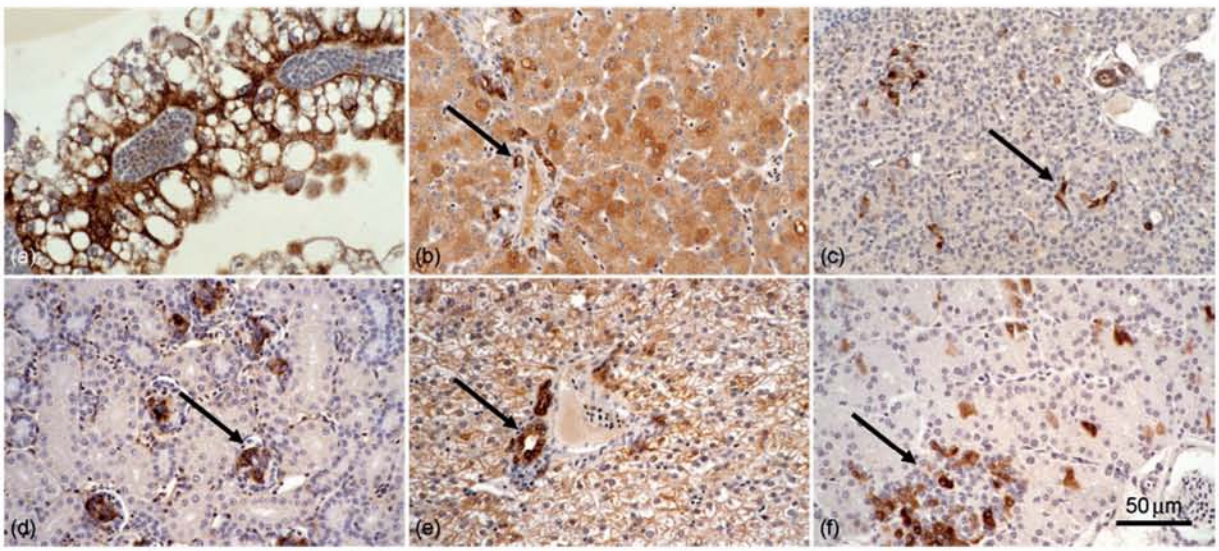

Figure 5 Hepatic and extrahepatic infection with DHBV of a 14-day-fertilized duck embryo (a–c) and a 2-week-old congenitally infected duck (d–f). Immunoperoxidase staining of DHBV core antigen in yolk sac (a), liver (b, e), pancreas (c, f), and kidney (d). DHBV is transmitted *in ovo* from the bloodstream of the persistently DHBV-infected female duck to the egg, resulting in DHBV replication in yolk sac cells (a), hepatocytes and bile duct cells (arrow) in the liver (b), and pancreatic acinar cells (c). DHBV infection persists in congenitally DHBV-infected ducks in glomerular cells in the kidney ((d); arrow), in >95% of hepatocytes and in bile duct cells of the liver ((e); arrow shows high levels of DHBV core antigen detection in bile duct cells), and in pancreatic acinar and islets cells ((f); arrow indicates a group of DHBV core antigen-positive pancreatic beta islet cells; alpha islets also positive (not shown)). Tissues were fixed in ethanol:acetic acid, immunostained with polyclonal anti-DHBV core antibodies and counterstained with hematoxylin.

HCC was detected in ducks in a Chinese province but in those areas aflatoxin exposure may have been common and the key contributory factor in the development of the liver cancers.

Conclusion

Although the avian hepadnaviruses share only 40% nucleotide sequence identity with HBV and the other mammalian hepadnaviruses, they are nearly identical in genome organization and replication strategy. Indeed, the molecular details of hepadnavirus replication were initially worked out with DHBV and later extended to HBV, and the similarities were found to be striking. The biology of infection of HBV and DHBV is also strikingly similar, with hepatocytes the primary target of infection and immune-mediated cell death the primary cause of liver disease in infected hosts.

The only major difference between the two viruses is how they are able to persist in their respective host populations. DHBV appears to be maintained primarily by vertical transmission to the developing embryo, whereas the primary route for maintenance of HBV in the human population is by horizontal transmission during the first year of life from mother to child, or among young children. Both routes lead to chronic infection, but it is generally believed that the degree of immune tolerance to the virus is much greater following vertical than horizontal transmission. This probably explains the greater disease activity in chronically infected humans than ducks. This difference is also seen in the woodchuck model. Chronic WHV infection results, as in HBV in humans, primarily from horizontal transmission, leading to a much more rapid disease progression than found in ducks.

HBV was discovered in 1967, WHV in 1978, and ground squirrel hepatitis B and DHBV viruses shortly thereafter. Among these, DHBV was the easiest to work with because of the ready availability of hosts from commercial sources. Thus, in the initial absense of a cell culture system, much of the early work on hepadnavirus replication focused on DHBV. As a result, DHBV provided much of the information on how the hepadnaviruses replicate as well as detailed early information on the biology of infection and virus spread, including possible identification of the cell surface receptor for the virus. Studies of DHBV have also provided important information on how cccDNA is made and on its high degree of stability in nondividing cells. In addition, the DHBV model has been used to demonstrate the reproducible and rapid kinetics of the spread of DHBV infection *in vivo* and to determine the high specific infectivity of DHBV, where one virus particle has been shown to be infectious in neonatal ducks.

Because of the reproducible nature of the kinetics of infection and the predictable outcomes of infection using defined doses of DHBV, the model is especially useful for the evaluation of new antiviral therapies and vaccine strategies for HBV infection in humans. Similarities in the replication strategy and polymerase enzymes of the avian

and human hepadnaviruses allow evaluation of new antiviral drugs in *in vivo* models of HBV infection, including the development of antiviral drug-resistant mutants and competition between wild-type and mutant DHBV strains.

Hepadnaviruses: General Features

Introduction

The infectious nature of viral hepatitis has been recognized throughout human history, including by documentation of epidemics of jaundice (campaign jaundice) associated with warfare. Parenteral transmission of hepatitis (serum hepatitis) was recognized from the end of the nineteenth century following transmission by routes such as tattooing, the reuse of syringes and needles, and contamination of vaccines by 'stabilization' with human 'lymph' or serum. The viral etiology of infectious and serum hepatitis was recognized in studies involving transmission to volunteers, during and after World War II. In addition, these studies established different incubation times for infectious (short incubation) and serum (long incubation) hepatitis. The terms hepatitis A and hepatitis B were coined and became accepted for infectious (or epidemic) and serum hepatitis, respectively.

Progress with hepatitis B began with the serendipitous discovery of the envelope protein of the virus, hepatitis B surface antigen (HBsAg), originally termed Australia antigen. This was discovered in 1965 by Blumberg, who precipitated an antigen–antibody complex by immunodiffusion of sera from a multiply transfused patient and an Australian aboriginal, during a study of blood and leukocyte antigens. The protein was later recognized to be associated with transmission of hepatitis and could be detected in the sera of a proportion of patients with viral hepatitis. Electron microscopic studies in the late 1960s led to the discovery of particles of around 20 nm diameter that are now known to be composed of membrane-embedded HBsAg, secreted from the hepatocytes as non-infectious, subviral particles. In 1970, Dane visualized larger, 42 nm particles with electron dense cores. Originally termed 'Dane particles', these are the hepatitis B virions and were shown later to contain a small circular

DNA genome that was partially single-stranded and associated with a DNA polymerase activity that could render the molecule fully double-stranded.

The development of tests for HBsAg, and for antibodies to hepatitis A virus, led to the recognition of transmission of hepatitis, termed non-A, non-B hepatitis (NANBH), potentially by other viruses. Post-transfusion (or parenterally transmitted), PT-NANBH is caused principally by hepatitis C virus and enterically transmitted, ET-NANBH, by hepatitis E virus. The genomes of these viruses were cloned in 1989. Earlier, in 1977, Rizzetto had described a novel antigen–antibody system, termed delta/anti-delta, in patients with hepatitis B. The delta antigen is now known to be the nucleocapsid protein of hepatitis D virus (HDV), a defective virus that requires HBsAg to form its envelope.

The Hepadnaviruses

Hepatitis B virus (HBV) is now recognized as the prototype of a family of viruses that infect mammals and birds. The *Hepadnaviridae* (named for *hepa*totropic *DNA* viruses) are divided into mammalian (*Orthohepadnavirus*) and avian (*Avihepadnavirus*) genera.

In the 1960s, it was noted by Snyder that eastern woodchucks (*Marmota monax*) in a colony in the Philadelphia Zoo were highly susceptible to the development of chronic hepatitis and hepatocellular carcinoma, and he proposed a viral etiology. The sera of animals with chronic hepatitis proved to contain a virus with similar biochemical properties to HBV and this was named woodchuck hepatitis virus (WHV). A search for similar viruses in relatives of the woodchuck turned up a closely related virus, ground squirrel hepatitis virus (GSHV) in the Beechey ground squirrel (*Spermophilus beecheyi*; *Spermophilus* and *Marmota* are genera of the family *Sciuridae*). Other related viruses are endemic in Richardson ground squirrels (*Spermophilus richardsonii*) in Canada (Richardson ground squirrel hepatitis virus, RGSHV) and arctic ground squirrels (*Spermophilus parryi kennicotti*) in Alaska (arctic squirrel hepatitis virus, ASHV).

Reports of hepatocellular carcinoma in farmed ducks in China led to the discovery of duck hepatitis B virus (DHBV; the 'B' is included to avoid confusion with the picornavirus, duck hepatitis virus, and is retained in the names of the other avian hepadnaviruses) in flocks of Pekin ducks (*Anas domesticus*) in China and the USA. In the USA, up to 10% of ducks in some commercial flocks are persistently infected. The discovery of DHBV was followed by the identification of related viruses in grey herons (*Ardea cinerea*) in Germany (heron hepatitis B virus, HHBV), in Ross's geese (*Anser rossii*; Ross's goose HBV, RGHBV) and snow geese (*Anser caerulescens*; snow goose HBV, SGHBV), in white storks (*Ciconia ciconia*; STHBV) and in grey crowned cranes (*Balearica regulorum*; CHBV). Recently, other hepadnaviruses have been isolated from a variety of exotic ducks and geese, including teal, widgeon, and sheldgeese. However, because these birds were kept in captivity, it is not clear that these novel viruses are native to the species from which they were first isolated. Indeed, RGHBV and SGHBV also were isolated from captive birds and are quite distinct viruses (**Figure 1**), despite the fact that the two avian species mix and may interbreed in the wild.

Biology of the Viruses

As noted above, hepadnavirus particles consist of a DNA-containing nucleocapsid enveloped with the surface proteins embedded in a lipid bilayer derived from the internal membranes of the host cell. Excess surface proteins are secreted as subviral particles, which may serve to subvert the immune response to the surface proteins. The surface open reading frame (ORF) in the mammalian viruses contains three, in-frame initiation codons leading to the synthesis of large (L, pre-S1+pre-S2+S), middle (M, preS2+S), and small (or major, S) surface proteins (**Figure 2(a)**). The pre-S1 region contains an endoplasmic reticulum-retention signal involved in virion assembly; its incorporation into subviral particles leads to the formation of tubular, rather than spherical, forms. The avian viruses have only large (pre-S+S) and small (S) surface proteins, the middle protein being absent (variants of HBV with small deletions that abrogate synthesis of the middle protein also seem to be viable). For both classes of virus, the ligand that interacts with the major cellular receptor seems to reside within the domain unique to the large surface protein and it is this interaction that seems to be responsible for the high degree of species specificity of this virus family. The primary receptor for DHBV is carboxypeptidase D but the receptors and co-receptors of the mammalian viruses remain to be identified.

Within the nucleocapsid, the genome (around 3.2 kbp for HBV, 3.3 kbp for the rodent viruses, and 3.0 kbp for the avian viruses) is composed of two linear strands of DNA held in a circular configuration by base-pairing of a short region where the 5′ ends overlap. As noted above, one strand (the plus strand) of the HBV genome is incomplete, usually being approximately 60–80% full length. On the other hand, the genome of DHBV tends to be almost completely double-stranded, while it has been reported that SGHBV produces a significant proportion of virions containing single-stranded DNA.

With its small size, the HBV genome was one of the first viral genomes to be cloned and sequenced completely.

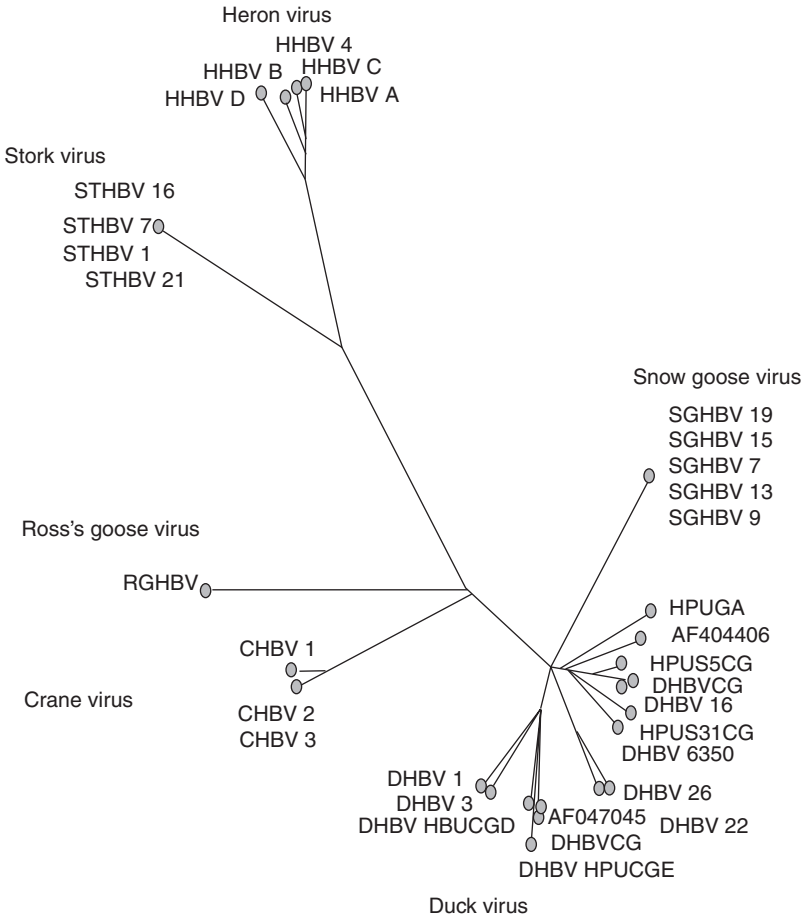

Figure 1 An unrooted phylogenetic tree showing the genetic relatedness between hepadnaviruses isolated from ducks, geese, herons, storks, and cranes. Reproduced from Prassolov A, Hohenberg H, Kalinina T, *et al.* (2003) New hepatitis B virus of cranes that has an unexpected broad host range. *Journal of Virology* 77: 1964–1976, with permission from American Society for Microbiology.

Four overlapping ORFs are conserved among the mammalian viruses (**Figure 2**(**a**)). These encode the surface and nucleocapsid proteins, the polymerase, and a small protein called x (HBxAg) for its unknown function. HBxAg is now known to be a transactivator of transcription and is presumed to act by upregulating the activity of the viral promoters and may be important in 'kick-starting' a new infection. The X ORF is absent from the genomes of the avian viruses (**Figure 2**(**b**)). However, the avian viruses do encode an ORF that resembles X but lacks an initiation codon; it is not know whether this is expressed during infection.

The hepadnaviruses replicate by reverse transcription of a pregenomic RNA and have been termed 'pararetroviruses'. The replication of HBV, many features of which were elucidated using as a model DHBV in its natural host, is discussed elsewhere in this encyclopedia. Briefly, the viruses are believed to enter the host cell via endosomes with delivery of the genomes to the nucleus, where they are converted to a covalently closed circular (ccc) form that is the template for transcription. The pregenomic RNA, which is also the mRNA for the nucleocapsid protein and polymerase, has a stem–loop structure near to the 5′ end. This is recognized by the polymerase, which also acts as a protein primer, and DNA synthesis begins, also signaling encapsidation. Reverse transcription and second-strand synthesis take place in immature cores in the cytoplasm; completion of the cores being followed by envelopment and exocytosis. Early in infection, some nascent cores cycle back to the nucleus to build up a pool of ccc DNA templates.

Genetic Variation and Epidemiology

HBV originally was typed serologically on the basis of the reactivity of HBsAg. All types share a common determinant known as *a*; this has been mapped to a hydrophilic region, roughly between amino acid residues (aa) 111 and 156 of the (226 aa) small surface protein, S. This highly

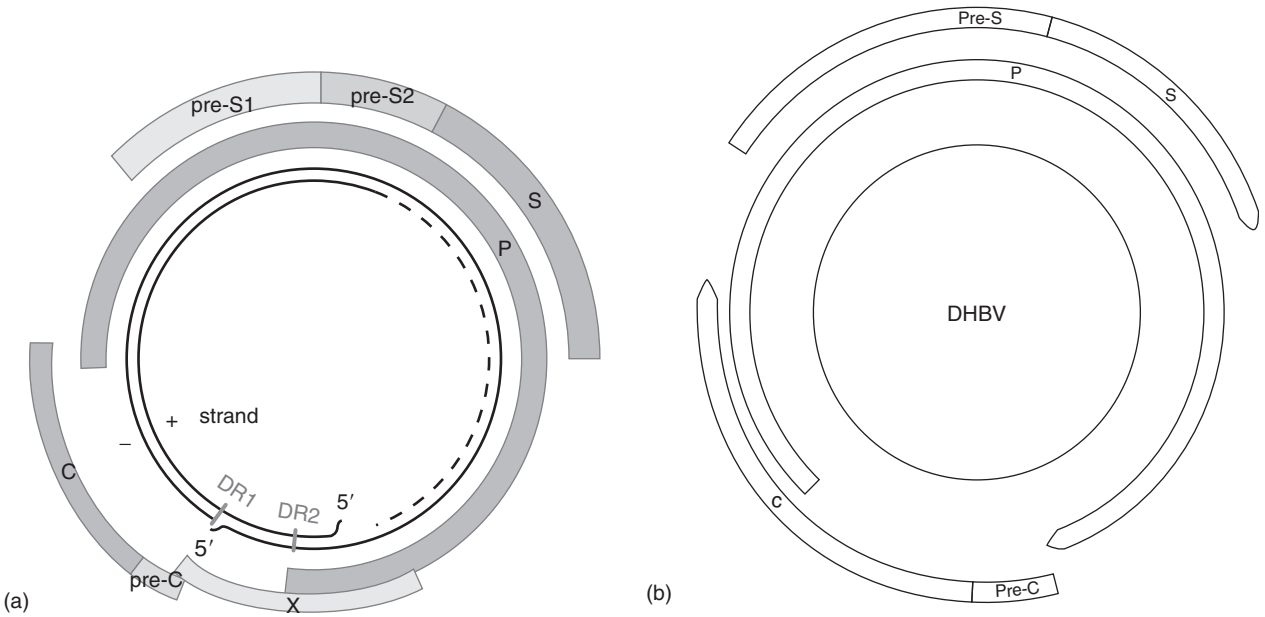

Figure 2 (a) Organization of the HBV genome. The inner circles depict the complete minus strand and incomplete plus strand and the positions of the direct repeats (DR) are indicated. The blocks surrounding the genome show the locations of the four overlapping ORFs; C and S contain two and three in-frame initiation codons, respectively. (b) Organization of the DHBV genome. A simplified view illustrating the single pre-S region and lack of an X ORF. (a) Reproduced from Kidd-Ljunggren K, Miyakawa Y, and Kidd AH, *et al.* (2002) Genetic variability in hepatitis B viruses. *Journal of General Virology* 83: 1267–1280, with permission from Society for General Microbiology.

conformational region, comprising a number of overlapping epitopes, is the main target of the humoral response, and antibodies synthesized during convalescence or in response to the hepatitis B vaccine are protective. Two pairs of mutually exclusive subdeterminants, *d* or *y* and *w* or *r*, correlate with variation (in both cases between lysine and arginine) at aa 122 and aa 160, respectively. Thus, four principal subtypes are recognized (*adw*, *adr*, *ayw*, and (rarely) *ayr*) and these show varying geographical distribution.

The error-prone nature of HBV DNA replication, via an RNA intermediate and without proofreading, is balanced by constraints on variation imposed by overlapping ORFs and the various *cis*-acting elements all being embedded in ORFs. Nonetheless, individual isolates of HBV vary by up to 10–14% of nucleotide positions and genotypes have been defined on the basis of >8% nucleotide sequence divergence. Currently, eight genotypes (A–H) are recognized and most of these have been divided further into subgenotypes. Genotype A is found in northern Europe and North America, B and C in east and Southeast Asia, D in a wide area though southern Europe and North Africa to India, E in western Africa, and F in South and Central America. Arguably, too few of the most recently described genotypes have been isolated to establish an epidemiological pattern, but G has been found in the USA and Europe, and H in the USA and Central America.

HBV has also been isolated from a variety of nonhuman primates. The first such complete sequence was derived from HBV from a captive chimpanzee and, at the time, it was not possible to determine whether this represented a divergent human isolate (i.e., the result of an unintentional human-to-chimpanzee transmission) or a genuine chimpanzee virus. Some years later, a related virus was isolated from a white-handed gibbon (*Hybolates lar*) and complete sequences now are available from a considerable number of chimpanzees, gorillas, orangutans, and gibbons. The most divergent of the primate hepadnaviruses sequenced at the time of writing is from the woolly monkey (*Lagothrix lagotricha*), a New World monkey. Woolly monkey HBV (WMHBV) shows around 20% nucleotide sequence divergence from HBV.

Figure 3 shows a dendrogram of the eight human HBV genotypes along with the primate viruses and rooted using WMHBV as an outgroup. Fewer genome sequences are available for the rodent hepadnaviruses. Isolates of WHV vary in fewer than 4% of nucleotide positions and differ from GSHV and ASHV in around 15% (no sequence is available for RGSHV). **Figure 4** shows a dendrogram of the primate and rodent hepadnavirus sequences, rooted using DHBV as an outgroup.

As noted above, the avian hepadnaviruses show somewhat less-restricted host specificity than those infecting mammals. **Figure 1** shows a phylogenetic tree of viruses isolated from ducks, geese, herons, storks, and cranes.

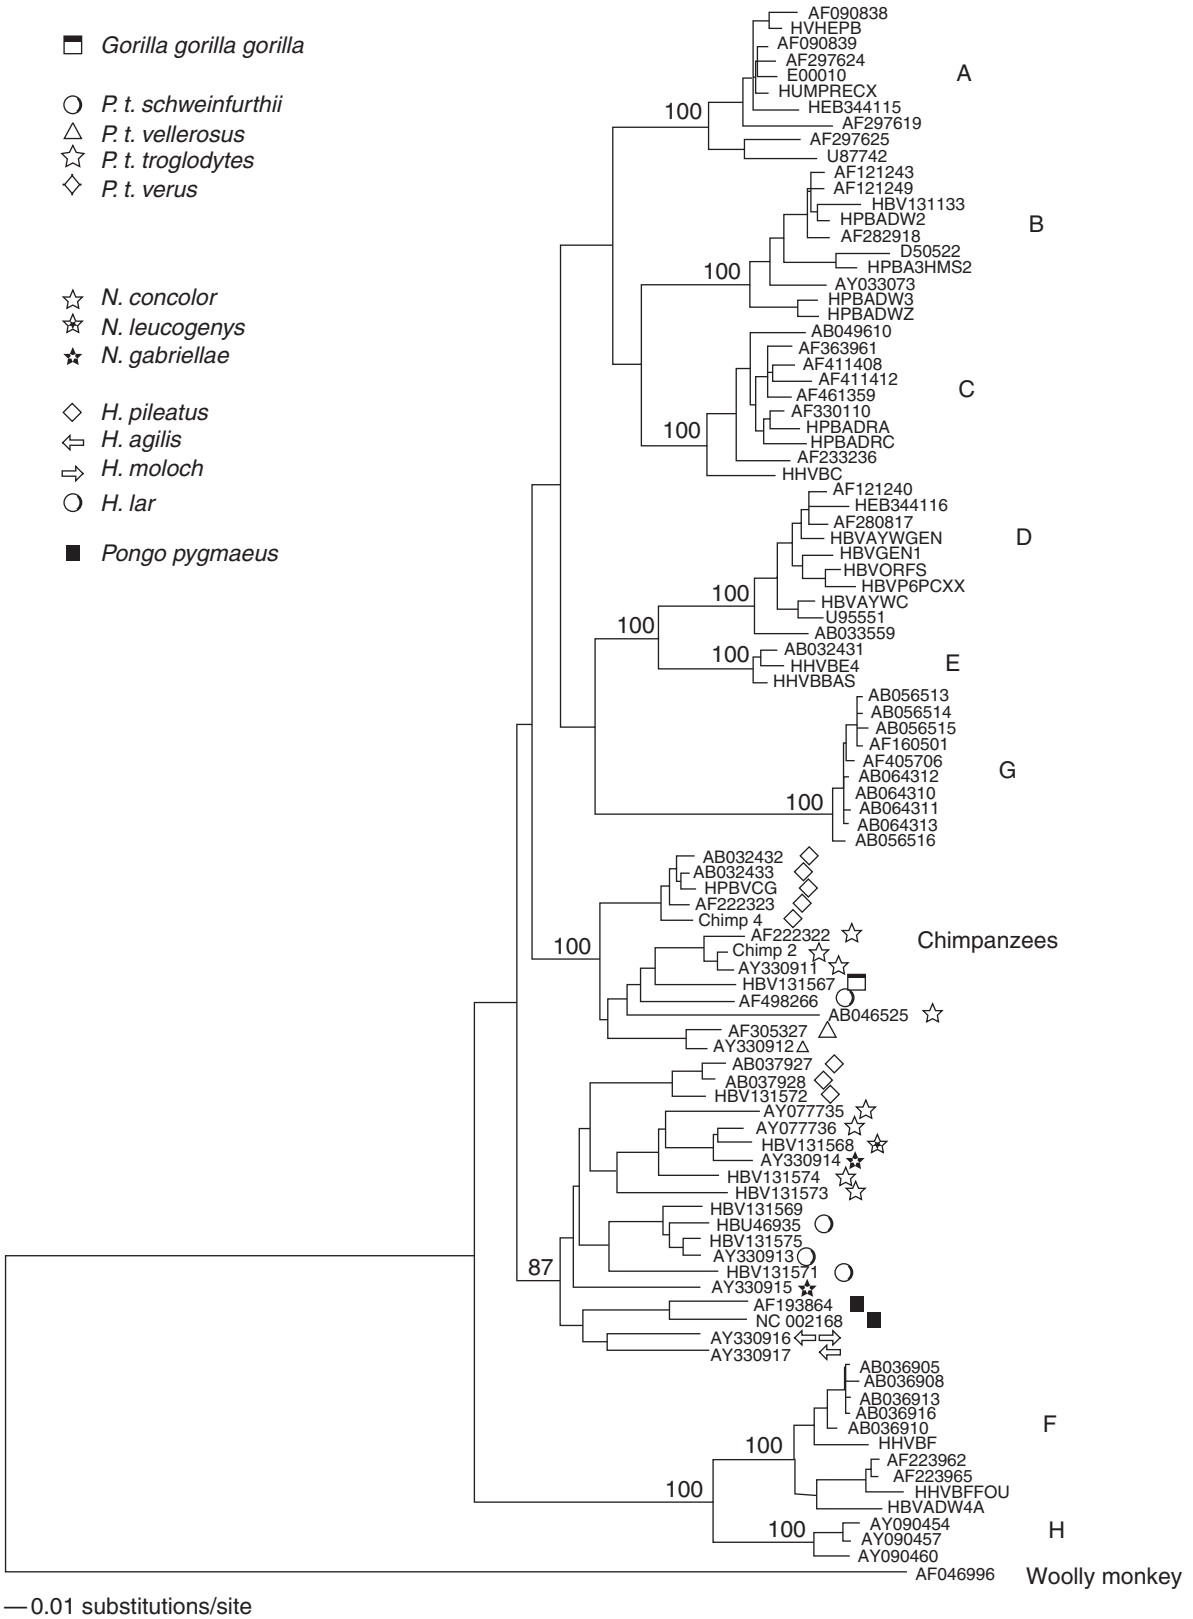

Figure 3 Dendrogram showing the relatedness of the eight genotypes of HBV and hepatitis B viruses isolated from nonhuman primates. The tree is rooted using the woolly monkey HBV sequence as an outgroup. Reproduced from Starkman SE, MacDonald DM, Lewis JCM, Holmes EC, and Simmonds P (2003) Geographic and species association of hepatitis B virus genotypes in non-human primates. *Virology* 314: 381–393, with permission from Elsevier.

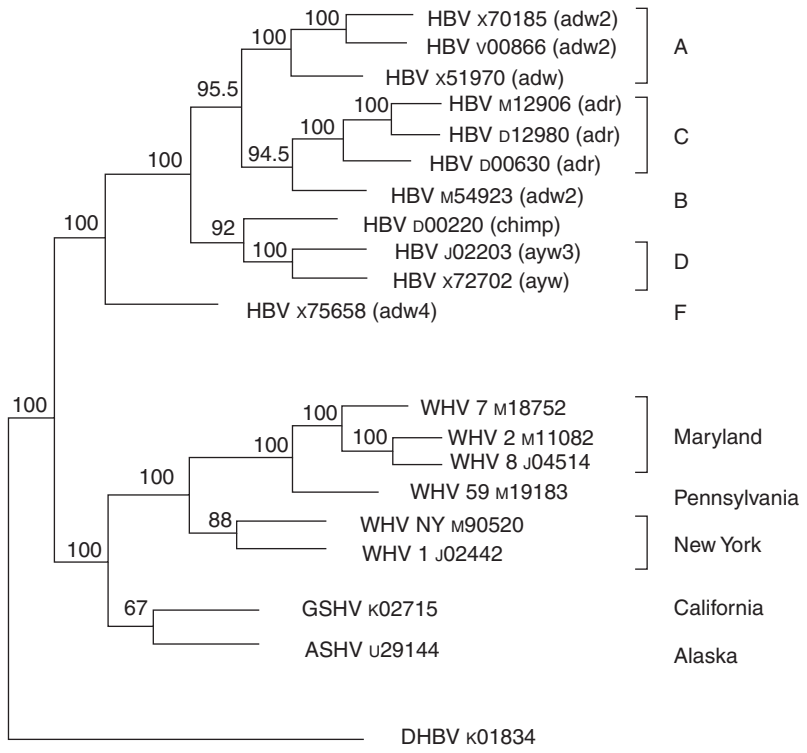

Figure 4 Dendrogram showing the relatedness of HBV and the rodent hepadnaviruses, rooted using DHBV as an outgroup. Reproduced from Testut P, Renard CA, Terradillos O, *et al.* (1996) A new hepadnavirus endemic in arctic ground squirrels in Alaska. *Journal of Virology* 70: 4210–4219, with permission from American Society for Microbiology.

Some of these viruses may originate from species of birds other than those from which they were first isolated, and it seems quite possible that many other varieties of avian hepadnaviruses remain to be described.

Clinical Features and Pathology

The clinical features of acute viral hepatitis in humans are nonspecific and are not dependent on the etiology of the infection; they include fatigue, anorexia, myalgia, and malaise. Jaundice may be evident in the more severe cases, but often the infections may be anicteric (without jaundice) or even asymptomatic. In hepatitis B, these clinical features are evidence of a robust immune response to the virus and a sign that the infection will be cleared by the immune system. In a minority of cases, less than 5% of immune competent adults, asymptomatic infections persist in individuals who do not mount a vigorous immune response. Such persistent infections, originally termed the chronic carrier state, are defined formally by the persistence of HBsAg in serum for more than 6 months.

When a persistently infected woman gives birth, she will almost invariably pass on the virus to her infant. HBV normally does not cross the placenta and transmission is believed to occur during or immediately after the birth process. Infants who are infected perinatally have a very high probability (>90%) of becoming persistently infected – they are extremely immune tolerant of the virus and the infection may persist even for life. A soluble protein, HBeAg, which is related to the nucleocapsid protein, is secreted from the infected hepatocytes and may cross the placenta and induce tolerance in the foetus. A protein equivalent to HBeAg is made by all of the hepadnaviruses, including the avian viruses.

HBV infections of children up to the age of 5 also are much more likely to progress to chronicity than those in adults. Thus, in regions of the world where HBV is highly endemic, and more than 8% of individuals are persistently infected, the virus is maintained in the population by mother-to-infant transmission and horizontal transmission from persistently infected young children to their peers. These regions include sub-Saharan Africa, China, and Southeast Asia (**Figure 5**). Areas of intermediate endemicity (2–7% of individuals persistently infected) include North Africa, Eastern Europe, and northern Asia. In areas of low endemicity, such as North America and Western Europe, important routes of transmission include sexual contact and parenteral exposure.

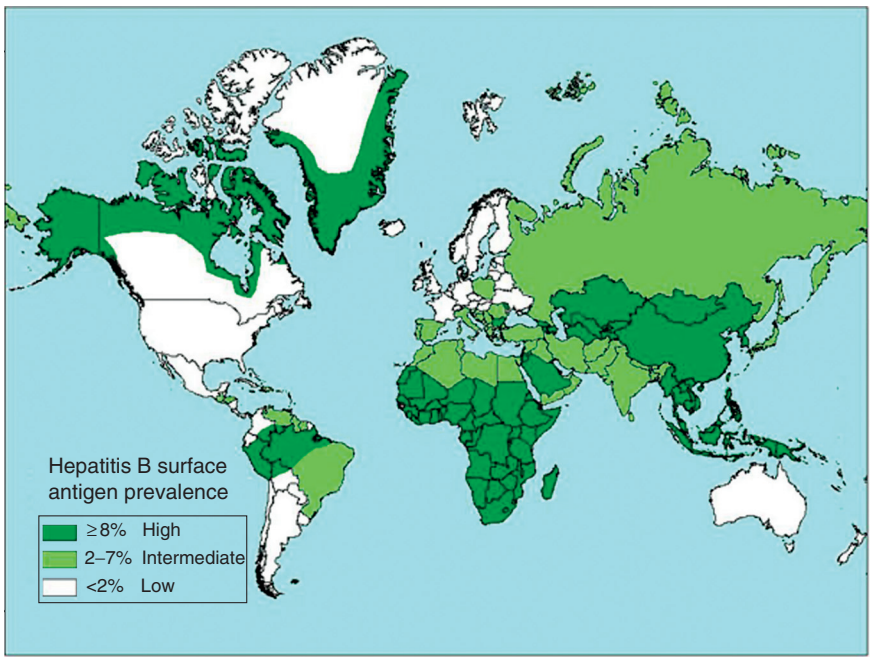

Figure 5 Global prevalence of persistent HBV infection (HBsAg in serum). Reproduced from http://www.cdc.gov/ncidod/diseases/hepatitis/slideset/hep_b/slide_9.htm, with permission from Central Food Technological Research Institute.

HBV seems not to be cytopathic and, in immune tolerant individuals, massive amounts of virus may be produced over long periods of time with little damage to the liver. However, such replication leads to the accumulation of hepatocytes with integrated (partial) copies of the viral genome and these seem to be at high risk of becoming neoplastic. Integration is not part of the HBV life cycle and seems to be a dead-end for the virus, but may be detected in almost all HBV-associated primary liver tumors.

In persistent infections, tolerance may break down over time, particularly with a cell-mediated immune response to the virus. Liver damage is attributable especially to the lysis of infected hepatocytes by cytotoxic T cells and peptides derived from the core (C) ORF seem to be a major target. In the long term, chronic active hepatitis may lead to the development of fibrosis, cirrhosis, and ultimately, end-stage liver failure. Cirrhosis also is a high risk for the development of primary liver cancer (hepatocellular carcinoma, HCC). However, almost all HCCs arising in HBV-infected livers contain chromosomally integrated HBV DNA and, in contrast to hepatitis C, in hepatitis B HCC may develop in the absence of cirrhosis and even on a background of almost normal liver histology.

The rodent hepadnaviruses can also become persistent in their natural hosts and chronic hepatitis, cirrhosis, and HCC may ensue. On the other hand, DHBV infection of ducks results in very little pathology, the infection may be passed vertically through the egg, and hatchlings are extremely immune tolerant of the virus. The avian and rodent systems have been studied experimentally. DHBV in its natural host has been especially useful. As noted above, the DHBV system had an important role in the elucidation of the mode of replication of the viral DNA. It has also been valuable for testing nucleoside and nucleotide analogs for potential therapeutic use. Despite their closer relatedness to humans, woodchucks are not best suited to experimentation; they are large, hibernate in the winter, and wild-caught animals have many parasites. Nevertheless, these animals have been used in various studies, including investigations of the actions of antiviral agents, the immune response in chronic infection, and the development of HCC.

Prevention and Treatment of Infection

HBV infection can be prevented by immunization, intramuscular administration of HBsAg leading to a protective anti-HBs response. The first vaccine (so-called plasma-derived vaccine) was produced by purifying HBsAg from the plasma of hepatitis B carriers. Second-generation vaccines contain HBsAg produced from yeast or (less commonly) mammalian cells by recombinant DNA technology. The World Health Organization recommends universal immunization of infants and this is now carried out in many countries. The key is to break the chain of transmission from infected mothers to their infants, and

giving the vaccine within 24 h of birth protects 70–90% of such babies. Protective efficacy may be increased by giving passive protection with hepatitis B immune globulin (HBIG) at a contralateral site. In Taiwan, one of the first countries with a high prevalence of HBsAg to introduce universal immunization of infants, that prevalence has been reduced from more than 10% to less than 1% in the immunized cohort. Furthermore, although HCC is very rare in children, the incidence of childhood HCC has been reduced and all indications are that universal immunization against hepatitis B will, in time, lead to a marked decrease the incidence of HCC worldwide.

Prior to the introduction of nucleoside and nucleotide analogs, persistent HBV infection was treated most often by the administration of interferon. Up to 30% of individuals so treated cleared the virus. Interferon seemed to work by upregulating the cytotoxic T-cell response to the virus, rather than by a direct antiviral action. Responses were notably poor in patients from China and the Far East, presumably because these individuals had been infected early in life and were very immune tolerant.

As noted above, HBV replicates via reverse transcription of an RNA pregenome, and some of the nucleoside and nucleotide analogs introduced for the treatment of human immunodeficiency virus (HIV) infection are also active against HBV. The first to be licensed for such use was lamivudine (3TC); monotherapy reduces the viral load considerably but resistance develops in around 15% of treated patients per year. Resistance parallels that seen in HIV, with mutations affecting the 'YMDD' motif in the active site of the polymerase. Resistance to adefovir dipivoxil arises less frequently and the drug is active against lamivudine-resistant HBV. Other drugs also have been licensed but regimens of combined therapy are less well developed than those used for HIV. It should be noted also that, while such treatments reduce the viral load considerably, they rarely result in complete clearance of the infection.

Hepatitis D Virus

HDV merits a brief mention because of its particular association with HBV. As noted above, a novel antigen, termed delta, was discovered in patients with hepatitis B and this turned out to be the nucleocapsid protein of HDV. The HDV genome is a single-stranded circle of RNA that resembles the viroids and virusoids of plants; it is believed to be replicated by the host RNA polymerase II, with cleavage and rejoining of the circle mediated by a ribozyme activity. Unlike the viroids and virusoids, the RNA contains (in the antigenomic sense) an ORF, encoding the delta antigen. HDV requires HBsAg for envelopment and exocytosis, and for subsequent binding and entry to the target hepatocyte. HDV has been transmitted experimentally to WHV-infected woodchucks and is there enveloped by WHsAg.

HDV was first discovered in Italy and is found in the Mediterranean area, reportedly with a declining prevalence, and also in the Far East and South America. The virus may be acquired as a coinfection with HBV or by super-infection of someone already HBsAg-positive. In both cases, disease may be more severe than with HBV alone, and chronic delta hepatitis may progress to cirrhosis more frequently, and more rapidly, than chronic hepatitis B. The hepatitis B vaccine also protects against coinfection but there is no licensed vaccine to protect hepatitis B carriers against HDV infection.

Glossary

Antibody prevalence The percentage of a population with antibodies against a certain disease at a given time.
Aplastic anemia Disease characterized by a decrease in blood cells resulting from underproduction due to bone marrow failure; also called hypoplastic anemia.
Incidence The rate of occurrence of new cases of a particular disease in a population in a certain period of time.
Polyprotein processing Cascade of proteolytic cleavage events resulting in release of mature proteins from the polyprotein.
Serine-like protease Proteolytic enzyme characterized by a catalytic triad similar to that in serine-type proteases with Ser, His, and Asp.

History

Jaundice has been known as an epidemic disease for centuries, but the earliest outbreaks of what was almost certainly hepatitis A were documented by Rayger, occurring in Preßburg, now Slovakia, in 1674 and 1697. Besides sporadic occurrence of the disease, characterized by a slow increase and slow decrease of the number of infected persons in the course of months (spread by person-to-person contact), with an overall small number of infections, larger vehement epidemics (spread by contaminated water and food) were reported in later times. The first pandemic wave occurred in the 1860s and the first considerable record of the disease was registered during the American Civil War.

In the second half of the nineteenth century, the disease became known as 'icterus catarrhalis' (catarrhal jaundice; inflammation of the biliary tract was supposed) or 'icterus epidemicus' (epidemic jaundice) as well as campaign jaundice, as epidemics are common in military medical history.

At the turn of the nineteenth to the twentieth century, the disease was recognized as infectious and transmissible by person-to-person contact. The terms 'hepatitis epidemica' (epidemic hepatitis) and 'hepatitis infectiosa' (infectious hepatitis) were introduced as synonyms for catarrhal jaundice.

Detailed epidemiologic recordings have been conducted since the beginning of the twentieth century. Two large pandemic waves were observed during the twentieth century, the first one originating during World War I and reaching its summit between 1918 and 1922, and the second one originating in the early 1930s reaching its widest distribution with the beginning of World War II.

During World War II, hepatitis had been demonstrated to be caused by at least two separate filterable agents, and the resulting diseases were called hepatitis A (infectious hepatitis) and B (serum hepatitis), and the etiological agents hepatitis A virus (HAV) and hepatitis B virus (HBV), respectively.

After World War II, epidemiologic studies in human volunteers showed that hepatitis A is spread by the fecal–oral route, and provided information on the duration of viremia and shedding of virus in feces. In the late 1960s and early 1970s, it was shown that marmoset monkeys and chimpanzees could serve as animal models for human hepatitis A, and replication of HAV in cell cultures was established between 1979 and 1981.

The etiologic agent was identified through immune electron microscopy by Feinstone *et al.* in 1973.

The molecular cloning of the HAV genome in the 1980s revealed that the genomic organization of HAV is similar to that of picornaviruses, and the first infectious cDNA clone of HAV was reported by Cohen *et al.* in 1987.

The disease manifestations by hepatocellular destruction could be attributed to an immunopathogenic mechanism in the late 1980s by Vallbracht *et al.*

An inactivated vaccine has been available since 1992.

Taxonomy

HAV is the only member of the genus *Hepatovirus* within the family *Picornaviridae.*

All human HAV strains known belong to only one serological group, but phylogenetic analysis of the VP1–2A junction region and the VP1 coding region, respectively, revealed that several distinct HAV genotypes (seven in the case of VP1–2A junction analysis, five in the case of VP1 region analysis), which include several subgenotypes, can be distinguished by the degree in their genetic heterogeneity. These genotypes correlate with the geographic origin of the virus isolates. Genotype I is the most common type worldwide, particularly genotype IA. The cell culture-adapted viruses most commonly used are variants of the Australian strain HM175 (genotype IB) and the German strain GBM (genotype IA).

Morphology and Physicochemical Properties

The infectious spherical virion is a nonenveloped particle with a diameter of *c.* 27 nm. The icosahedral capsid, which embodies the viral RNA genome, contains 60 copies of each of the three major proteins, VP1 (also known as 1D), VP2 (1B), and VP3 (1C) (see **Table 1**). It is not known whether the small protein VP4 (1A) is integrated into the capsid. The mature HAV virion seems to have a different structure than other picornaviruses, as a usually prominent feature of picornaviruses and one which represents the viral attachment site to cellular receptors, the canyon surrounding the fivefold symmetry axes, is obviously missing.

The HAV particle has a buoyant density of *c.* 1.33 g cm^{-3} in CsCl and a sedimentation coefficient of *c.* 160S. Empty capsids found in feces have a sedimentation constant of about 70S. HAV is extremely resistant to acid (pH 1.0 for 2 h at room temperature) and thermal inactivation (60 °C for 1 h).

Genome Organization and Expression, Replication, Morphogenesis

The linear, single-stranded, positive-sense RNA genome of HAV is ~7500 nt in length and is not capped but covalently linked by a tyrosine-O^4-phosphodiester bond to the 2.5 kDa viral protein 3B (also known as VPg; see **Table 1**). It encompasses a structurally complex 5′ nontranslated region (NTR) of ~740 bases, followed by a single open reading frame encoding a polyprotein (*c.* 250 kDa; ~2230 amino acids) and a 3′ NTR of ~60 bases which terminates with a poly(A) tail of about 60 nt. In the polyprotein, the capsid proteins and those with functions during virion assembly represent the N-terminal third (VP4, VP2, VP3, VP1, also known as P1 region, and 2A) (see **Table 1** and **Figure 1**) with the remainder of the polyprotein comprising a series of proteins required for RNA replication (2B and 2C followed by 3A to 3D) (see **Table 1** and **Figure 1**).

The viral polyprotein is translated directly from the messenger-sense genomic RNA, which is released into the cellular cytoplasm after uncoating of the virion. An internal ribosomal entry site (IRES) located within the 5′ NTR (see **Table 1**) is involved in the cap-independent initiation of protein synthesis. The IRES of HAV differs from that of other picornaviruses and forms its own group (type III picornavirus IRES). Translation from the HAV IRES requires all of the initiation proteins, including eIF4E and intact eIF4G, and infection with HAV does not result in cleavage of the translation initiation factor eIF4G to block cap-dependent host protein synthesis, as featured by other picornaviruses. The HAV IRES directed initiation of translation, which depends on the entire 5′ NTR, is enhanced by sequences of the 5′ terminal coding region and by the cellular protein poly(A) binding protein (PABP), which mediates circularization of the template RNA and seems to be necessary for HAV protein translation. Involvement of the host cells poly(C) binding protein 2 (PCBP2), polypyrimidine tract binding protein (PTB), and glyceraldehyde 3-phosphate dehydrogenase (GAPDH) is described, but the functional significance of these interactions is uncertain.

Proteolytic processing of the primary polyprotein (see **Figure 1**) occurs simultaneously with translation and is largely carried out by the viral 3C protease, which is a serine-like protease in which cysteine replaces the nucleophilic serine in the catalytic triad of the active center and for which, in contrast to other picornaviruses, no additional cellular substrate has been described so far.

Synthesis of viral RNA by the viral 3D polymerase follows the accumulation of the nonstructural proteins spanning 2B to 3D, which induce the assembly of a macromolecular replication complex on membranes that are recruited from the endoplasmatic reticulum. The proteins 2B, 2C, and 3A may be involved in the structural rearrangements of the intracellular membranes. RNA transcription is most likely protein-primed, with the uridylylated VPg protein 3B representing the primer for the negative-sense RNA replication intermediate and the subsequent positve-sense genomic RNA synthesis. A participation of the 5′ terminal NTR structures in the switch from translation to replication on the same viral RNA is suggested.

HAV morphogenesis is poorly understood. The primary polyprotein cleavage event occurs at the 2A/2B junction mediated by the 3C protease resulting in the structural precursor P1–2A. The steps then resulting in particle formation are not entirely clear, but the following model is suggested (see **Figure 1**). The P1–2A structural precursors assemble to a pentameric structure and are further cleaved by the 3C protease to generate the precursors VP4–VP2 (also known as VP0) and VP1–2A, as well as VP3 resulting in the structural building block $(VP0, VP3, VP1–2A)_5$. The 2A C-terminal extension of VP1 is a critical structural intermediate in virion morphogenesis, maybe clamping the pentamer at the fivefold symmetry axis. After assembly of 12 such pentamers with the genomic RNA to provirions ($12 \times (VP0, VP3, VP1–2A)_5$-RNA), two subsequent maturation cleavage events occur. First, the cleavage at the VP1/2A junction leading to the removal of 2A seems to result from the action of an unknown host protease and, second, VP0 is cleaved into VP4 and VP2 by an unknown mechanism. 2A has never been identified in infected cells, which may indicate an extracellular cleavage event for the VP1–2A processing, and the role of VP4 in virion morphogenesis is mysterious. While the HAV polyprotein appears to

Table 1 HAV regulatory genomic regions and HAV proteins; all numbering refers to HAV strain HM175 (accession no. NC_001489)

Regions/proteins	*Nucleotide position*	*Length in amino acids*	*Proposed or known function*	*Remarks*
5′ nontranslated region (5′ NTR)	1–734		5′ stem–loop region (nucleotides 1–94): required for RNA replication	Mechanisms regulating switch from translation to replication are not clear
			Polypyrimidine tract pY1 (nucleotides 99–138): unknown function	
			Internal ribosomal entry site (IRES) (nucleotides 152–734): directs cap-independent initiation of translation	Picornaviral type III IRES
3′ nontranslated region (3′ NTR)	7416–7478		Involved in regulation of RNA replication	
			Extended by 40–80 adenylates, which are structurally involved in translation (closed-loop model)	
1A	735–803	23	VP4	Not myristoylated
			Morphogenesis	So far not identified in mature virions
1B	804–1469	222	Capsid protein VP2	During morphogenesis, precursor VP4–VP2 (VP0), presumably cleaved autocatalytically
1C	1470–2207	246	Capsid protein VP3	
1D	2208–3023/ 3026/ 3029	272 273 274	Capsid protein VP1	Heterogeneous C-terminus, presumably depending on HAV strain and host cell
				During morphogenesis, precursor VP1–2A, presumably cleaved by cellular protease

2B	3243–3995	251	Structural rearrangements of intracellular membranes for replication	Peripheral association with membranes
				Influence on membrane permeability
				Mutations accompany adaptation to growth in cell culture
2C	3996–5000	335	Structural rearrangements of intracellular membranes for replication	Integral association with membranes
				Mutations accompany adaptation to growth in cell culture
3A	5001–5222	74	As 3AB VPg precursor (pre-VPg)	Interacts with membranes, may anchor pre-VPg to cellular membranes through a central region of 21 hydrophobic amino acids
3B	5223–5291	23	VPg (virus protein genomic)	Tyr^{3} attached to 5′ terminus of genomic RNA
			Supposed protein primer for RNA replication	
3C	5292–5948	219	Sole protease	Serine-like protease, with replacement of Ser by Cys in catalytic triad: Cys^{172}, His^{44}, Asp^{84}
3D	5949–7415	489	RNA-dependent RNA polymerase	

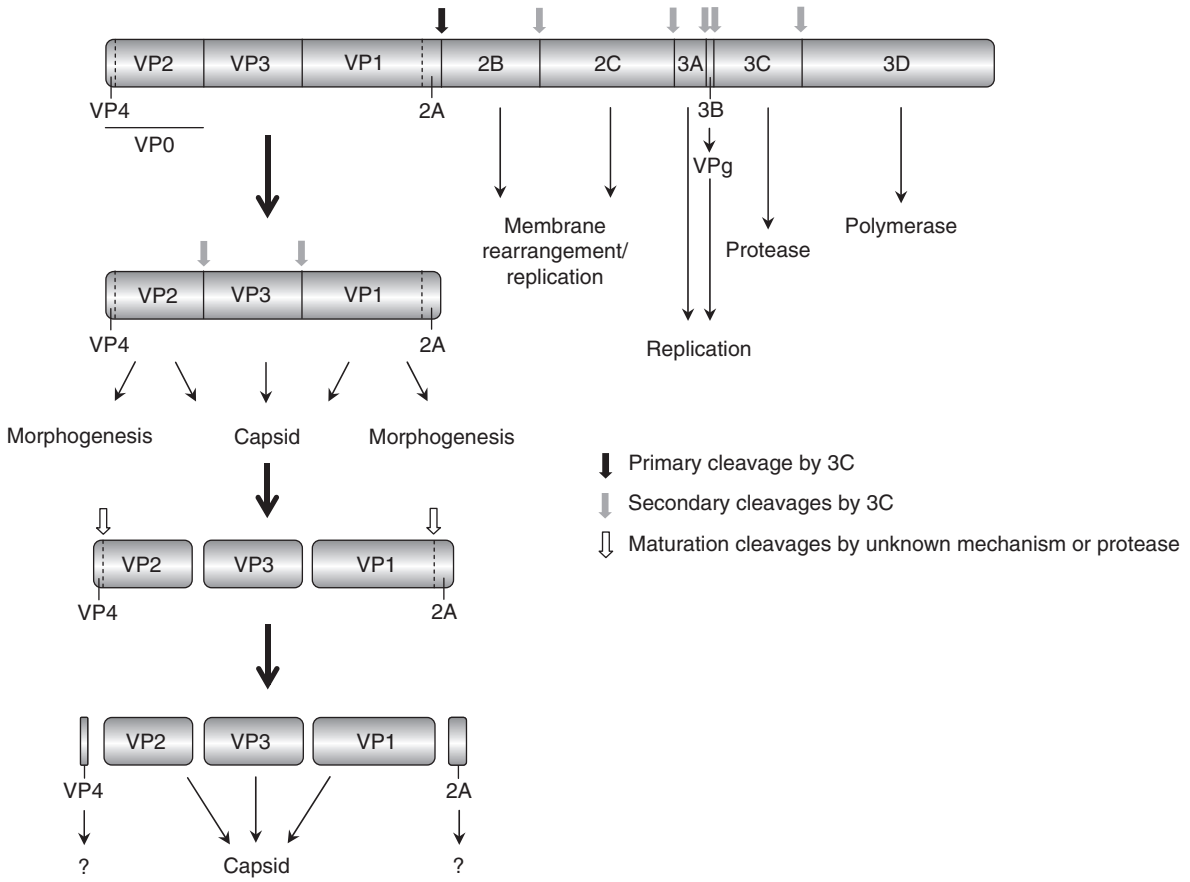

Figure 1 HAV polyprotein processing and known or supposed functions of the viral proteins during morphogenesis and replication. The polyprotein that results from IRES-directed translation is cleaved by the viral protease 3C to release certain precursor proteins with biologically relevant functions as well as the mature nonstructural proteins. Primary cleavage results in release of the structural precursor VP4–VP2–VP3–VP1–2A, which associate to assembly intermediates (pentamers), which are stabilized by 3C cleavage of the VP3 junctions (VP4–VP2 (VP0), VP3, VP1–2A)$_5$. After assembly of the intermediate protein building blocks and the viral genome to provirions, maturation cleavages occur through an unknown proteolytic activity to release VP4 from VP2 and by a so far unknown cellular protease to release 2A from VP1, resulting in the infective virion with 60 copies of each of the main structural proteins VP1, VP2, and VP3.

possess the short VP4 segment at its N-terminus, this putative VP4 moiety has never been identified in virions. Moreover, the HAV-VP4 sequence does not contain a myristoylation signal, which is important for the morphogenesis of other picornaviruses.

Host Range, Transmission, and Tissue Tropism

Under natural conditions, only humans and certain species of nonhuman primates seem to be susceptible to HAV. These primates, which are also used as animal models, include chimpanzees, marmosets, and owl monkeys.

HAV is transmitted via the fecal–oral route. As the virus is excreted in feces, it is typically acquired by ingestion of feces-contaminated food or water. Direct person-to-person spread occurs under poor hygienic conditions.

The site of replication is the liver. The events that occur during the passage of HAV across the intestinal epithelium into blood, in which the virus reaches the liver, are not clearly understood. Although HAV antigen and the T-cell immunoglobulin mucin 1 (TIM1; function so far unknown) protein, which has been identified as a cell surface protein binding HAV (HAV_{cr1}), could be detected in different organs, such as kidney, spleen, and gastrointestinal tract, no extrahepatic sites of HAV replication have been clearly identified. Furthermore, it was demonstrated that infection of polarized intestinal cells does not result in penetration of the epithelium. A functional cellular receptor, whose selective expression in the liver is assumed, could not be identified so far. Some studies suggest that the hepatotropism of HAV may be supported by immunoglobulin A (IgA)-virus complexes (HAV/IgA), as HAV/IgA uptake via the hepatocellular asialoglycoprotein receptor (ASGPR) results in infection of hepatocytes (IgA-carrier hypothesis).

The virus progeny produced in the liver is then released back into the intestinal tract via bile.

Cell Culture and Growth Characteristics

HAV can infect a variety of primate and nonprimate cell lines, including nonhepatic cells, *in vitro*. The virus exhibits a protracted replication cycle and normally establishes a noncytolytic, persistent infection with low virus yields, and there is no evidence that HAV notably interferes with the macromolecular synthesis of its host cell. After infection of cultivated cells with wild-type virus, a minimum of 8 weeks elapses before HAV can be isolated. Although a more rapid replication and higher virus titers are obtained after serial virus passages in cultivated cells resulting in cell culture-adapted viruses, even the replication of these virus variants is not detectable within the first few days after infection. Adaptation of HAV to growth in cultivated cells seems to be achieved by varying sets of multiple interacting mutations, with adaptive mutations within the IRES enhancing viral translation in a cell-type-specific fashion, and mutations clustering in the 2B and 2C proteins (see **Table 1**) increasing replication regardless of the cell line used.

The virus apparently downregulates its own replication and this may, for example by supporting the ability of HAV to inhibit innate cellular antiviral defense mechanisms, be important for the establishment of persistent infections. A large proportion of the virus progeny remain cell associated, but extensive release of HAV from the cells also occurs, caused by an unknown mechanism.

Several cytopathogenic variants of HAV have been isolated which induce apoptosis resulting in cell death. These variants are highly cell culture adapted and characterized by a rapid replication phenotype and high virus yields. In these variants, both the downregulation of viral replication and the ability to inhibit the innate defense mechanisms are less effective. The molecular mechanisms resulting in apoptosis are not known.

Clinical Features and Pathology

Infections with HAV may produce a wide spectrum of manifestations ranging from silent infections, over icteric courses to fatal fulminant hepatitis. The acute icteric course of infection varies between common, over prolonged to relapsing hepatitis A. Persistent infections or chronic disease have not been described.

The clinical presentation of the disease depends on the age of infection. The likelihood of having symptoms and the severity of the disease increases with the age of the patient. Inapparent infections (asymptomatic or at least anicteric) are normally observed in very young children, under the age of 2. However, clinically obvious disease can occur even in infancy (aged 2 weeks to 8 months) and may be characterized by prolonged courses. In children under 5 years of age *c.* 3%, in children 5–15 years old *c.* 30%, and in individuals over the age of 18 years as many as 70% may develop a clinically apparent disease.

Common Course of Infection

The incubation period ranges from 2 to 6 weeks with a mean duration of 4 weeks. The prodromal (preicteric) period of normally 4–6 days (which may vary from 1 day to more than 2 weeks) is characterized by nonspecific symptoms, like anorexia, nausea with vomiting, malaise, abdominal pain, loss of appetite, accelerated pulse, rash, headache, and fever (38–39 °C) as well as by gastrointestinal symptoms, normally in form of obstipation, but diarrhea is also observed.

The prodromal symptoms disappear with the onset of jaundice, which is seldom abrupt (in 15% of the cases no obvious prodrome is observed before appearance of jaundice). The icteric phase, which ranges from 2 to >22 days (mean duration 3 weeks), is marked by jaundice, which may start with scleral icterus, dark beer-colored urine (conjugated bilirubinuria), clay-colored stool, and clearly decelerated pulse.

The reconvalescence period ranges from 3 to 6 weeks, but fatigue, dullness, right upper quadrant tenderness, and fast exhaustion may remain for 2–4 months. In almost all cases the liver is enlarged.

The clinical symptoms are accompanied by several biochemical parameters (see **Figure 2**). Elevation of aminotransferase levels in serum (alanine aminotransferse (ALT) and to a lesser degree aspartate aminotransferase (AST)), which reflect hepatocellular damage with release of the liver enzymes into the circulation, roughly correlate with the severity of the disease. Elevation of serum alkaline phosphatase activity and in the serum bilirubin level relate to intrahepatic cholestasis.

At the onset of symptoms, seroconversion to anti-HAV occurs.

Large amounts of HAV, which are produced in the liver and released into the gastrointestinal tract via bile, already occur in the feces during the late incubation period when no clinical symptoms are observable and are shed for approximately three weeks until a few days after the onset of elevated levels of liver enzymes in the serum. Fecal shedding of HAV reaches its maximum just before the onset of hepatocellular injury.

Viremia occurs a few days before and during the early acute stage of the clinical and biochemical hepatitis, in which it roughly parallels the shedding of virus in feces, but at a lower magnitude.

More sensitive methods (especially nucleic acid amplification technologies) demonstrated that low levels of viral RNA may be present in feces and blood for many weeks.

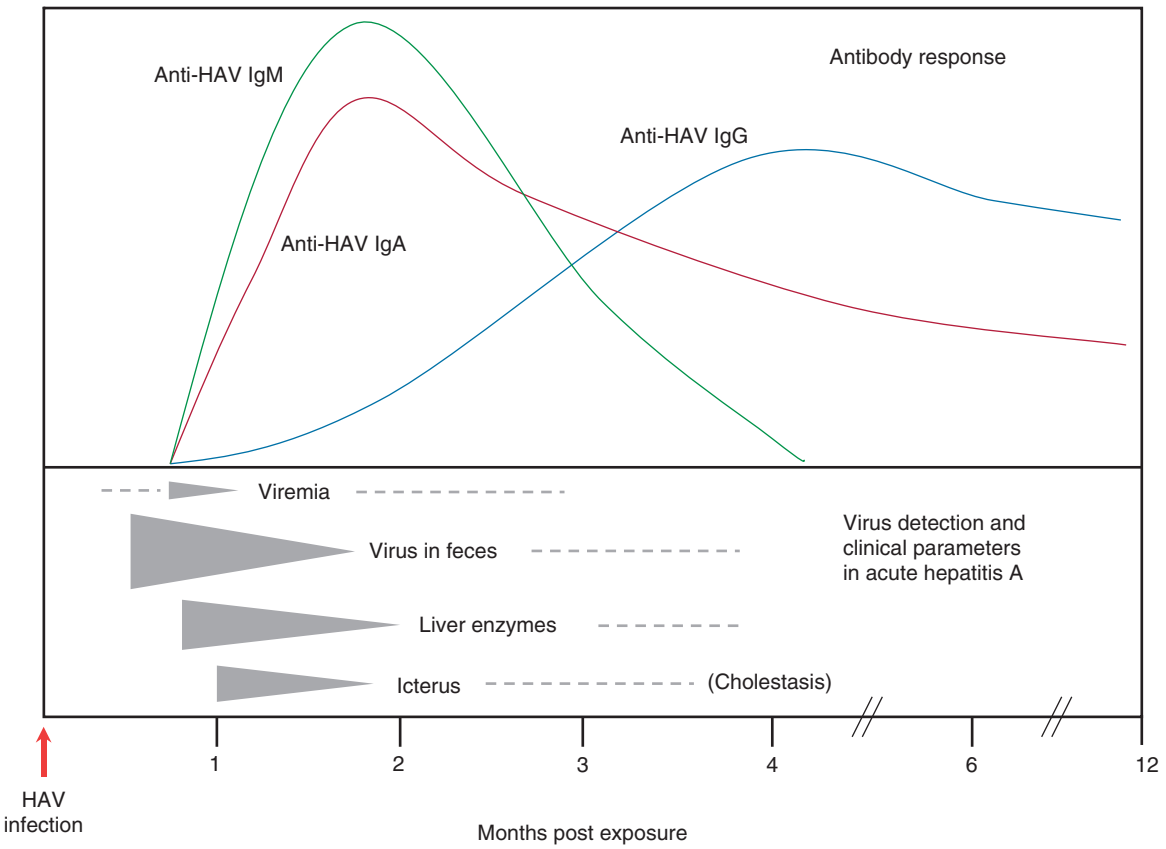

Figure 2 Course of clinically relevant events in acute hepatitis A. This figure schematically shows the mean duration and intensity of certain parameters. The dotted lines indicate that the duration and intensity of the events may vary.

Prolonged Hepatitis A

In 8.5–15% of the cases, jaundice lasts for up to 17 weeks. The biochemical abnormalities are resolved by 5 months. Occasionally, prolonged courses are accompanied by high serum bilirubin levels persisting for months (cholestatic hepatitis A). The cholestatic form is marked by extensive itching of the skin.

Relapsing Hepatitis A

After initial improvement in symptoms and liver test values (serum aminotransferase levels), one or more relapses of the disease (mostly biphasic) are described for up to 20% of the patients. These relapses occur between 30 and 90 days after the primary episode, when high titers of neutralizing antibodies are already present. The severity of symptoms, the biochemical abnormalities, and the immunoglobulin M (IgM) response are essentially the same as observed during the initial phase, with a tendency to greater cholestasis. The pathogenesis of relapsing hepatitis is not understood and basically two hypotheses are suggested: that the disease is a manifestation of a persistent viral infection, or, alternatively, that the relapse may represent a manifestation of an enterohepatic cycling of HAV, which may be supported by anti-HAV IgA (IgA-carrier hypothesis). But none of these hypotheses is currently supported by *in vivo* data.

Fulminant Hepatitis A

In rare cases, acute hepatitis A results in a fatal deterioration in liver function with massive destruction of liver cells. Surprisingly, no vigorous inflammatory response is observed. The fatality rate is below 1.5% of all hospitalized icteric cases. This course of the disease is accompanied with fever over 40 °C. This outcome is more frequent in adults, especially in patients over 50 years of age, than in children, and the risk is increased in patients with underlying chronic liver disease.

Extrahepatic Manifestations

Extrahepatic manifestations of the disease are rare and the etiology is uncertain. Besides frequently observed transient suppression of hematopoiesis, rare cases of aplastic anemia (pancytopenia) with a lethality rate of over 90% are described, and it was demonstrated that HAV infects monocytes and inhibits their further differentiation. In some patients, interstitial nephritis was observed. In connection

with the finding that the HAV-binding receptor HAV_{cr1} is identical with the T-cell immunoglobulin mucin 1 (TIM1), a protein suggested to play a role in asthma susceptibility, and by statistical evaluation of medical records, it was suggested that HAV exposure may leave a protective effect on the development of asthma and allergic diseases.

Pathology

The pathology of the liver in acute hepatitis A has been studied in humans and several animal models. The pathological lesions, which are caused by an immunopathogenic mechanism, are characterized by hepatocellular necrosis, which is most prominent in periportal regions, accompanied with large inflammatory infiltrates of mononuclear cells.

Innate and Adaptive Immune Response

Innate Immune Response

HAV, which does not interfere with the replication of other viruses, prevents the synthesis of beta-interferon (IFN-β), but is not resistant to alpha- and beta-interferon (IFN-α/β) exogenously added to persistently infected cells. It could be demonstrated that HAV does inhibit dsRNA-induced transcription of IFN-β by blocking effectively interferon regulatory factor 3 (IRF-3) activation due to an interaction of HAV with the mitochondrial antiviral signaling protein MAVS (also known as IPS-1, VISA, or Cardif), which is a component of the retinoic acid-inducible gene I (RIG-I) and melanoma differentiation-associated gene 5 (MDA-5) signaling pathway. Signaling through the Toll-like receptor 3 (TLR-3) pathway may also be partially impaired.

HAV also has the ability to prevent apoptosis induced by accumulating dsRNA, but the underlying mechanism is not clear.

Gamma interferon (IFN-γ) produced by HAV-specific HLA-dependent cytotoxic T lymphocytes (CTLs) may contribute to the elimination of HAV infections by inducing an antiviral state in the later course of the infection.

Adaptive Immune Response

Neutralizing anti-HAV IgM antibodies are present in almost all patients at the onset of the symptoms (see **Figure 2**). These antibodies disappear in the course of 3 months, but in the case of prolonged courses IgM can be detected up to 1 year after onset of icterus. Anti-HAV IgA antibodies are also detectable at the onset of the symptoms (see **Figure 2**). This response reaches its peak titer 50 days post infection and may last for >5 years. The majority of the IgA remains as serum IgA in circulation and is not secreted into the intestinal tract as secretory IgA by the polymeric immunoglobulin receptor (pIgR) pathway. But a significant fraction of this serum IgA is released into the gastrointestinal lumen via bile by liver functions under participation of the hepatocellular IgA-specific asialoglycoprotein receptor (ASGPR). The role of IgA antibodies in the protection against HAV infections appears to be limited, and studies suggest that HAV-specific IgA may serve as a carrier molecule for a liver-directed transport of the virus, supporting the hepatotropic infection by uptake of HAV/IgA immunocomplexes via the ASGPR (IgA-carrier hypothesis). Neutralizing anti-HAV immunoglobulin G (IgG) antibodies are also detectable 3 weeks post infection for the first time, but this response develops slowly, reaching its peak titer 4 months post infection (see **Figure 2**). Anti-HAV IgG persists lifelong, although the titer may fall to undetectable levels after several decades. Neutralizing antibodies, which are effective in eliminating the virus from the blood, do recognize a conformational epitope clustered into a major, immunodominant antigenic site involving residues contributed by VP3 and VP1.

HAV-specific, HLA-restricted cytotoxic $CD8^+$ T lymphocytes (CTLs) have been detected within the liver during acute HAV infection and play prominent roles both in eliminating the virus and in causing liver injury (immunopathogenesis). Gamma interferon (IFN-γ), released by these CTLs, may stimulate HLA class I expression on hepatocytes and in the following promote upregulation of the normally low level display of antigen on liver cells. Specific T-cell epitopes have not been identified so far.

Diagnosis

Since the clinical presentation of hepatitis A cannot be distinguished from hepatitis due to the other hepatitis viruses, serologic tests or nucleic acid amplification techniques are necessary for a virus-specific diagnosis.

The routine diagnosis of acute hepatitis A is made by detection of anti-HAV IgM in the serum of patients (see **Figure 2**). A further option is the detection of virus in the feces.

In order to improve the safety of blood and blood products, blood screening with HAV-specific polymerase chain reaction (PCR) is performed, which reduces the window period of up to 3 weeks post infection during which HAV infection fails to be diagnosed by serologic assays.

Epidemiology

HAV occurs worldwide and accounts for over 1.5 million clinical cases reported annually. The seroprevalence pattern ranges from high endemicity, such as in Africa, South Asia, and Latin America, where infection normally occurs in childhood, over intermediate endemicity, such as in Eastern Europe and the northern parts of Asia, to low endemicity, such as in Western Europe and North

America, where the majority of the population remains susceptible to HAV infection. However, the epidemiology pattern is complex and continuously changing, with considerable heterogeneity among different countries. In general, the anti-HAV antibody prevalence inversely correlates with the quality of the hygienic standards, and the incidence declines in many populations through improvements in public sanitation and living conditions. These improvements result in an increase of the pool of susceptible adults, with a shift in the age of infection to older age groups, in which a more severe disease is observed, leading to an increased morbidity.

A minor seasonal distribution of HAV infections is observed, with a peak occurring during fall and winter, mentioned in almost all earlier and contemporary reports, nowadays possibly as a result of exposure during summer vacation spent in endemic countries.

At special risk for acquisition of hepatitis A are international travelers from areas of low endemicity to endemic areas, employees of child-care centers and sewage plants, gully workers, injecting drug users, homosexually active men, and persons with an increased risk of developing a fulminant disease, such as persons with chronic hepatitis C virus (HCV) infections.

The high physical stability of HAV provides a good opportunity for common-source transmission. Community-wide outbreaks are reported in association with infections of food handlers, and linked to contaminated food and drink, or uncooked clams from contaminated water. Hepatitis A is most commonly acquired by sharing the household with an infected person.

Prevention and Control

There is no specific treatment for hepatitis A. As almost all HAV infections are spread by the fecal–oral route, good personal hygiene, high-quality standards for public water supplies, and proper disposal of sanitary waste are important measures to reduce virus transmission.

Until the availability of an active prophylaxis, the disease could be prevented for up to 5 months with a certainty of 80–90% by passive immunization with pooled IgG of at least 100 IU anti-HAV. IgG is still used for postexposure prophylaxis. If administered within 2 weeks after exposure, either development of the disease is prevented or the severity of the disease as well as virus shedding is reduced.

Since 1992, inactivated vaccines for active immunization have been available. These vaccines contain purified, formalin-inactivated virions produced in cell culture, which are absorbed to an aluminum hydroxide adjuvant. They are highly immunogenic and protect against both infection and disease caused by all strains of HAV with 100% efficacy for at least 10 years, which is consistent with the finding that all human HAV strains belong to one single serotype.

Candidate live, attenuated HAV vaccines have been developed using virus adapted to growth in cell culture, but were poorly immunogenic. Nonetheless, such a vaccine has been widely used in China and appears to be capable of inducing protective levels of antibody.

Glossary

Icterus Jaundice, or yellowing of the skin and particularly the whites of the eyes, due to failure to excrete bilirubin, a bile pigment.

History

It was not until the mid-1960s that hepatitis A (HAV) and B (HBV) viruses were recognized as the causative agents for infectious and serum hepatitis, respectively. These studies, performed by Krugman and colleagues at the

Willowbrook State School for mentally handicapped children, were preceded a few years earlier by the description of the Australia antigen in the sera of patients with leukemia. The connection between Australia antigen, or hepatitis B surface antigen (HBsAg) as it is now known, and HBV became apparent in later studies performed by the teams of Prince and Blumberg. These studies set the groundwork for the subsequent serological tests for the diagnosis of HBV and allowed detailed investigations into the epidemiological and virological aspects of infection.

Electron microscopic studies in 1970 by Dane and Almeida and their colleagues led to the visualization of the infectious virion or Dane particle, and the nucleocapsid core, respectively. This was followed in the early 1970s by the characterization of the virus genome, the virion-associated proteins, and the detailed definition of the serological profiles in acute and chronic HBV infection, performed primarily by Robinson's group at Stanford. The connection between the virus and the development of hepatocellular carcinoma (HCC) followed soon after, but the absence of a cell culture system for propagation of the virus impeded the study of its molecular biology. This changed in the early 1980s with the development of genetic engineering techniques that allowed the cloning of the viral genome, the study of its protein funtions, and the unravelling of the fascinating mechanism of its replication strategy. The polymerase chain reaction (PCR) allowed the speedy amplification and sequencing of virus isolates that led to the identification of quasispecies, virus mutants, and genotypes by bioinformatic approaches. In 1987, Carman and colleagues described the molecular basis of HBe antigen negative viremia (precore stop mutation – see below) and described the first, and most common, vaccine escape variant (arginine 145) in vaccinated children born to HBV-infected mothers (see below).

The introduction of a plasma-derived vaccine, following its extensive evaluation by Smuzness and colleagues in chimpanzees, constitutes another historical landmark in HBV research. This was soon followed by the production of a recombinant vaccine, which has effectively reduced the prevalence of the infection in many countries of the world where the virus was endemic. Almost concurrently, interferons were used for the first time in the treatment of chronic hepatitis B. These remain, with the subsequently introduced nucleos(t)ide analogs, the main treatment options in order to prevent progression of chronic liver disease to cirrhosis and HCC.

Taxonomy and Classification

Hepatitis B is the prototype virus of the family *Hepadnaviridae*, a name that signifies the hepatotropism and DNA nature of the genome of its members. There are two genera within the family. The genus *Orthohepadnavirus* contains members that infect mammals, and, other than HBV, includes hepadnaviruses that infect rodents such as woodchucks (woodchuck hepatitis virus, WHV) and squirrels (70% nucleotide identity). In recent years, HBV-like isolates have also been obtained from primates such as chimpanzees, gibbons, gorillas, orangutans, and woolly monkeys. These are more closely related to HBV and may in fact represent progenitors of the human viruses (**Figure 1**). The *Avihepadnavirus* genus on the other hand contains members that infect birds such as ducks (duck hepatitis B virus, DHBV), herons, storks, and geese. Over the years, the woodchuck and duck animal models, as well as chimpanzees, which are susceptible to infection with human HBV isolates, have proved invaluable in the study of the replication of these viruses, the natural history of

infection, and the testing for efficacy of vaccines and antiviral drugs.

Distribution and Epidemiology

Conservative estimates place the number of persons chronically infected with HBV at over 350 million worldwide. The prevalence of HBV infection varies by geographical region, so that in northwestern Europe, North America, and Australia it is 0.1–2%. In the Mediterranean region, Eastern Europe, Middle East, Indian subcontinent, and Central and South America, it is 3–7%, while in Africa and the Far East it is 10–20%. This geographical distribution of HBV infection is mirrored by the incidence of HCC in the same regions. In areas of high endemicity, the virus is transmitted perinatally from carrier mothers to their infants, or horizontally from infected siblings and other children in early childhood. In areas of intermediate endemicity apart from perinatal transmission, household and sexual contact, as well as percutaneous exposure, are likely routes of infection. Finally, in Western countries, transmission is nowadays through sexual contact or intravenous drug use.

Virion Structure and Genome Organization

The infectious virion or Dane particle measures about 42 nm in diameter and consists of an outer envelope containing hepatitis B surface proteins (HBsAg) in a lipid bilayer (**Figure 2**). This in turn encloses the nucleocapsid core of the virus, within which lies the viral genome and a copy of its polymerase. Apart from virions, liver hepatocytes release into the circulation subviral particles devoid of nucleic acid and consisting entirely of HBsAg. These are the 22 nm spheres and the filamentous forms of similar diameter, which outnumber the virions by 100–10 000-fold.

The viral genome is a relaxed circular, partially double-stranded DNA molecule of 3.2 kbp in length, and contains four wholly or partially overlapping open reading frames (ORFs) (**Figure 3**). In addition, all regulatory elements such as enhancers, promoters, and encapsidation and replication signals lie within these ORFs. The Pre-S/S ORF encodes the three envelope glycoproteins, which are known as the large (L), middle (M), and small (S) HBsAgs, produced by differential initiation of translation at each of three in-frame initiation codons. The proteins are therefore co-terminal and the sequence of the more abundant small protein is shared by the other two. The M protein has an additional 55 amino acid residues at its N-terminus encoded by the Pre-S2 region, while the L protein includes in addition another 125 residues from the Pre-S1 region. The Pre-S1 protein is thought to contain the region responsible for the virus interaction with the hepatocyte receptor. All three proteins are glycosylated, while the L and S proteins may also be present in an unglycosylated form in particles.

The precore/core ORF contains two in-frame initiation codons and therefore yields two translation products. Initiation of translation from the first results in synthesis of the precore polypeptide, which forms the precursor of the soluble hepatitis B e antigen (HBeAg). This protein contains a signal peptide at its N-terminus that anchors the protein in the endoplasmic reticulum membrane. Cleavage by signal peptidase in the lumen is followed by further processing of the C-terminus. The resulting protein is the HBeAg, a nonstructural protein and marker of active virus replication. Moreover, the protein is thought to have a tolerogenic effect on the immune response to the virus. The nucleocapsid or core protein is synthesized following initiation of translation at the second initiation codon. The HBeAg and core proteins are translated from two separate transcripts known as the precore mRNA and the pregenomic RNA (pgRNA), respectively. The

latter also encodes the polymerase ORF of the virus, which covers almost all of the genome. The polymerase has multifunctional enzymatic actions as described below. Finally, the fourth ORF encodes for the X protein, which modulates host cell signal transduction and acts as a gene transactivator under experimental conditions.

Replication Strategy

The life cycle of the virus begins with its attachment to the appropriate hepatocyte receptor, which still remains unknown. In contrast, the region between residues 21 and 47 of Pre-S1 has long been known to be involved in virus binding to the hepatocyte membrane (**Figure 4**). The virion is internalized and uncoated in the cytosol, whence the genome translocates to the nucleus, where it is converted into a double-stranded covalently closed circular DNA (cccDNA) molecule, following completion of the shorter positive (+)-strand and repair of the nick in the negative (–)-DNA strand. The cccDNA constitutes the template for viral transcript synthesis by the host RNA polymerase II. All the transcripts terminate at a common polyadenylation signal situated within the proximal end of the core ORF, and their synthesis is controlled by individual promoters and the two enhancer elements, Enh 1 and 2.

The pgRNA is longer than genome length (3.5 kbp) and, apart from encoding the core and polymerase proteins, also forms the template for (–)-DNA strand synthesis (**Figure 5**). The polymerase has three functional domains, each one in turn involved in DNA priming (terminal protein), reverse transcription (rt), and pgRNA degradation (RNase H). There is also a spacer region of unknown function between the terminal protein and the rt domain. Once synthesized, the polymerase engages epsilon (ε), a secondary RNA structure at the 5′ end of the pgRNA, triggering encapsidation of the complex by the core protein. The subsequent steps in virus nucleic acid synthesis then take place within the nucleocapsid. Host cell factors including chaperones from the heat shock protein family are thought to be instrumental in aiding encapsidation, stabilization, and activation of the polymerase.

As pgRNA is longer than genome length, its terminal sequence duplicates the elements contained in its 5′ end

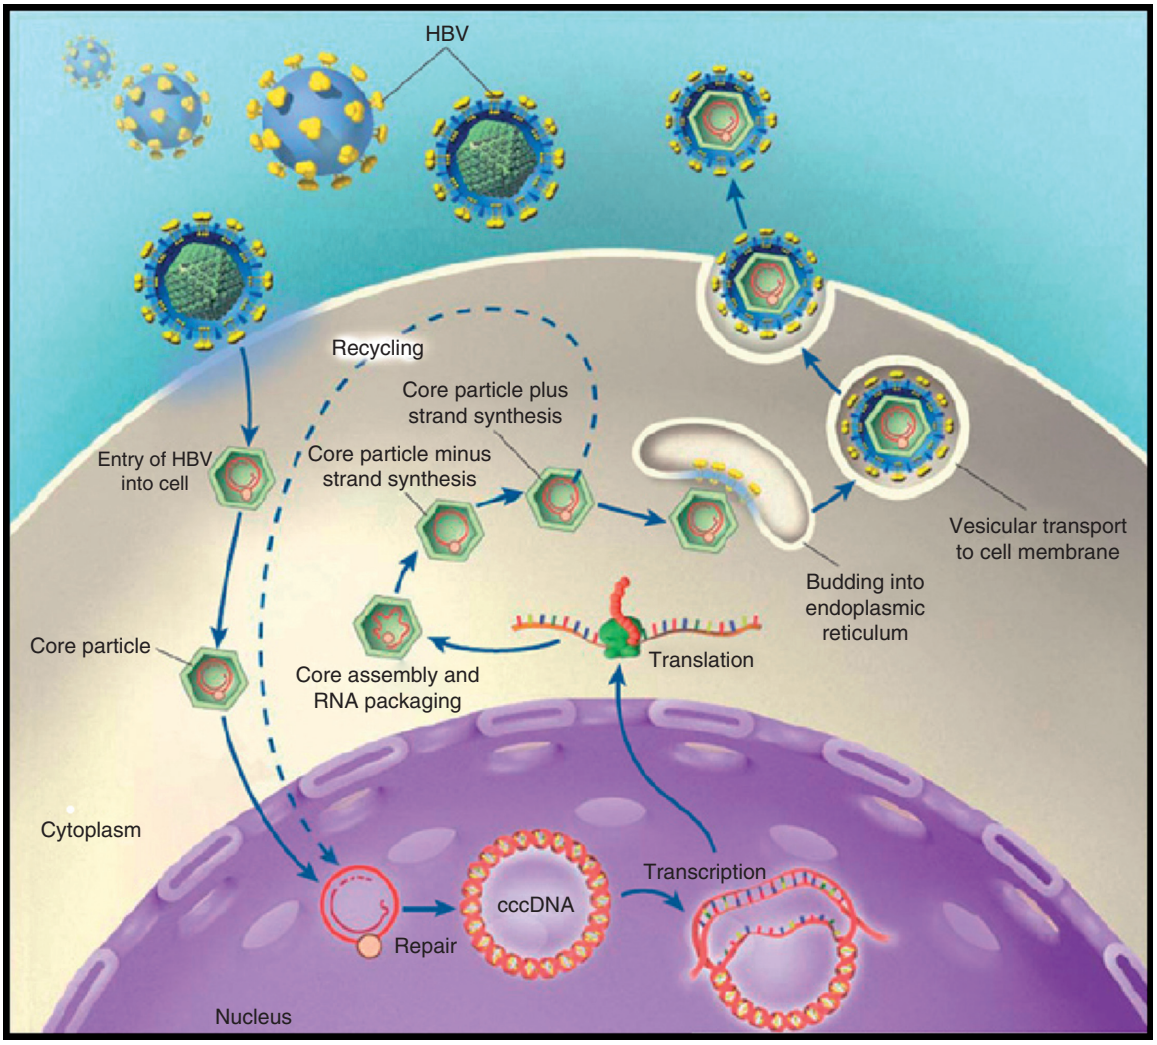

Figure 4 Diagrammatic representation of the life cycle of the virus. Reproduced from Ganem D and Prince AM (2004) Hepatitis B virus infection – Natural history and clinical consequences. *New England Journal of Medicine* 350: 1118–1129, with permission from Massachusetts Medical Society.

and includes the direct repeat 1 (DR1) and ε (**Figure 5**). The bulge of the ε structure serves as a template for the synthesis of a 3–4-nt-long DNA primer, which is covalently attached to the polymerase through a phosphodiester linkage between dGTP and the hydroxyl group of a tyrosine residue in the terminal protein (96). This event involves the ε structure at the 5′ end of the pgRNA, and is then followed by the translocation of the polymerase–primer complex to the 3′ end, where it hybridizes with the DR1 region with which it shares similarity. How this translocation occurs remains unknown. As the complex proceeds toward the 5′ end of the pgRNA, the (−)-DNA strand is synthesized by reverse transcription and the RNA template is concurrently degraded by the RNase H activity of the polymerase, except for the final 18 or so ribonucleotides. A second translocation event then occurs during which the ribonucleotide primer hybridizes with the DR1 region at the 5′ end of the newly synthesized (−)-DNA strand. A template exchange occurs that allows the (+)-DNA strand synthesis to proceed along the 5′ end of the complete (−)-DNA strand, effectively circularizing the genome. (−)- and (+)-DNA strand synthesis occurs within the nucleocapsid as already mentioned, and this is facilitated through pores allowing entry of nucleotides. Once the maturing nucleocapsid is enveloped by budding through the endoplasmic reticulum membrane, the nucleotide pool within the capsid cannot be replenished, hence the incomplete nature of the (+)-DNA strand.

Subtypes

The S protein sequence shared by all three envelope proteins contains the major immunogenic epitope of the virus referred to as the '*a*' determinant. This epitope, shared by all isolates of the virus, is recognized by

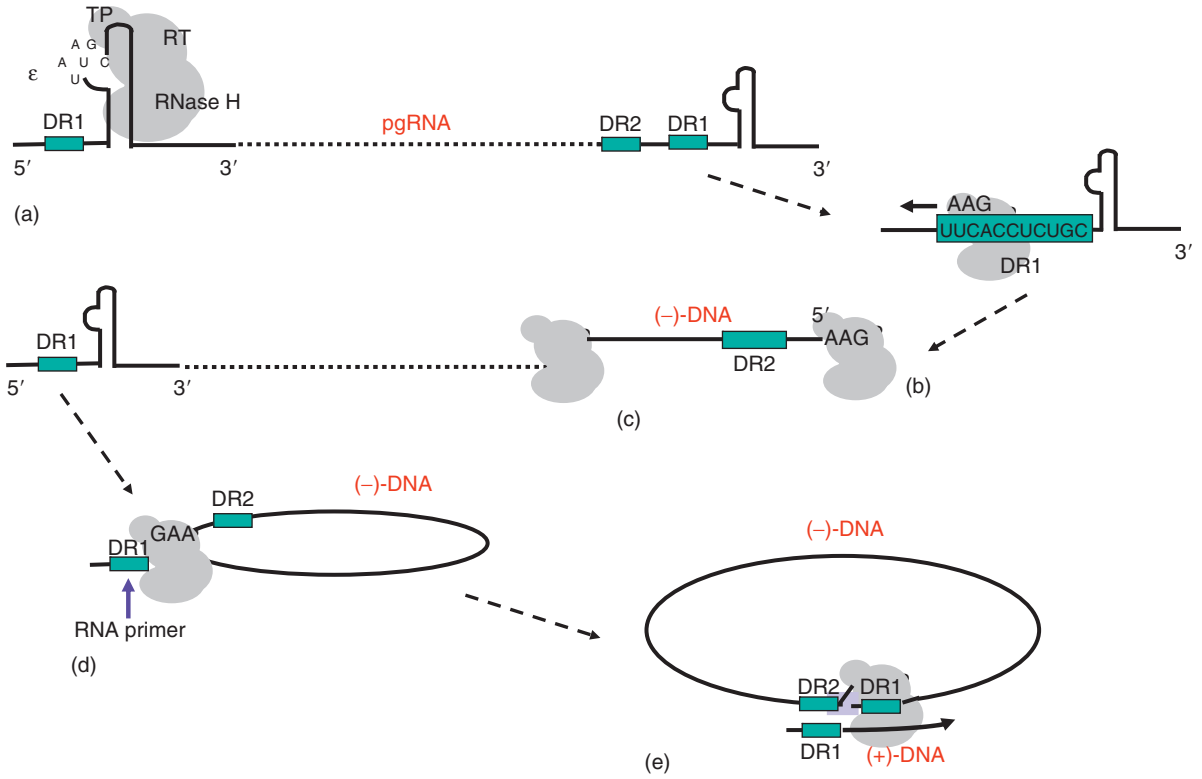

Figure 5 Replication strategy of the virus. (a) Primer synthesis; (b) translocation and binding to DR1; (c) synthesis of the (–)-DNA strand; (d) RNA primer fragment preserved from the degradation of the pgRNA; (e) (+)-DNA strand synthesis. neutralizing antibodies and is conformational in nature, probably encompassing residues 110–160. In addition, there are subtypic specificities originally detected by antibodies. The presence of lysine (K) or arginine (R) at position 122 confers *d* or *y* specificity, respectively. Similarly, specificities *w* and *r* are conferred by the presence of K or R at position 160. Moreover, the *w* subdeterminant can be further divided into *w*1–*w*4 specificities. There are nine subtypes of the virus (**Table 1**) depending on the presence of other subtype-determining residues elsewhere in the '*a*' determinant region.

Genotypes

Nucleotide sequencing studies soon established that the virus could be divided into genotypes based on sequence divergence of >8% (**Table 1**). There are currently eight genotypes, designated A–H, with characteristic geographical distribution. Genotypes A and D occur frequently in Africa, Europe, and India, while genotypes B and C are prevalent in Asia. Genotype E is restricted to West Africa, and genotype F is found in Central and South America. The distribution of genotypes G and H is less clear, but these have been described from isolates in central America and Southern Europe. These genotypes can be further subdivided into a total of 21 subgenotypes; A1–3, B1–5, C1–5, D1–4, and F1–4. Subgenotypes of B and C differ in their geographical distribution, with B1 dominating in Japan and B2 in China and Vietnam, while B3 and B4 are confined to Indonesia and Vietnam, respectively. Subgenotype C1 is common in Japan, Korea, and China, C2 in China, Southeast Asia, and Bangladesh, C3 in Oceania, and C4 in Australian aborigines. Recombinants between genotypes A and D, as well as between B and C, have also been described.

Likely differences between genotypes in relation to pathogenesis and response to antiviral treatment are beginning to emerge. Genotype C is more frequently associated than B with abnormal liver function tests, lower rates of seroconversion to anti-HBe, higher levels of serum HBV-DNA, cirrhosis, and HCC. Moreover, there is a better sustained response to interferon treatment in patients with genotype B than those with C, and in patients with genotype A than those with D. Genotype A infection appears to be associated with biochemical remission and clearance of HBV-DNA more frequently than genotype D, and has a higher rate of HBsAg clearance compared with genotype D.

[a]R or K.

In contrast to the differences observed in response to interferon therapy, treatment with nucleos(t)ide analogs does not show differential responses between genotypes.

Variants

The HBV genome is not as invariant as originally thought. As HBV replicates through an RNA intermediate that is reverse-transcribed, this step in the replication cycle of the virus is prone to errors made by the viral reverse transcriptase. It is estimated that the HBV genome evolves at a rate of $1.4–3.2 \times 10^{-5}$ nucleotide substitutions/site/year. The virus therefore circulates in serum as a population of very closely related genetic variants, referred to as a quasispecies. Although a lot of these variants would have mutations that would be deleterious to the virus, as a result of constraints imposed by the overlapping ORFs, some would be advantageous, either offering a replication advantage or facilitating immune escape. These are discussed below in the clinical settings in which they have been described.

Markers of Infection

Serological diagnosis of HBV infection relies on the detection of HBsAg in serum, and its persistence for longer than 6 months indicates progression to chronic infection. Appearance of anti-HBs (antibody to HBsAg) indicates recovery from infection, or acquired immunity after preventive vaccination. Detection of HBeAg denotes active viral replication, as does the detection of serum HBV-DNA by qualitative or quantitative PCR tests. Seroconversion to anti-HBe occurs after recovery from acute infection, and less often during the chronic phase, either spontaneously or after therapeutic intervention. In the latter case, this leads to a quiescent phase of disease that can be long term, but does not necessarily mean that virus replication ceases completely (see below). Detection of antibody to core antigen (anti-HBc) of IgM class at high level is a marker of acute infection, whereas total anti-HBc (primarily IgG) is detectable during both acute and chronic infection.

Natural History of the Disease

Exposure to HBV may result in asymptomatic, acute icteric, or, in some instances, fulminant hepatitis (0.1–0.5%). Approximately 5% of adults and 95% of perinatally infected young children become persistently infected. The outcome depends on the age of the patient and genetic factors determining the efficiency of the host immune response. Genetic factors influencing outcome (in more than one study) include polymorphisms of the MHC class II glycoproteins, which influence presentation of viral peptides during induction of the cellular immune response, and mannin-binding lectins, which bind to mannose-terminated carbohydrate residues such as those present on the C-terminus of the Pre-S2 region of the middle envelope protein facilitating phagocytosis. The risk of chronicity in children decreases with increasing age. A small proportion of carriers each year may become HBsAg negative (0.05–2%, depending on age of infection), thus leading to resolution of the hepatitis.

Acute HBV Infection

The incubation period following exposure is 3–6 months. In the week before icterus appears, some patients develop a serum sickness-like syndrome including arthralgia, fever, and urticaria. The clinical picture varies from asymptomatic anicteric infection to protracted icterus and, in some patients (<1%), liver failure (fulminant hepatitis). The acute infection is self-limiting and most patients recover within 1–2 months after the onset of icterus.

Chronic HBV Infection

This is defined as persistent viremia of more than 6 months duration and accompanied by hepatic inflammation. The latter is based on histological examination of liver biopsy material that is followed by assigning of scores for necroinflammatory activity (out of 18) and stage of fibrosis (out of 6), which are used to decide whether a patient needs therapy.

Course of Chronic Infection

Chronic HBV infection is quite variable and is typically characterized by four phases. These phases are the immune tolerant, the immune clearance, the nonreplicative (immune-controlled low-level infection), and the reactivation phase that may be seen in some patients, particularly in Southern Europe and the Far East (**Figure 6**). During the immune-tolerant phase, the patient is HBsAg- and HBeAg-positive with high levels of HBV-DNA, but with near-normal or minimally elevated alanine aminotransferase (ALT) levels. Children infected at birth or soon after are more likely to go through this phase, which may last for 2–3 decades. During the immune clearance phase more commonly seen in those infected in adult life, HBeAg and HBV-DNA levels decrease, ALT levels increase, and necroinflammatory changes are seen in liver biopsies. Loss of HBeAg may be accompanied by an ALT flare, culminating in seroconversion to anti-HBe and entry to the nonreplicative phase when the infection is under

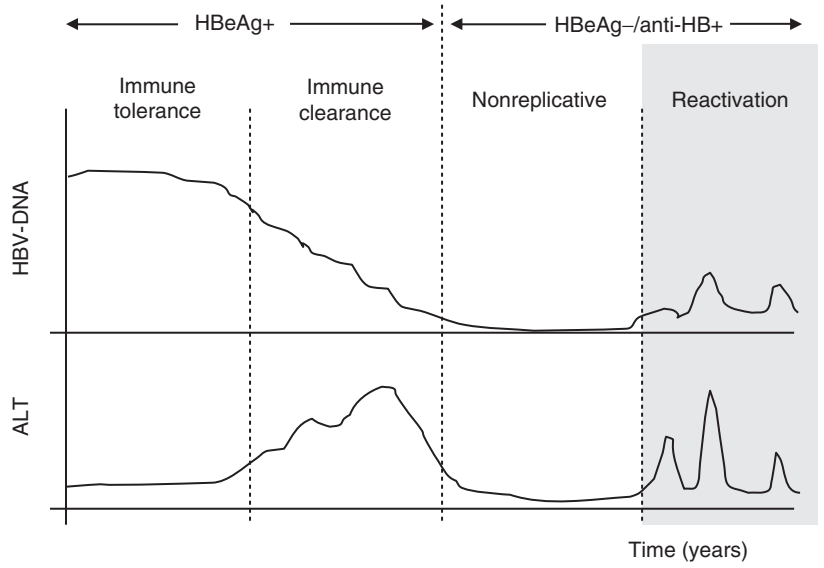

Figure 6 Diagram of the natural history of chronic HBV infection showing the immune tolerant, immune clearance, nonreplicative, and reactivation phases. Reproduced from Karayiannis P, Carman WF, and Thomas HC (2005) Molecular variations in the core promoter, precore and core regions of hepatitis B virus, and their clinical significance. In: Thomas HC, Lemon S, and Zuckerman AJ (eds.) *Viral Hepatitis* 3rd edn., pp. 242–262. London: Blackwell, with permission from Blackwell Publishing.

immune control. Viral DNA integration into the host genome may take place during chronic infection and persist during the nonreplicative (low replicative) phase. During this phase, plasma HBV-DNA may or may not be detectable, while ALT levels return to normal. This serological profile characterizes the 'inactive carrier state', which is maintained thereafter. Some patients, however, for reasons that still remain unknown, show disease reactivation accompanied by ALT rises and return of viremia. Such patients may exhibit fluctuations in ALT levels with occasional severe exacerbations. Continued necroinflammatory activity may lead to fibrosis, and faster development of cirrhosis and HCC.

Mutant Viruses and Chronic Infection

Anti-HBe-positive patients in the reactivated phase of the disease are also referred to as the HBeAg-negative viremic group. Genomic analyses has revealed that such patients carry natural mutants of the virus that have either reduced levels (core promoter variants) or complete abrogation of HBeAg (precore variants) production. These variants are selected at the time of, or soon after, seroconversion, and become dominant during the reactivation phase. The most common precore mutation is the G1896A substitution, which creates a premature stop codon in the precursor protein from which HBeAg is elaborated. This mutation affects the stem of the ε encapsidation signal, but leads to stronger base pairing with the A1896 change in genotypes with a T at position 1858 of the precore region, such as B, C, D, and E. The double mutation affecting the core promoter region (A1762T, G1764A) is thought to result in decreased transcription of the precore mRNA, with a knockon effect on HBeAg production, while pgRNA production remains the same or is even upregulated. It is now apparent that additional mutations in this region may contribute to this phenotype.

Vaccination

Prophylactic vaccination offers the only means of interrupting the transmission of the virus. Vaccines currently used consist of recombinantly expressed HBsAg in yeast such as *Saccharomyces cerevisiae*. In adults, the vaccine is administered intramuscularly into the deltoid at 0, 1, and 6 months. In countries of high and medium seroprevalence, universal vaccination programmes have been instituted, and HBV vaccination is recommended for infants born to carrier mothers within 12 h of birth, given together with hepatitis B immune globulin (HBIg). The response to the vaccine is determined by measuring anti-HB levels 1–4 months after the last dose of the vaccine, and the minimum protection level is set at 10 mIU ml^{-1}.

Development of anti-HBs following vaccination has been recorded in 90–95% of healthy individuals, with lower response rates in hemodialysis and hemophiliac patients (70%). Recent studies on the duration of antibodies have shown maintenance of levels above the 10 mIU ml^{-1} cutoff for 12 years, in up to 80% of individuals immunized at a young age. Booster immunizations therefore may not be required for at least 10 years after

vaccination, and some countries are reconsidering the necessity for this.

The beneficial effects of HBV vaccination are becoming increasingly apparent, particularly in reducing new infections. There has been a dramatic drop in HBV prevalence in populations where the disease was endemic. In Taiwan, 15 years after the start of the vaccination programme, the prevalence of HBsAg in children under 15 years of age has decreased from 9.8% in 1984 to 0.9% in 1999. Similarly, the incidence of HCC has been on the decline from 0.7 per 100 000 children between 1981 and 1986, to 0.57 and 0.36 in 1986–90 and 1990–94, respectively.

Vaccine Escape Mutants

In spite of vaccination and the presence of a satisfactory antibody level, it has been observed that in some instances breakthrough infections occur, the commonest of which involves a mutant with a G145R substitution in the '*a*' determinant region of HBsAg. This and additional mutations in this region have been shown to result in altered antigenicity, accompanied by failure of HBsAg recognition by neutralizing antibody. Such mutant viruses have also been described in the liver transplantation setting, where use of HBIg or monoclonal anti-HBs is recommended in an attempt to prevent infection of the new liver graft.

Treatment

The agents currently available for the treatment of chronic HBV infection are divided into two main groups: the immunomodulators, which include interferon-alpha (IFN-α), and nucleos(t)ide analogs such as lamivudine (3TC), adefovir dipivoxil (Hepsera), entecavir (Baraclude), and telbivudine (Tyzeka or Sebivo), which are currently approved for this purpose. The immunomodulators act by promoting cytotoxic T-cell activity for lysis of infected hepatocytes and by stimulating cytokine production for control of viral replication. Nucleos(t)ide analogs on the other hand are chain terminators acting at the stage of DNA synthesis.

HBeAg-Positive Patients

Treatment with pegylated IFN-α-2, the current standard treatment administered once a week for up to 1 year, achieves seroconversion to anti-HBe in 32% of patients, compared to 18%, 12%, 21%, and 23% with lamivudine, adefovir, entecavir, and telbivudine, respectively. The latter drugs are taken orally daily, in contrast to the weekly intramuscular injections of pegylated interferon. These responses are sustainable in over 95% of patients.

HBeAg-Negative Patients

Treatment of these patients with pegylated interferon for a year results in virologic remission (HBV-DNA $<20\,000$ IU ml^{-1}; equivalent to 105 copies ml^{-1}) in about 44% of them, followed by ALT normalization. This response appears durable in around 20%. Similarly, treatment with nucleos(t)ide analogs for a year leads to HBV-DNA becoming undetectable in between 65% and 90% of treated patients. However, on stopping therapy, only a small minority have a sustained response at the end of 24 weeks of follow up.

Protracted Treatment

To manage such relapses following initial interferon treatment, nucleos(t)ide therapy should be started and continued long term in both HBeAg-positive and -negative patients not achieving a sustained response after a trial of pegylated interferon for 6–12 months. In HBeAg-positive patients, prolonged treatment with lamivudine, for example, leads to increased seroconversion rates from 17% in year 1 to 27% and 40% for years 2 and 3, respectively. Besides, prolonged treatment leads to normalization of ALT levels and an obvious improvement in the histological findings of liver biopsy material. Unfortunately, in many cases, there are breakthrough infections which are attributed to the development of resistance as described below. In such cases, virological breakthrough is soon accompanied by biochemical (ALT rise) and histological relapse. The latter can be avoided by switching to a different nucleos(t)ide analogue that has no cross-resistance with the previous one. Monitoring at three monthly intervals for viral resistance, using molecular assays, is essential.

Resistance

Lamivudine resistance develops in about 24% of patients at year 1 rising to >70% by year 5. Adefovir resistance on the other hand is delayed, being 0% at year 1, 3% at year 2, and rising to 28% by year 4. Entecavir resistance has only been seen so far in patients with lamivudine resistant strains. Longer term follow-up with this nucleoside analogue is ongoing. Nevertheless, it appears that this analog has a high genetic resistance barrier while lamivudine has a low one. Resistance to telbivudine is already a problem after a year of treatment but it appears initially to be more potent than lamivudine.

Molecular Basis of Drug Resistance

The rt domain of the HBV polymerase contains six subdomains (A–F) that are spatially separated, but closely associated with, the normal function of the protein. The characteristic YMDD (tyrosine-methionine-aspartate-aspartate) motif of the catalytic site is located within

subdomain C. Subdomains A, C, and D are most likely involved with dNTP binding and catalysis, whereas subdomains B and E interact with the pgRNA template and primer. Amino acid substitutions that confer resistance to lamivudine predominantly affect the YMDD motif, so that the methionine (M) at position 204 is changed either to valine (YVDD, rtM204V) or isoleucine (YIDD, rtM204I). The former mutation is almost always associated with a second one in subdomain B, involving a substitution of leucine with methionine at position 180 (rtL180M). Adefovir resistance is conferred by mutations rtN236T in subdomain D and rtA181V in subdomain B. In the small number of entecavir-resistant cases detected so far, in addition to the lamivudine-resistant substitutions additional ones that include rtI169T, rtT184G, rtS202I, and rtM250V have been identified.

Glossary

Pseudogene Nonfunctional DNA sequence that is very similar to that of a known gene.
Tolerogen A substance that produces immunological tolerance.

Introduction

Hepatitis B virus (HBV) is the prototype of the family *Hepadnaviridae*, a group of viruses that infect mammals (primates and rodents) and birds. These viruses are distantly related to the retroviruses and, although their genomes are DNA, they are replicated by the reverse transcription of an RNA pregenome.

Structure and Replication of HBV

The 42 nm hepatitis B virion is composed of the DNA genome packaged together with a copy of the virus-encoded polymerase in an icosahedral nucleocapsid made up of dimers of the hepatitis B core antigen, HBcAg. In turn, the nucleocapsid is covered by an envelope composed of a lipid bilayer derived from internal cellular membranes and embedded with the hepatitis B surface protein, HBsAg. The open reading frame (ORF) encoding HBsAg has three in-frame initiation codons (**Figure 1**) which are used for the translation of the large (L, pre-S1 + pre-S2 + S), middle (M, pre-S2 + S), and small (S or major) surface proteins. All three proteins, which share the same C-terminus, are found in the virions.

The early events in infection of the hepatocyte are not well understood, but begin with the virion binding to an unidentified receptor (and, most likely, co-receptors) on the plasma membrane. The first contact seems to involve a domain located near to the N-terminus of L (and not present in M or S), and other interactions involving S also seem to be important. Virus entry likely is via the endosomal route and results in the delivery of the genome, with or without the nucleocapsid, to the nucleus.

The 3.2 kbp genome is composed of two linear strands of DNA held in a circular configuration by base pairing of a short region ('cohesive end region') where the 5′ ends overlap (**Figure 1**). The plus strand is incomplete so that the circle is partially single-stranded. After delivery to the

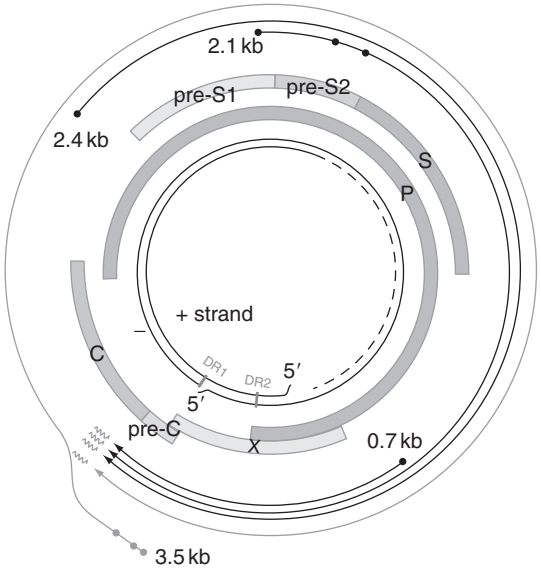

Figure 1 Organization of the HBV genome. The inner circles depict the complete minus strand and incomplete plus strand, and the positions of the direct repeats (DRs) are indicated. The blocks surrounding the genome show the locations of the four overlapping ORFs; C and S contain two and three in-frame initiation codons, respectively. The outer arrows show the viral transcripts, solid circles indicate the positions of the 5′ ends, and the arrowheads indicate the common polyadenylation site. Reproduced from Kidd-Ljunggren K, Miyakawa Y, and Kidd AH (2002) Genetic variability in hepatitis B viruses. *Journal of General Virology* 83: 1267–1280, with permission from Society for General Microbiology.

nucleus, the plus strand is completed (probably by a host enzyme), the primers that remain attached to the 5′ ends of both strands are removed, and the ends are ligated with the introduction of superhelical turns to yield covalently closed circular (ccc)-DNA. This cccDNA associates with histones and other host proteins and resides in the nucleus as a 'minichromosome', the template for transcription of the viral RNAs.

The genome encodes four overlapping ORFs, specifying the core and surface proteins, the polymerase, and a small protein known as HBx (**Figure 1**). All of the *cis*-acting elements, including two enhancers, four promoters, and the single polyadenylation signal, are embedded within the ORFs. Two families of RNAs (2.1 and 3.5 kb in size) are sufficiently abundant to be detectable by northern blotting of RNA from HBV-infected human liver. The 2.1 kb family is translated from a promoter (surface promoter 2, SP2) in the pre-S1 region and encodes M and S. The 3.5 kb RNAs, transcribed from the core promoter, include the precore RNA, which is translated to yield hepatitis B e-antigen (HBeAg), described in detail below, and the pregenomic RNA, which also encodes HBcAg and the polymerase. Surface promoter 1 (SP1), upstream of the surface ORF, transcribes a less-abundant 2.4 kb RNA that encodes L, and the X promoter transcribes an RNA of ~0.7 kb, HBx. All of the RNAs are 3′ co-terminal, being polyadenylated in response to a polyA signal in the core (or C) ORF (**Figure 1**).

The pregenomic RNA is the 3.5 kb transcript that is reverse-transcribed to the HBV genome and also acts as the mRNA for HBcAg and the polymerase. HBcAg forms dimers and has arginine-rich motifs at the C-terminal end that are believed to interact with the viral nucleic acid in the nucleocapsid. Less frequently, the downstream ORF is translated to yield the polymerase, probably following a ribosomal translocation that bypasses the core initiation codon. There is a stem–loop structure, termed epsilon (ε), near to the 5′ end of the pregenomic RNA (**Figure 2**(**a**)), and the polymerase binds to a bulge on the stem, priming first strand synthesis and signaling packaging of the pregenome and polymerase into 'precores', as the dimers of HBcAg self-assemble around the RNA–protein complex. The primer is the N-terminal domain of the polymerase, in which a tyrosine residue is covalently linked to guanosine, and this is extended by a further three residues on the bulge. The extended primer then translocates to a complementary sequence near to the 3′ end of the RNA (**Figure 2**(**b**)).

The direct repeats (DR1 and DR2) are motifs of 11 nt that occur twice in the HBV genome (**Figure 1**). Located at the positions of the 5′ ends of the two strands, they play an important role in template switches during viral DNA synthesis. The translocated primer binds within DR1, and minus-strand synthesis commences with concomitant degradation of the template by an RNaseH activity in the C-terminal domain of the polymerase (**Figure 2**(**c**)). Completion of minus-strand synthesis leaves a capped oligoribonucleotide (which was the 5′ end of the pregenome) containing the DR1 sequence (**Figure 2**(**d**)). This translocates to the copy of DR2 near to the 5′ end of the minus strand and primes plus-strand synthesis, which then proceeds to the 5′ end of the minus strand (**Figures 2**(**e**) and **2**(**f**)). The short (~8 nt) terminal redundancy of the minus strand allows another template switch and circularization of the genome. Completion of the nucleocapsid during plus-strand synthesis starves the polymerase of the substrate, leaving the characteristic partially single-stranded structure that typifies the HBV genome (**Figures 2**(**g**) and **2**(**h**)).

Mature cores then bud through cellular membranes containing HBsAg (S, M, and L) and are exocytosed. A vast excess of subviral particles, which lack nucleocapsids and are noninfectious, are also secreted from the hepatocyte and are presumed to overwhelm the immune response of the host. These comprise 22 nm spheres, composed of S and M, and tubular forms of the same diameter, composed of S, M, and L (**Figure 3**). An endoplasmic-retention signal within the pre-S1 domain of L is involved in the formation of the virions and tubular subviral particles.

The Surface Protein, HBsAg

The 226-amino-acid (aa) residue S protein is quite hydrophobic and structural models suggest that it contains four membrane-spanning regions (**Figure 4**(**a**)). The major hydrophilic loop is exposed on the surface of viral particles and is the main target of the immune response to HBsAg. This domain is rich in cysteine residues, which are believed to be linked by disulfide bridges, forming a complex structure that includes the *a* determinant and *d*/*y* and *w*/*r* subdeterminants. Antibody (anti-HBs) responses to this domain give immunity to infection in convalescence or following immunization with hepatitis B vaccine. Approximately half of the S residues are N-glycosylated at aa 146 (in the *a* determinant) so that the protein exists in two forms, p24 and gp27.

The N-terminus of S is exposed on the surfaces of the virions and subviral particles and, in M, is extended by 55 aa (the pre-S2 region). The pre-S2 region is glycosylated in M to give two proteins, gp33 and gp36, depending upon the glycosylation of asparagine 146 in the S domain. M is much less abundant than S in the virion and subviral particles. The SP2 promoter lacks a 'TATA box' and the 5′ ends of the 2.1 kb RNAs are heterogeneous, most being located downstream of the pre-S2 initiation codon (**Figure 1**). Furthermore, that codon is in a poor 'Kozak' context for recognition by the ribosome; consequently, much more S than M is produced.

The large surface protein, L, has a further extension of the N-terminus by the pre-S1 region. Again, there are two forms, p39 and gp42, depending on glycosylation at aa 146 of S (the pre-S2 region is not glycosylated in L). The glycine at aa 2 of the pre-S1 region is myristylated and embedded in the membrane. L has a dual topology: upon expression, the pre-S loop may translocate into the endoplasmic reticulum (ER) lumen, so that it is exposed on the exterior of the particle and presents the

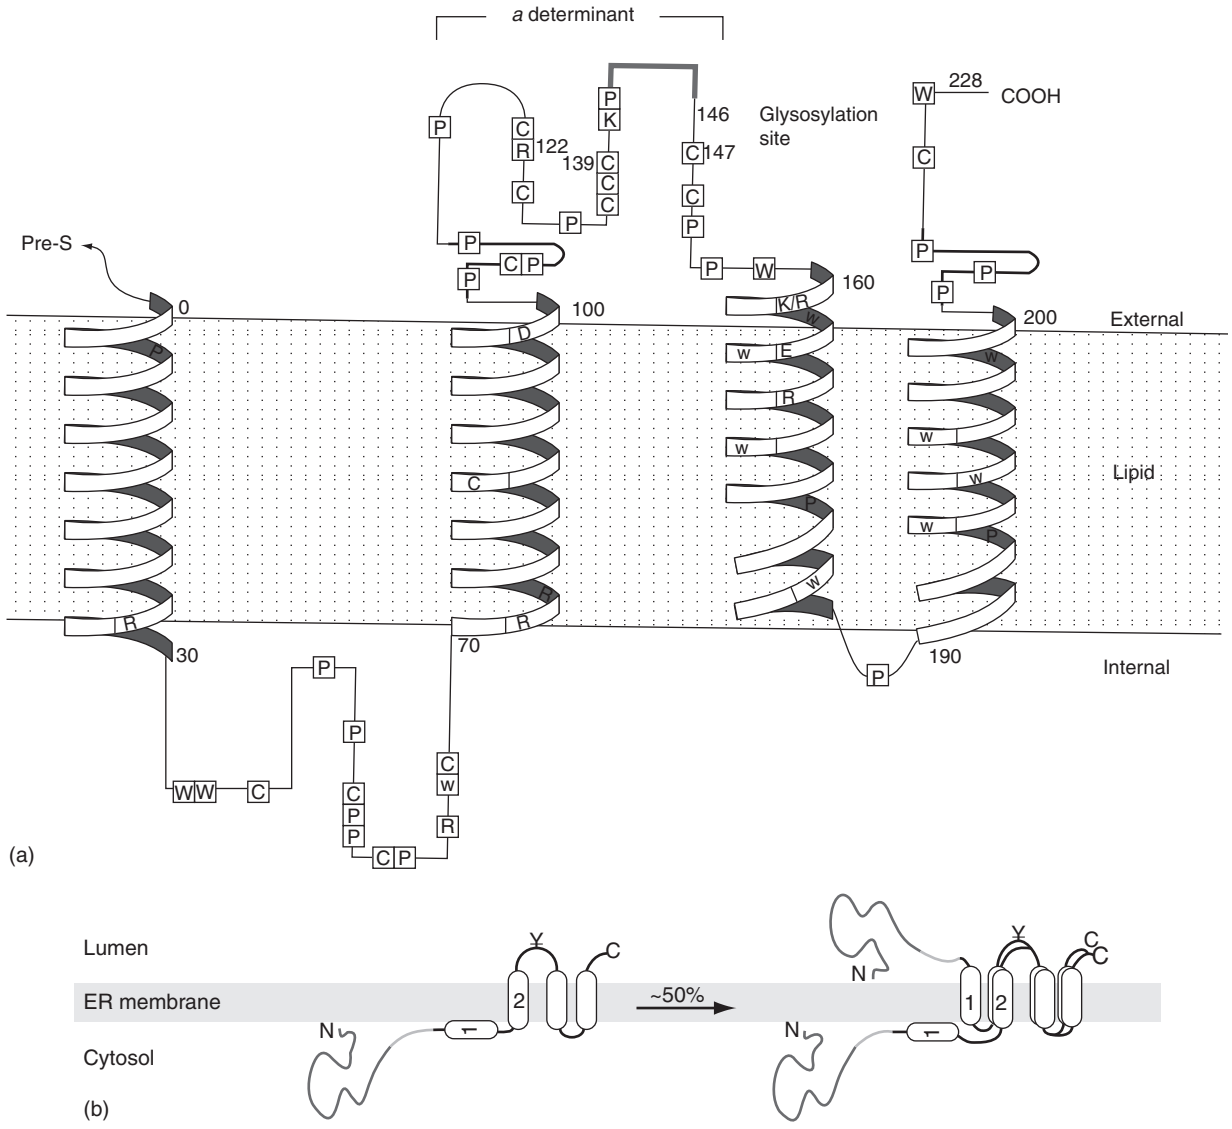

Figure 4 (a) Predicted structure of the major surface protein, S. Note the abundance of cysteine residues in the major hydrophilic region. (b) Dual topology of the large surface protein, L. (a) Reproduced from Stirk HJ, Thornton JM, and Howard CR (1992) A topological model for hepatitis B surface antigen. *Intervirology* 33: 148–158, with permission from Karger Publishers. receptor-binding domain. However, in around 50% of the L molecules, the loop does not translocate but remains in the cytosol and is believed to interact with the nucleocapsid during budding and maintain this contact in the virion (**Figure 4**(**b**)).

The Hepatitis B Vaccines

The hepatitis B vaccines contain HBsAg and are given via an intramuscular injection to stimulate a protective anti-HBs response. The first-generation (so-called 'plasma derived') vaccine was produced by purifying HBsAg from donated blood. Despite some worries that blood-borne viruses (particularly human immunodeficiency virus (HIV)) potentially might contaminate particular batches, this method of vaccine production is safe provided that manufacturing protocols, including steps that inactivate potential infectivity, are adhered to strictly. Even today, plasma-derived vaccines constitute the majority of doses given worldwide. Currently, most doses of hepatitis B vaccine given in the West are produced by expression of HBsAg in yeast (*Saccharomyces cerevisiae*), and several vaccines based on expression in mammalian cells also have been licensed.

Most individuals produce a protective immune response with the standard, three-dose regimen of immunization,

but there is a problem of nonresponsiveness in up to 5% of recipients, particularly the immune-suppressed and older individuals, and especially males. The vaccines contain only S and there has been interest in whether vaccines containing pre-S epitopes may circumvent this problem of nonresponsiveness. Up to 50% of nonresponders may sero-convert following immunization with a vaccine containing pre-S epitopes and the nonresponsiveness of many of the remainder seems to be genetically based.

Most countries worldwide have now introduced universal immunization of infants. Although the vaccine may be incorporated into the Expanded Programme of Immunization, it is essential that it is given as soon as possible after birth to the infants of infectious mothers, in order to break the chain of mother-to-infant transmission (see below). Immunization within 12 h of birth protects around 70% of the infants of carrier mothers and up to 90% success may be achieved when passive immunization with hepatitis B immune globulin (HBIG) also is given, at a contralateral site, to neutralize any maternal virus that reaches the newborn infant. Rarely, however, the antibody may select variants with mutations that alter the amino acid sequence of the *a* determinant. Such 'antibody escape' variants may also be selected in liver-transplant recipients given HBIG in an attempt to prevent HBV infection of the graft and, indeed, in the natural course of infection, with seroconversion to anti-HBs. The most common mutations affect the highly conserved codons 144 and 145 (for aspartic acid and glycine, respectively) of S. Fortunately, there is no evidence that these 'antibody escape' variants can be transmitted to individuals with vaccine-induced immunity.

Hepatitis B e-Antigen, HBeAg

This antigen circulates as a soluble protein in the plasma of some persistently infected individuals and is recognized as a marker of infectivity. The synthesis of HBeAg is nonessential for virus replication and its function is thought to be as a tolerogen; it may be especially important in perinatal transmission. HBV does not cross the placenta, but HBeAg is believed to do so and to circulate in the fetus. The infants of viremic mothers almost invariably become infected at or around the time of birth. At least 90% of such infants become persistently infected and often are extremely immune-tolerant of the virus, with very high viral loads that may persist for decades or even for life. When they are females, they infect their children in turn; thus, HBeAg seems to be important in maintaining HBV in the human population through the generations.

As noted above, the pregenomic RNA is translated from the second initiation codon in the core ORF to produce the nucleocapsid protein. The precore RNA has its cap site further upstream, so that it contains the precore initiation codon and the entire core ORF is translated (**Figure 5**). There are an additional 29 aa, encoded by the precore region, at the N-terminus of the precursor to HBeAg (p25) and these include a signal sequence that targets the protein to the ER. Here, the cellular signal peptidase cleaves this sequence and the protein is secreted with further proteolysis, removing the arginine-rich domain at the C-terminus.

Seroconversion from HBeAg positivity to anti-HBe, with clearance of HBV replication, is often a feature of recovery from persistent infection. However, a significant proportion of patients with circulating anti-HBe remain viremic, infected with HBV variants that do not synthesize, or synthesize reduced quantities of, HBeAg. The most common mutation affects codon 28 in the precore region, changing it from a tryptophan to a termination codon and preventing the synthesis of p25. Because this mutation affects base-pairing in ε, it is constrained in some genotypes and subgenotypes of HBV. Other, less common 'precore mutations' introduce termination codons elsewhere in the precore region, destroy the precore initiation codon, or modify the signal peptidase cleavage site.

Another class of mutations found in HBV from anti-HBe-positive individuals affects the core promoter. These mutations decrease the transcription of the precore RNA (and may increase the transcription of the pregenomic RNA), resulting in reduced synthesis of HBeAg. Core promoter mutations may be associated with a particularly high risk of developing hepatocellular carcinoma (HCC), especially in genotype C.

Treatment of Chronic Hepatitis B

Prior to the introduction of specific antiviral therapeutics, persistent HBV infection was treated with interferon, with mixed success. In some studies, up to one-third of treated individuals cleared the virus, but the treatment was rather less successful in certain populations, particularly individuals from the Far East. Interferon seems to work by modulating the immune response of the host, rather than a direct antiviral effect, and was found to be most successful in individuals who had evidence of hepatitis or, in other words, already were mounting a cellular immune response to the virus.

Because the HBV genome is replicated via an RNA intermediate, treatment with nucleoside and nucleotide analogs is an option. The predicted amino acid sequence of the HBV polymerase is similar to those of retroviruses and a motif, Tyr-Met-Asp-Asp (YMDD), in the active site is highly conserved. The HBV polymerase has not been crystallized but its structure is inferred from those of other RNA-dependent DNA polymerases, particularly that of HIV type 1 (HIV-1). Several conserved regions,

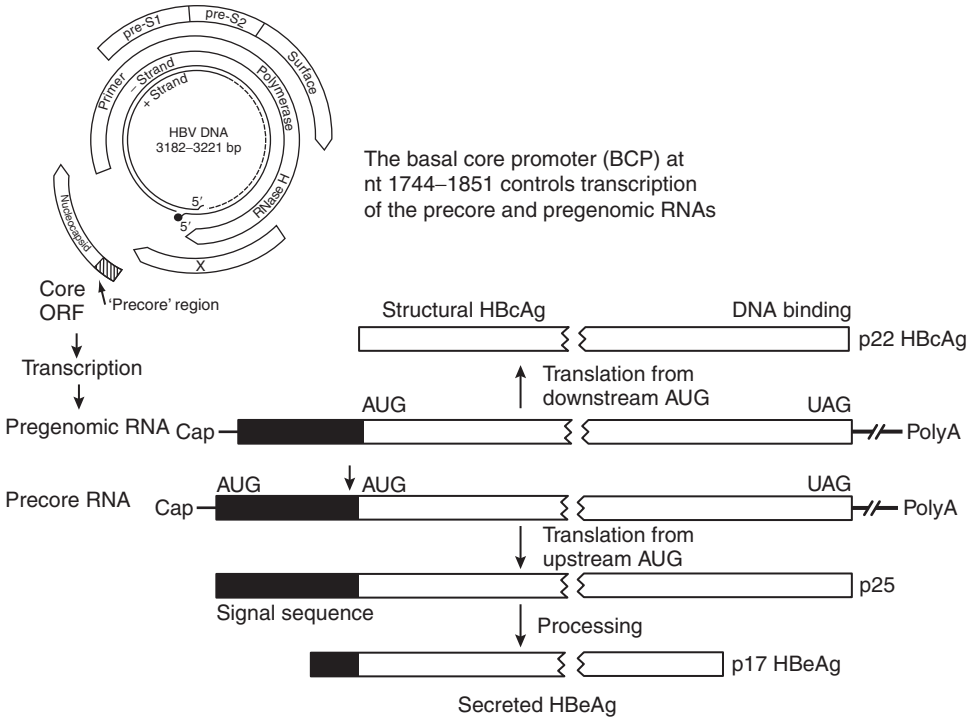

Figure 5 Expression of the HBV core ORF. The pregenomic RNA is translated from the second initiation codon in the ORF to yield HBcAg. The precore RNA is translated from the upstream initiation codon to p25, which is processed to HBeAg. The arrow indicates the position of the most common precore mutation, changing a tryptophan to a termination codon. designated A–F, are recognized within the reverse transcriptase domain and the YMDD motif is located within conserved region C (**Figure 6**).

Despite the similarity between the HIV and HBV polymerases, many of the nucleoside analogs first used against HIV, such as zidovudine, were found not to be effective against HBV. Lamivudine, a deoxycytidine analog which acts as a chain terminator during reverse transcription of the pregenome and can result in a 4–5 $\log_{10}$ suppression of viral load, was the first nucleoside analog to be used successfully and licensed for therapy of hepatitis B. However, prolonged monotherapy with lamivudine results in the emergence of resistant virus in approximately 40% of patients after 2 years of therapy (and 65% after 5 years). Resistance to lamivudine is associated with point mutations which result in substitution of the methionine residue in the YMDD motif by either valine or isoleucine, changes which parallel lamivudine resistance in HIV-1. The valine (but usually not the isoleucine) substitution is associated with a second, leucine-to-methionine substitution in the upstream, conserved region B and this seems to compensate partially for the adverse effect of the former on replication efficiency.

Another nucleoside analog, adefovir dipivoxil, inhibits the replication not only of wild-type HBV but also of lamivudine-resistant mutants. Resistance to adefovir emerges at a slower rate than to lamivudine, reaching around 22% after 2 years for patients initially treated

with lamivudine, and perhaps less frequently for nucleoside-naive individuals. Adefovir resistance is associated particularly with substitutions in conserved regions D or B and these mutants are susceptible to lamivudine. The absence of substitutions in conserved region C is consistent with the concept that adefovir inhibits the priming of reverse transcription, rather than chain elongation, and suggests that combination therapy with lamivudine and adefovir may inhibit the emergence of resistant mutants.

In vitro, the deoxyguanosine analog entecavir inhibits priming of reverse transcription as well as chain elongation of both the minus and plus strands. The drug is active against lamivudine- and adefovir-resistant HBV. Resistance to entecavir has been described in patients who had been treated previously with lamivudine and in whom lamivudine-resistant mutants had already been selected, but resistance seems to arise in otherwise treatment-naive patients at a rate of less than 1% per year. Other analogs, including telbivudine, which is similar in structure to lamivudine but seems to have better efficacy, have also been licensed recently for use in hepatitis B but the design of regimens for combination therapy lags way behind that for HIV.

HBV and HCC

When tests for HBsAg were first developed, it became clear that regions of the world with a high prevalence of chronic hepatitis B and a high annual incidence of HCC were coincident and that, in those regions, most individuals with HCC were HBsAg-positive. In Taiwan, a large prospective study confirmed the increased risk of HCC for carriers of HBsAg, and there is now evidence that the hepatitis B vaccine will reduce considerably the risk of developing the tumor. Although the importance of hepatitis C virus as a cause of HCC has increased considerably over recent decades, HBV remains a critical and preventable cause of one of the most common cancers of humans.

Cloning of the HBV genome enabled the use of virus-specific DNA sequences as probes in Southern hybridization assays, leading to evidence of chromosomal integration of viral sequences in at least 80% of HBV-associated HCCs. The chromosomal sites of integration of viral DNA seem to be random. Nevertheless, the tumors are clonal with respect to the integrated HBV DNA (often with multiple copies or partial copies of the genome), suggesting they arise from a single cell and that integration is the first step in the oncogenic process. In fact, integrated HBV DNA often can be detected by Southern hybridization of DNA from liver biopsies of infected patients who do not have HCC, suggesting that clonal expansion of hepatocytes containing integrated HBV DNA may be common in persistent infection.

Although the chromosomal sites of integration are random, there are hot spots in the viral genome, particularly around the direct repeats, for recombination with human DNA. A double-stranded linear form of HBV DNA, an aberrant product (and not a replicative intermediate) generated when the plus-strand primer fails to translocate and primes *in situ* (**Figure 2(i)**), may be that which recombines with the host DNA. Integration seems to be of no value to the virus, it is not a part of the replication cycle, and the integrants often are rearranged and never have sufficient redundancy to act as templates for the transcription of the 3.5 kb pregenome. On the other hand, the surface ORF often is expressed from integrants and many HBV-associated HCCs secrete HBsAg.

Despite considerable study, there is no consensus regarding the mode of HBV oncogenesis. Interest has focused on the product of the X ORF; this acts as a transactivator of transcription and seems to be important in 'kick-starting' the infection by stimulating transcription from the viral promoters. The protein seems to have pleiotropic effects in the cell, including stimulating various signal pathways and perhaps also preventing apoptosis. Transgenic mice with liver-specific expression of HBx develop HCC. Truncated middle surface proteins, produced following transcription of incomplete surface ORFs in integrated HBV DNA, also may act as transactivators, perhaps by locating in the plasma membrane and interacting with the receptors that initiate various signaling cascades. Some mice with the entire HBV genome as transgenes show accumulation of the large surface protein (L) in the ER of the hepatocytes and the resultant ER stress also seems to lead to the development of HCC.

Researchers have also investigated the hypothesis that HBV acts as an insertional mutagen, perhaps by inactivating a tumor suppressor gene or causing the inappropriate expression of a normally quiescent gene. Early studies, based on the analysis of genomic libraries of tumor DNA, identified insertions in or next to human genes, such as for cyclin A and the retinoic acid receptor β gene. However, these were isolated instances and no common targets were identified. More recently, amplification of virus–host junctions using polymerase chain reaction (PCR)-based techniques has identified further examples, particularly the human telomerase reverse transcriptase (hTERT), which seems to be a target of integration in several tumors. It is worth noting that, while the initial sites of HBV DNA integration are random, the integrants in tumors are a selected subset that may be implicated in the oncogenic process.

Woodchuck hepatitis virus (WHV) also causes HCC in its natural host. In contrast to HBV, in woodchuck tumors WHV DNA often is integrated within or adjacent to myc family oncogenes (c-myc or N-myc). In fact, woodchucks possess an additional copy of N-myc, a retrotransposed pseudogene that lacks introns. Insertion of the

WHV enhancer 5′ or 3′ of the myc-coding region activates transcription from the myc promoter.

Glossary

Pseudotypes Retroviral vector particles bearing heterologous glycoproteins on their surfaces.
Replicon DNA or RNA molecule capable of self-replication in a cell or in an adequate *in vitro* system (e.g., cell lysate).
Sustained virological response (**SVR**) Continuous absence of HCV RNA from the serum starting 6 months after cessation of antiviral therapy.

Introduction

In the 1970s, when blood tests for the detection of hepatitis A virus (HAV) and hepatitis B virus (HBV) became available, many blood samples responsible for post-transfusion hepatitis were negative when tested for these two viruses. Therefore, this third form of transfusion-associated hepatitis was named non-A, non-B hepatitis. However, in 1989, Choo and co-workers discovered hepatitis C virus (HCV) as the causative agent of parenterally transmitted non-A, non-B hepatitis. Initially, they isolated a viral complementary DNA clone from the serum of a chimpanzee experimentally infected with non-A, non-B hepatitis and used it to establish a screening test for antibodies in patients infected with this agent. By using this initial cDNA clone as a hybridization probe, Choo and colleagues then isolated a near full-length viral genome that was readily classified as a close relative of the animal pathogenic pestiviruses based on similarities of genome organization and virion properties.

Taxonomy and Geographical Distribution

HCV has been classified as the only member of the genus *Hepacivirus* and grouped together with the genera *Pestivirus*, *Flavivirus*, and tentatively the GB-viruses, in the family *Flaviviridae*. According to phylogenetic analyses, HCV is more closely related to the pestiviruses than to the flaviviruses.

Based on genomic heterogeneity, six major genotypes, having more than 30% nucleotide sequence divergence, and more than 70 subtypes differing from each other by 10–30% at the nucleotide sequence level, have been defined. Subtypes are designated by lowercase letters following the number of the genotype (e.g., genotype 1 subtype b = 1b). While genotype 1 and 2 viruses are prevalent almost worldwide, HCV genotypes 3–6 are to a large extent restricted to distinct geographical regions, including the Indian subcontinent and Southeast Asia (genotype 3), Africa and Middle East (genotype 4), South Africa (genotype 5), and Southeast Asia (genotype 6). Individual genotypes have not been ascribed to particular disease manifestations, except for a higher prevalence of

steatosis with patients infected with genotype 3 viruses, but genotypes are important predictors of therapy outcome (see below).

Transmission

HCV is mainly transmitted by parenteral exposure to blood and blood products. The development of effective screening tests for blood and blood products and the implementation of viral disinfection procedures have almost excluded this route of transmission in countries where these measures are in place. Thus, the major remaining risk factor for acquiring HCV infection in developed countries is the use of contaminated needles in injection drug use. In some countries, HCV infection has been spread primarily by the use of inadequately sterilized medical instruments. In contrast to HBV infection, sexual transmission and maternal–infant spread of HCV are much less frequent.

Clinical Manifestation

Acute HCV infections are usually asymptomatic or, in about 30% of cases, associated with nonspecific symptoms such as abdominal pain, fatigue, weakness, poor appetite, and nausea. During an incubation period of 15–75 days, HCV RNA becomes detectable in serum by reverse transcription-polymerase chain reaction (RT-PCR), and virus titers usually peak at 10^5–10^7 genomes/ml between weeks 6 and 10, irrespective of disease outcome (**Figure 1(a)**). Two to four weeks after onset of viremia serum alanine aminotransferase (ALT) levels begin to rise, indicative of hepatocellular injury. Due to these nonspecific signs and symptoms, acute infection often remains unrecognized. The duration of viremia in acute hepatitis C is unpredictable and can vary from 2 to more than 4 months. Some patients even become HCV RNA negative during early convalescence but later on viremia rebounds. Overall 50–80% of HCV infections lead to a chronic carrier state (**Figure 1(b)**). About 30% of these chronically infected persons progress to liver cirrhosis 10–30 years after primary infection and hepatocellular carcinoma occurs in up to 2.5% of these patients. In contrast to chronic hepatitis B, in case of persistent HCV infection a hepatocellular carcinoma only develops on the basis of prior cirrhosis.

Pathology and Histopathology

Hepatocytes are the primary target of HCV. Therefore, the histological alterations of chronic hepatitis C are hepatocellular injury, portal and parenchymal inflammation, and necrosis. The injury of the hepatocyte is thought to be induced primarily by the immune reaction rather than by viral cytopathogenicity. Liver damage is typically spotty and focal with accompanying chronic inflammatory cells, macrophages, and, eventually, variable degrees of fibrosis. The progression rate of hepatic fibrosis is the major determinant for the outcome of chronic hepatitis C in terms of developing cirrhosis and hepatocellular carcinoma. Unfortunately, there are only a few histological markers that are more often associated with hepatitis C than with other causes of hepatitis, such as steatosis. Although the liver is the primary target, persistent HCV infection is often associated with extrahepatic symptoms, such as renal complications, lymphoma, and diabetes. A high proportion of patients with chronic hepatitis C develop cryoglobulinemia, which may account for some of these extrahepatic manifestations.

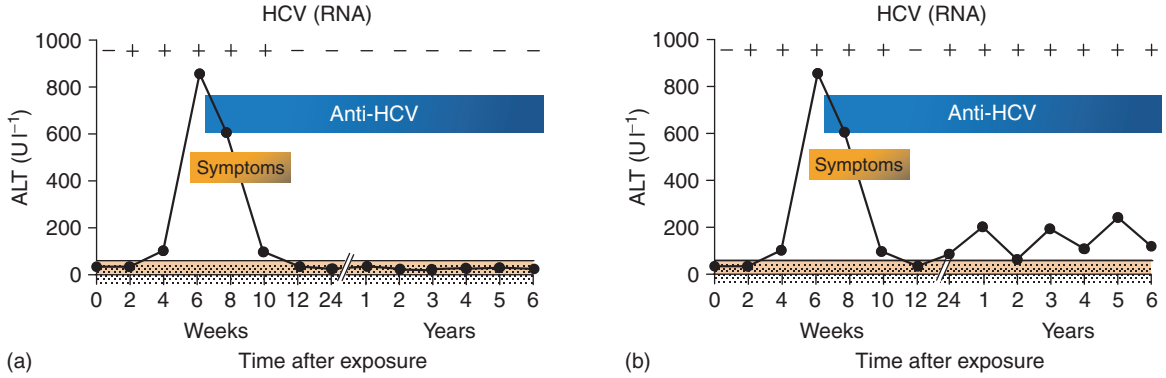

Figure 1 Course of acute and chronic HCV infection. (a) In acute HCV infection, viral RNA is typically detectable between weeks 2 and 10 after virus exposure. ALT levels rise between weeks 4 and 10 peaking around week 6. This is also the time when the first symptoms manifest. HCV-specific antibodies arise late in infection. In self-limiting infection HCV is cleared as measured by RNA levels and ALT returns to normal levels. (b) In chronic hepatitis C the early phase is similar to acute infection but later on the virus persists. In the chronic phase, ALT levels fluctuate as does viremia.

Genome Organization

The genome of HCV is a 9.6 kb single-stranded RNA molecule of positive polarity (**Figure 2(a)**). It is flanked by two highly structured nontranslated regions (NTRs). The 5′ NTR contains an internal ribosome entry site (IRES) (**Figure 2(b)**), mediating cap-independent translation of a polyprotein of *c.* 3000 amino acids in length. The 3′ NTR is composed of a 40-nt-long variable region, a polypyrimidine tract (heterogeneous length), and the 98-nt-long highly conserved 3′ terminal X-tail (**Figure 2(b)**). Both the 5′ and the 3′ NTRs contain *cis*-acting RNA elements (CREs) that are required for viral replication. Within the 3′ terminal part of the NS5B gene, three additional CREs are localized (5BSL3.1–5BSL3.3), wherein 5BSL3.2 is absolutely required for viral RNA replication by forming a long-distance RNA–RNA interaction with the middle loop in the X-tail.

The organization of the HCV polyprotein and the functions of the individual gene products are depicted in **Figure 2(a)**. The structural proteins, core and the envelope proteins 1 (E1) and 2 (E2), are located within the N-terminal part of the polyprotein preceding the p7 protein which appears to be an ion channel and therefore was grouped into the viroporin protein family. The nonstructural (NS) proteins NS2, NS3, NS4A, NS4B, NS5A, and NS5B are encoded in the remainder. The NS2 protein together with the N-terminal protease domain of NS3 is responsible for the autocatalytic cleavage of the NS2–NS3 junction (**Figure 2(a)**). It is a dimeric cysteine protease with a composite active site. The same NS3 protein domain carries a serine-type protease that after association with its cofactor NS4A cleaves the residual junctions between the NS proteins. Moreover, the same protease also cleaves two cellular signaling molecules involved in the induction of the innate immune response (see below). Two additional enzymatic

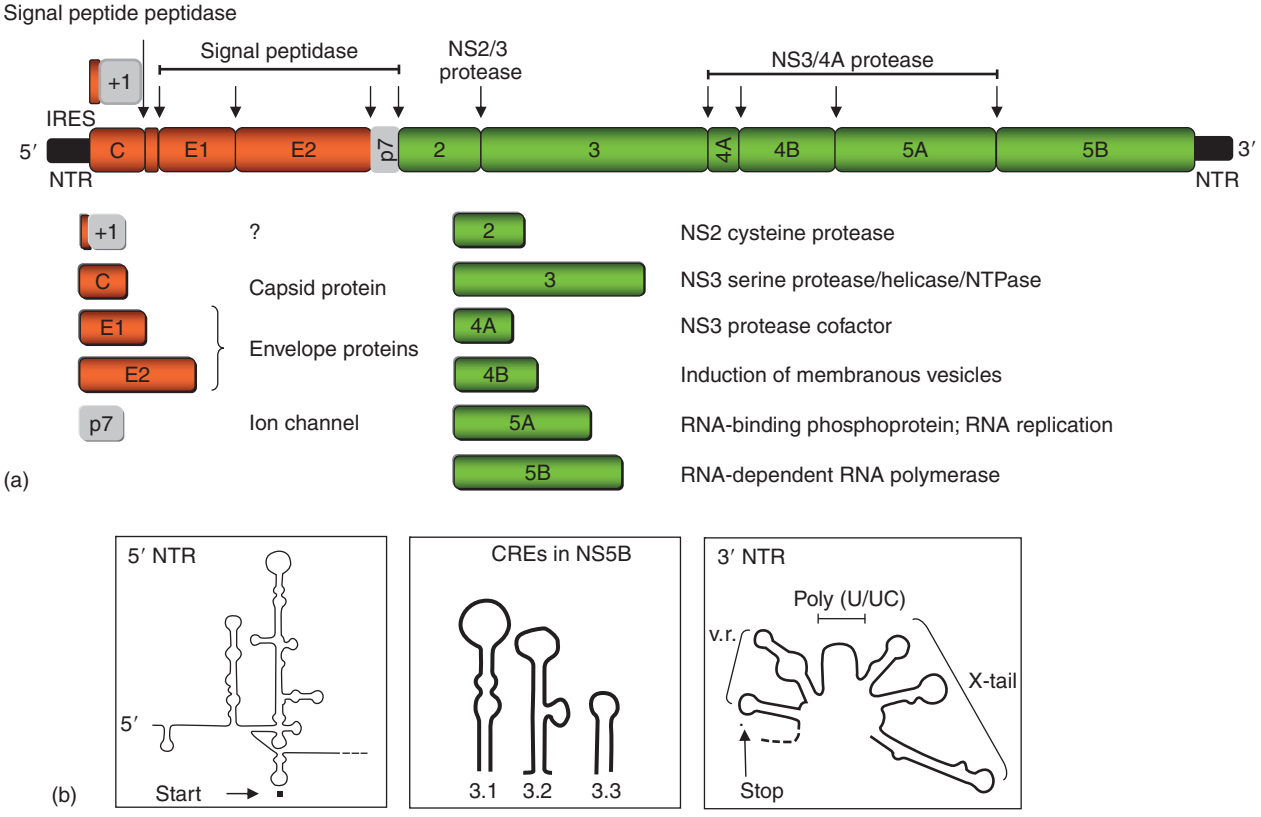

Figure 2 Illustration of the HCV genome organization, gene products, and *cis*-acting RNA elements (CREs). (a) HCV genome organization, gene products, and their functions in the replication cycle. The HCV coding region is shown as bar with arrows above indicating the positions of polyprotein cleavage and involved proteases. The structural region in the N-terminal third of the polyprotein is drawn in orange, and the region encoding the nonstructural proteins is drawn in green. The core+1 protein(s) and the p7 protein are drawn in gray. The HCV coding region is flanked by two nontranslated regions (5′ and 3′ NTR), indicated in dark gray. The 5′ NTR contains an internal ribosome entry site (IRES). Functions of the individual gene products are given in the lower panel. (b) Schematic representation of CREs. The 5′ NTR (left panel) contains the IRES as well as structures important for viral RNA replication. Three CREs are located in the 3′ terminal part of the NS5B coding region (middle panel). The loop region of stem–loop 5BSL3.2 forms a long-distance RNA–RNA interaction essential for RNA replication with the loop region of the middle stem–loop in the X-tail. The right panel displays the organization of the 3′ NTR with variable region (v.r.), poly(U/UC) tract, and X-tail. Positions of start and stop codons are indicated with dots.

activities (RNA helicase and nucleoside triphosphatase) reside in the C-terminal two-thirds of NS3. Alterations of intracellular membranes, in particular membranous vesicles, are mainly induced by the 27 kDa integral membrane protein NS4B. These vesicles accumulate in the perinuclear region, are called the membranous web, and are the site of viral RNA replication. So far, the role of the phosphorylated zinc metalloprotein NS5A in the viral replication cycle is unclear. NS5A is composed of an N-terminal amphipathic α-helix serving as a membrane anchor and three largely cytosolic domains. The X-ray crystal structure of RNA-binding domain I was resolved and shown to form homodimers resulting in a basic groove. NS5A phosphorylation is mediated by cellular kinases, in particular the α isoform of the protein kinase CKI. The NS5A phosphorylation state appears to affect replication efficiency indicating that NS5A is an important replication factor. Furthermore, NS5A may also contribute to interferon-alpha (IFN-α) resistance that is often observed with genotype 1 and 4 viruses. The 68 kDa protein NS5B is the RNA-dependent RNA polymerase (RdRp). It is a membrane-associated enzyme with a structural organization similar to that of other polymerases with palm, finger, and thumb subdomains. However, it differs from most other RdRps by having a fully encircled active site, which is due to tight interactions between the finger and thumb subdomains.

In addition to the polyprotein, a heterogeneous group of HCV proteins is expressed either by ribosomal frameshifting into the +1 ORF or by internal translation initiation. The resulting proteins, collectively designated core +1, are not essential for replication and virus production in cell culture, and their role *in vivo*, if any, remains to be elucidated.

HCV Replication Cycle

HCV infection starts by binding the envelope glycoprotein E1/E2 complex on the surface of the virus particle to its cognate receptor(s) presumably leading to clathrin-mediated endocytosis and a subsequent fusion step from within an acidic endosomal compartment (**Figure 3**). Cellular factors implicated in virus binding and entry are glycosaminoglycans, scavenger receptor class B type 1 (SR-B1), CD81, and low-density lipoprotein (LDL) receptor. However, for most of these factors, the precise role is not well understood and one or several additional factors may be required for productive entry. Upon release of the RNA genome, the polyprotein is expressed by IRES-dependent translation occurring at the rough endoplasmic reticulum (rER) where host cell signal peptidases, signal peptide peptidases, and viral proteases catalyze polyprotein cleavage.

During or after cleavage, the membrane-associated replication complex, which catalyzes the RNA amplification via negative-strand RNA intermediates, is formed (**Figure 3**). These membrane-associated complexes are composed of viral RNA, viral proteins, and most likely host cell factors. Newly synthesized positive-strand RNAs either are used for translation or serve as templates for further RNA synthesis or interact with the core protein to form the viral nucleocapsid. The E-proteins are retained at rER membranes indicating that viral envelopes are generated by budding into the lumen of this organelle. Progeny particles are thought to be exported by the secretory pathway and after fusion of the transport vesicle with the plasma membrane, virions are released. However, most of these steps are poorly understood and several assumptions were made that are based on studies with heterologous expression systems and analogies to closely related viruses.

Virion Properties

HCV particles are enveloped and spherical and have a diameter of 55–60 nm as determined by filtration and electron microscopy (**Figure 4**). By analogy to other flaviviruses, HCV particles are composed of at least the genomic RNA, the core protein, and the two envelope proteins E1 and E2 which are embedded into the lipid envelope. The core protein forms the internal viral capsid (presumably 30–35 nm in diameter) that shelters the single-stranded RNA genome (**Figure 4**). The S_{20W} is approximately 200S and infectious HCV virions isolated from the plasma sample of infected patients and chimpanzees have low buoyant densities in the range of 1.05–1.10 g ml^{-1}.

Tissue Tropism and Host Range

Hepatocytes are considered to be the natural target cells for HCV. Viral RNA was also detected in peripheral blood mononuclear cells (PBMCs) and bone marrow cells but it is unclear whether productive infection occurs in these cells. In cell culture, HCV RNA replication was demonstrated in non-liver cells like human T- and B-cell lines or embryonic kidney cells (293). Furthermore, certain mouse cell lines can support replication of HCV replicons demonstrating that the viral replication machinery is also functional in a murine host cell environment.

Experimental Systems

Animal Models

Possibilities to propagate HCV *in vivo* are rare. For many years HCV could be propagated only in chimpanzees after experimental inoculation with virus containing samples from patients or synthetic *in vitro* transcripts derived from cloned infectious genomes. More recently, transgenic mice

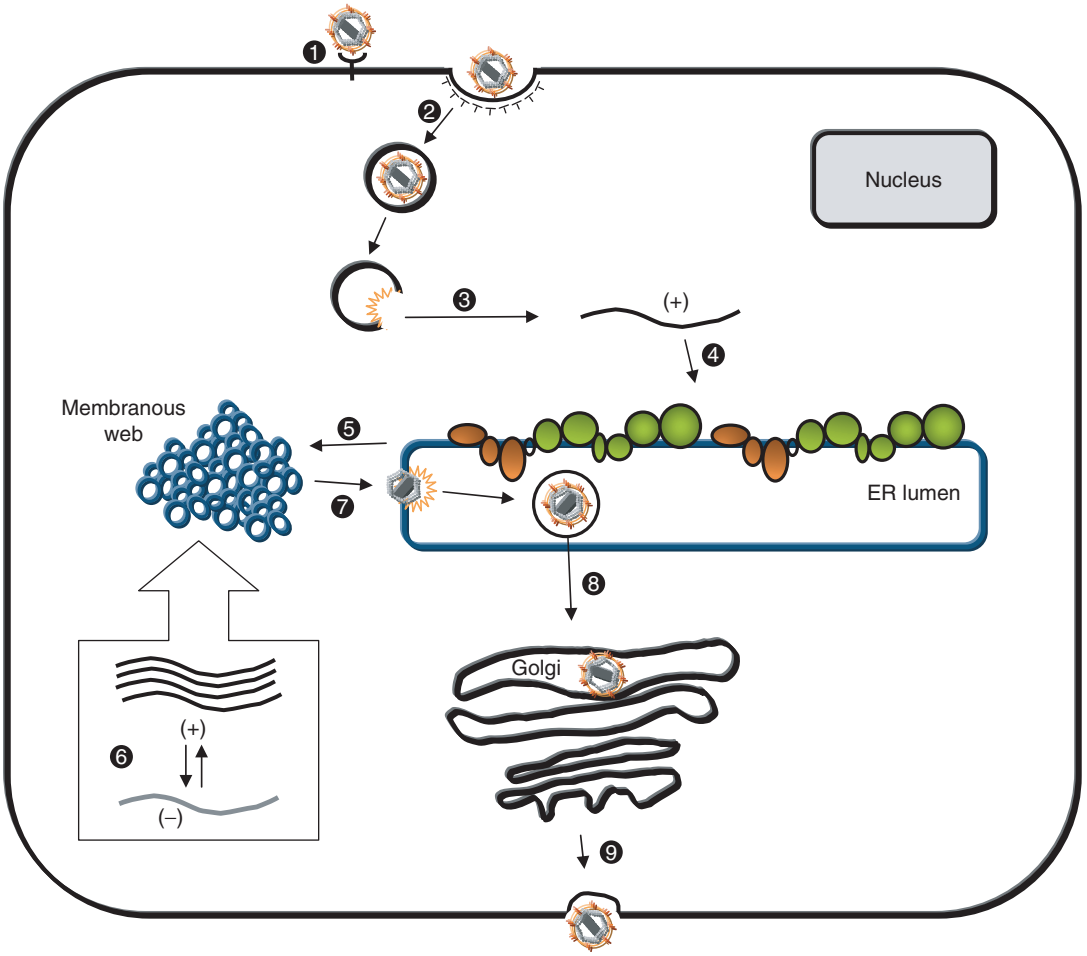

Figure 3 HCV replication cycle. (1) HCV virion binds to one or several receptors on the surface of the cell. Glycosaminoglycans, SR-B1, CD 81, and eventually LDL receptor are required for or contribute to virus binding and entry. (2) The virus particle supposedly enters the cell via clathrin-mediated endocytosis. (3) After a low-pH-mediated fusion step from within an acidic endosome and uncoating, the HCV genome is liberated into the cytoplasm of the host cell. (4) The viral RNA genome is translated at the rough endoplasmic reticulum (rER). (5) The membranous web presumably originating from ER membranes is formed. (6) It is the site of viral RNA amplification which occurs via negative-strand RNA intermediates. Newly synthesized positive-strand RNA is either used for translation or replication or the RNA is packaged into nascent capsids (7). This may occur at the ER where the E-proteins are retained. It is assumed that virions are generated by budding into the ER lumen. (8) Progeny virions are thought to be exported by the secretory pathway and, after fusion of the transport vesicle with the plasma membrane, virions are released (9).

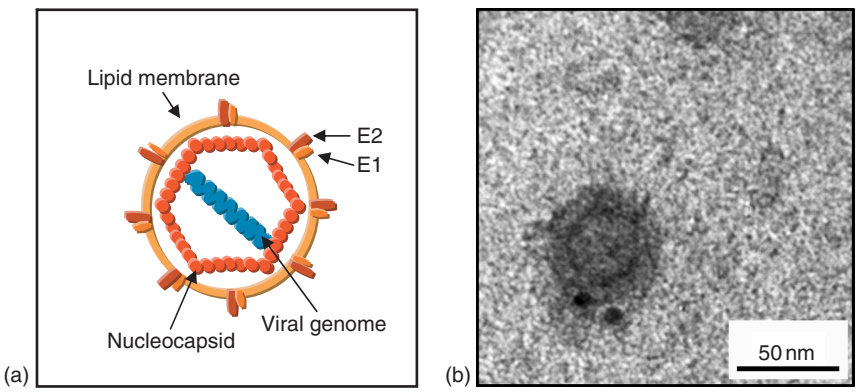

Figure 4 Composition of HCV particles. (a) Schematic of the HCV virion. (b) Electron micrograph of HCV virion produced in cell culture. The spherical particle has an outer diameter of about 60 nm and an inner core of about 30 nm. E2 was detected by immunoelectron microscopy using an E2-specific antibody and a secondary antibody conjugated to 10 nm gold particles.

xenografted with primary human hepatocytes were found to be susceptible to HCV infection. Virus replication occurs in the transplanted human tissue but, given the technical challenge, this mouse model is not widely available. Alternative models to study HCV *in vivo* are the closely related GB-viruses, especially GBV-B that replicates in tamarins (*Sanguis* sp.), causing an acute self-limiting infection of the liver or, under certain experimental conditions, a persistent infection.

Cell Culture Systems

Development of efficient cell culture systems for HCV propagation was difficult and was not successful until more than 10 years after the discovery of the virus. The first breakthrough was the development of subgenomic replicons composed of the NTRs, a selectable marker (*neo*), and a heterologous IRES directing translation of the HCV replicase (NS3–NS5B) (**Figure 5**(**a**)). When transfected into a human hepatocarcinoma cell line (Huh-7) and subjected to selection (e.g., with G418 in case of replicons containing the *neo* gene), stable cell lines were established that carry autonomously replicating HCV replicons. These viral RNAs replicate to very high levels and are maintained persistently when the cells are passaged under conditions of continuous selective pressure (e.g., G418). Owing to its high efficiency, this replicon system was of enormous value for studying HCV replication and HCV–host interaction, and for the development of antivirals targeting any of the viral replicase components (e.g., NS5B RdRp or the NS3 protease).

Since the first description of this system in 1999 numerous improvements have been made. These include the identification of replication-enhancing mutations (so-called adaptive mutations), different replicon formats allowing short-term replication analyses, and high-throughput screening assays. Thus far, replicons from different HCV isolates and two genotypes (1 and 2) are available, as are various cell lines, including two of murine origin.

Studies of the early steps of the HCV replication cycle are often performed using HCV pseudoparticles (HCVpp) (**Figure 5**(**b**)). These are retroviral capsids harboring a retroviral vector RNA into which a reporter gene has been inserted and which are surrounded by a lipid envelope carrying mature HCV E1/E2 glycoprotein complexes. This HCVpp system is an important tool to analyze the infection process and to measure HCV neutralization.

Robust production of infectious HCV particles in cell culture finally became possible in 2005 (**Figure 5**(**c**)). Key to this achievement is a particular HCV isolate designated JFH-1 (abbreviation for Japanese fulminant hepatitis) that was cloned from the serum of a patient with fulminant hepatitis C. When the JFH-1 genome is introduced into Huh-7 cells, virus particles are released that are infectious for naive Huh-7 cells, chimpanzees, and mice with human liver xenografts. Efficiency of this virus system has been increased by the construction of chimeric JFH-1 genomes, cell-culture-adapted virus variants, and by using highly permissive Huh-7 cell clones for HCV replication and entry. Very recently, a highly cell-culture-adapted variant of a genotype 1a HCV isolate has been

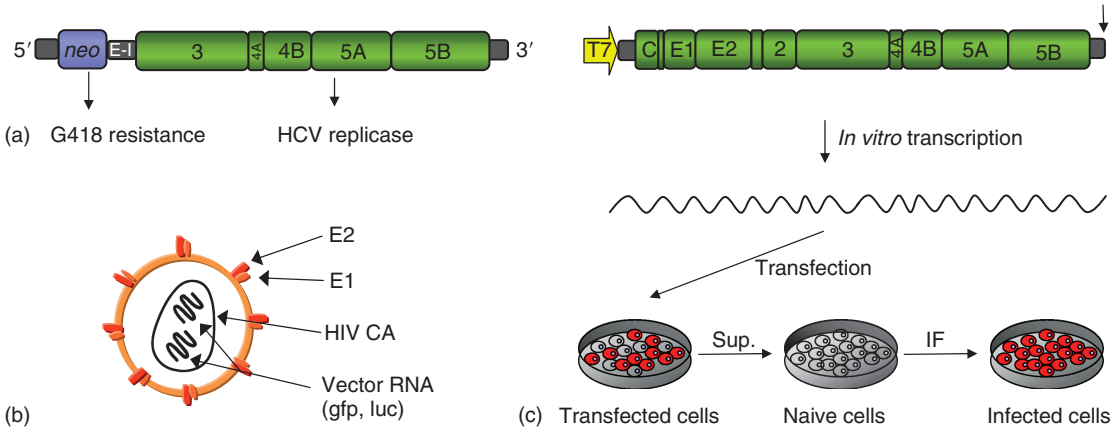

Figure 5 Cell-based systems for HCV. (a) Schematic illustration of the structure of a subgenomic HCV replicon carrying the selectable marker *neo* that confers G418 resistance. Translation of *neo* is directed by the 5′ NTR of HCV whereas translation of the replicase (NS3 to NS5B) is directed by the encephalomyocarditis virus (EMCV)-IRES. (b) Schematic of an HCV pseudoparticle (HCVpp). The retroviral vector RNA carries a reporter gene encoding, for example, for the green fluorescent protein (gfp) or the luciferase (luc). Two copies of vector RNA are packaged into the viral capsids surrounded by a lipid envelope carrying functional E1/E2 complexes. (c) Principle of the HCV infection system. Viral genomes are synthesized by *in vitro* transcription using a plasmid encoding a DNA copy of the viral genome. The T7 promoter at the 5′ end and a ribozyme or a restriction site (arrow) at the 3′ end are used to obtain run off transcripts with authentic termini. *In vitro* transcripts are transfected into Huh-7 cells and virus containing supernatant is transferred onto naive Huh-7 cells. Infection of these cells is detected, for example, by immunofluorescence (IF).

constructed that also supports virus production in Huh-7 cells, but virus titers are extremely low.

HCV–Host Interaction

Replication Factors

Several cellular proteins appear to contribute to HCV replication. For example, the ubiquitously expressed human vesicle-associated membrane protein-associated protein A (VAP-A) and its isoform VAP-B were identified as interaction partners of NS5A and NS5B. NS5A hyperphosphorylation seems to disrupt the VAP-A association and thereby negatively regulates HCV RNA replication. It is thought that VAP-A directs HCV nonstructural proteins to cholesterol-rich, detergent-resistant membranes, which are the presumed sites of HCV RNA replication.

Another host cell factor interacting with NS5A is FBL-2 belonging to the family of proteins that contain an F box and multiple leucine-rich repeats. FBL-2 is modified by geranylgeranylation which is important for NS5A interaction. FBL-2 appears to be required for HCV RNA replication. Likewise, Cyclophilin B (CyPB), a cellular protein interacting with the NS5B RdRp, seems to contribute to replication of genotype 1 isolates by promoting RNA-binding capacity of NS5B. CyPs are a family of peptidyl-prolyl *cis–trans*-isomerases which catalyze the *cis–trans*-interconversion of peptide bonds N-terminal of proline residues, facilitating changes in protein conformation. Cyclosporine or derivatives thereof potently block HCV RNA replication and it is assumed that this is due in part to sequestration of CyPB, which binds to cyclosporine with high affinity.

Also the host cell lipid metabolism plays a fundamental role in the HCV replication cycle. Treatment of replicon cells with lovastatin, an inhibitor of 3-hydroxy-3-methylglutaryl CoA reductase, or with an inhibitor of protein geranylgeranyl transferase I induced the disintegration of the HCV replication complex. Fatty acids can either stimulate or inhibit HCV replication, depending on their degree of saturation. Saturated and monounsaturated fatty acids stimulate viral replication, whereas polyunsaturated fatty acids impair replication.

Innate Immunity

Both in cell culture and in the majority of patients treated with IFN-α, a rapid and efficient block of HCV replication occurs. This result is somewhat surprising given the high rate of persistence of HCV infections (50–80%) and the finding that, in infected liver, type 1 IFN-induced genes are activated. In several studies it was concluded that HCV proteins, such as core, interfere with the various steps of the IFN-α/β-induced signaling and that some HCV proteins appear to block individual IFN-α/β-induced effectors. One prominent example is NS5A, assumed to block activity of the double-strand RNA-activated protein kinase PKR by binding to PKR via a particular NS5A region. This region overlaps with the so-called interferon-sensitivity-determining region in NS5A, assumed to correlate with outcome of antiviral therapy. However, this original assumption is still contradictory and it is still unclear whether HCV indeed interferes with one or several type 1 IFN-induced effector molecule(s). It also remains to be clarified by which mechanism interferons block HCV RNA replication.

Much less controversial are the mechanisms by which HCV interferes with the induction of innate antiviral defense. Several studies have shown that the NS3 protease proteolytically cleaves two signal-transducing molecules: TRIF, linking the activation of Toll-like receptor 3 to kinase complexes responsible for the phosphorylation of interferon response factor-3 (IRF-3) and CARDIF (also called MAVS, ips-1, VISA) relaying the activation of retinoic-acid-inducible gene 1 (RIG-1) also to IRF-3 phosphorylation. As a result, IRF-3-dependent genes are not expressed including IFN-β and IRF-7 and cells remain sensitive to virus infection. Although linking the block of IFN-β expression to persistence is attractive, it is unclear if and to what extent that is the case. On one hand blocking IRF-3 activation would not affect the antiviral program induced by type 1 IFN (e.g., produced by activated dendritic cells or administered during therapy), whereas on the other hand this block may affect the secretion of cytokines required for the development of a vigorous adaptive immune response and its attenuation may facilitate persistence.

Adaptive Immunity

The role of HCV-specific antibodies in controlling viral infection is not clear. They appear to be dispensable for viral clearance and do not protect from reinfection, neither in experimentally infected chimpanzees nor in humans after multiple exposure to HCV. However, there is evidence that the presence of HCV-specific antibodies at least partially attenuates infection. For instance, antibodies neutralizing HCV virions of different genotypes have been detected in sera of chronic hepatitis C patients but the frequency of these antibodies appears to be low. Control of acute HCV infection is primarily achieved by a rigorous and multispecific T-cell response. Thus, successful antiviral response generally encompasses multiple major histocompatibility complex (MHC) class-I and class-II restricted T-cell epitopes and a profound expansion of $CD8^+$ and $CD4^+$ T cells. In contrast, persistent infections are characterized by oligoclonal T-cell responses and a low frequency of HCV-specific T cells. The underlying reasons for the weak response

in the majority of patients are not clear but several possibilities have been suggested: (1) an impaired antigen presentation that might be due to interference of HCV with dendritic cell function; (2) $CD4^+$ T-cell failure due to deletion or anergy; (3) mutational escape in important T- (and B-)cell epitopes; and (4) functional impairment of HCV-specific $CD8^+$ T cells. How T-cell impairment is brought about is unclear but one attractive possibility is that the defect induced in innate immunity results in a defect in $CD4^+$ T-cell help. In fact, HCV-induced loss of T-cell help appears to be the key event of immune evasion.

Diagnosis

Routine screening tests for detecting HCV infections are based on serological assays measuring HCV-specific antibodies (most often by enzyme-linked immunosorbent assay (ELISA)) and nucleic acid-based tests to determine viral RNA. Current ELISA assays have a specificity of >99% and they are positive in 99% or more of immunocompetent patients in whom viral RNA is detectable. Given the higher sensitivity, the diagnostic window can be reduced by using nucleic acid-based tests. Qualitative RNA detection assays have been implemented in many blood banks in European Union countries and in the US. The risk to acquire transfusion-associated hepatitis C in such countries has been reduced to <1/million blood donations. Determination of HCV genotypes, which is an important parameter for current antiviral therapy, is based on analyzing viral RNA either by hybridization or direct sequence analysis or by using genotype-specific primers for PCR.

Treatment

Current antiviral therapy is based on the combination of a polyethylene glycol conjugated form of IFN-α with ribavirin resulting in an overall sustained virological response (SVR) of about 60%. However, the success rate depends very much on the genotype of the infecting virus. While up to 85% of genotype 2- and 3-infected patients develop SVR, only about 45% of patients infected with genotype 1 viruses do so. In addition, this therapy has numerous side effects, such as flu-like symptoms, including increased body temperature, headache and muscle pain; neuropsychiatric alterations and hemolytic anemia are also severe side effects of this combination therapy. Thus, therapy often has to be discontinued and many patients are not eligible for this treatment. Numerous efforts are therefore undertaken to develop selective drugs targeting viral functions without causing side effects. The first promising candidates are currently in clinical trials and have shown potent antiviral efficacy. Most advanced are inhibitors of the NS3 protease and the NS5B RdRp. However, monotherapy with these compounds leads to rapid selection for therapy-resistant HCV variants. Future therapy of HCV infection most likely will be based on a combination therapy, which may include a selective drug and IFN.

Hepatitis Delta Virus

Glossary

Antigenome For hepatitis delta virus (HDV), the antigenome refers to an exact complement of the genome. It also is a single-stranded circular RNA.
Editing In recent years it has become clear that many RNAs undergo nucleotide sequence changes relative to the nucleic acid templates from which they are derived. There are many different forms of this process, collectively known as editing. It can occur during or after the process of RNA transcription. HDV RNA undergoes a specific form of post-transcriptional editing in which certain adenosines are deaminated to inosine.
Genome For a virus the genome is that nucleic acid species present within virus particles. For HDV, the genome is a single-stranded circular RNA.
Ribozyme When it was realized that certain RNA molecules could have enzymatic activities similar to certain proteins, such RNAs were defined as ribozymes. Both the genomic and antigenomic RNAs of HDV contain regions that undergo specific self-cleavage, and are thus defined as ribozymes.
Rolling-circle replication For agents that have a circular genome, whether it be of DNA or RNA, there is the possibility that replication can initiate at one or more locations, leading to the synthesis of species longer than the original circle. Such multimers may then undergo processing (e.g., by cleavage and ligation) to form new unit-length products. Such a mechanism, which is referred to as rolling-circle replication, applies to certain agents and has been implicated for the replication of HDV.
Viroid Among the infectious agents of plants there are small circular single-stranded RNAs that seem to replicate without the aid of a helper virus or the synthesis of any encoded protein. These agents do not fulfill the definition of a virus and so have been named viroids.

Classification

Hepatitis delta virus or hepatitis D virus (HDV) was discovered in patients with a more severe form of human hepatitis B virus (HBV) infection. HDV is a subviral satellite of HBV. HDV is often called a virus but strictly speaking it does not satisfy the definition of a virus and should be called subviral; HDV infection and assembly of new virus particles depends upon the envelope protein provided by the natural helper virus, HBV. HDV is also called a satellite of HBV because there is no nucleotide homology between the genomes of HBV and HDV.

No other infectious agents of animals resemble HDV. There are agents in plants that share several important characteristics of RNA genome structure and replication. These plant agents include the viroids and certain satellite RNAs and satellite viruses. Nevertheless, there are also enough major differences between HDV and these plant agents that the International Committee on Taxonomy of Viruses has agreed to assign HDV as a separate genus, *Deltavirus*, with only itself as a member.

Structure

HBV, the natural helper virus of HDV, encodes three envelope proteins. These are also used for the assembly of HDV, but in a different way.

Infectious HBV particles are roughly spherical with a diameter of about 42 nm. Inside these is an icosahedral nucleocapsid of about 27 nm diameter. HBV assembly is inefficient in that infectious particles are found in serum in the presence of a 1000–1 000 000-fold excess of empty particles. These empty particles consist of 25 nm spheres and filaments with a 22 nm diameter and a heterogenous length.

Infectious HDV particles contain a ribonucleoprotein composed of the HDV RNA genome in a complex with more than 70 copies of the delta antigen, the only protein encoded by HDV. It is considered from electron microscopy and filtration studies that infectious HDV particles are spherical and at least 38 nm in diameter. However, such studies are not as clear-cut as for HBV. First, they do not show which particles actually contain RNA. Second, they do distinguish which of the RNA-containing particles are infectious. What seems clear is that the same HBV envelope protein domains are needed for HDV and HBV infectivity. That is, it is likely that for infection HDV uses the same as yet unidentified receptor as HBV.

The internal ribonucleoprotein complex of the HDV RNA genome and delta proteins has been demonstrated but the actual structure has not been clarified yet.

Replication

The RNA genome (**Figure 1**) is a single-stranded RNA of about 1700 nt in length. It is unique for many reasons

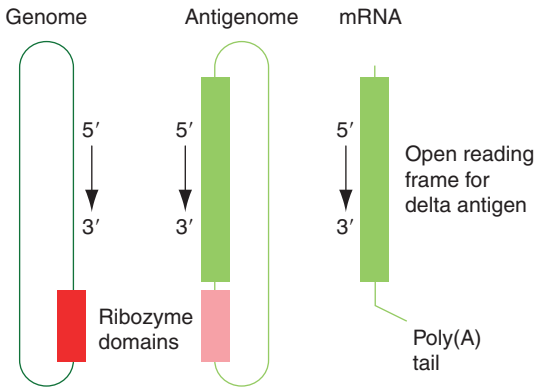

Figure 1 A representation of the three RNAs detected during the replication of HDV. The first is the 1679 nt single-stranded circular RNA found within virions, and thus defined as the genome. The second is an exact complement of the genome, defined as the antigenome, and it along with the genome is found in infected cells. A third RNA, the least abundant, is cytoplasmic, 5′-capped and 3′-polyadenylated, and is the mRNA for the translation of the delta protein. The genome and antigenomic circles are drawn as elongated in order to represent their ability to form extensive intramolecular base pairing and fold into an unbranched rod-like structure. Note that both the genome and the antigenome each contain a domain that will act as a self-cleaving ribozyme.

including its very small size and its circular conformation. The replication takes place by a mechanism that is fundamentally different from the reverse transcription pathway used by the helper virus HBV. HDV replicates with RNA rather than DNA intermediates. Inside infected cells we find not only the circular RNA genome but also an exact complement, the antigenome, which is also circular (**Figure 1**). A third RNA is also complementary to the genome. It is about 800 nt in length, 5′-capped and 3′-polyadenylated, and acts as the mRNA for the translation of the delta protein (**Figure 1**).

HDV genome replication seems to take place in the nucleus and involves redirection of the host RNA polymerase II. Because the genomic RNA is circular, it is possible for transcription to make multimeric RNAs from this template, in what is called a rolling-circle mechanism. Both the genomic and antigenomic RNAs contain a ribozyme that cleaves the RNA at a unique location. A detailed structure for one of these ribozymes has been reported. Ribozyme cleavage allows the processing of the multimeric RNAs into unit-length species, that are then somehow ligated to makes circles. The RNases of animal cells are mainly exonucleases and so circular RNAs are much more stable than the corresponding linear species. In infected liver tissue, the circular genomic RNAs accumulate to around 300 000 copies per average cell.

The mRNA of an infectious HDV needs to be translated into what is known as the small delta protein. This 195 amino acid protein is highly basic. It can dimerize using a region near the N-terminus, through what is known as an antiparallel coiled-coil domain. It can also bind with specificity to HDV RNAs, and localize to the nucleus. For a combination of these and maybe additional reasons, the small delta protein is essential for genome replication. However, during this replication, some of the antigenomic RNAs are post-transcriptionally modified at a specific location, by a form of RNA-editing. The editing involves a double-stranded RNA-specific adenosine deaminase, now known as ADAR. The editing occurs in the middle of the amber termination codon for the open reading frame of the small delta protein. This leads to the translation of a protein that is 19 amino acids longer. This 214-amino-acid long delta protein is a dominant negative inhibitor of genome replication. However, it also has a positive role. Most of it becomes farnesylated at a cysteine located four amino acids from the new C-terminus. This modified protein is essential for the late phase of HDV replication, the assembly of new virus particles, using the envelope proteins of the helper virus, HBV.

Epidemiology

HDV infections are transmitted via infected blood or blood products. There are two main classifications of HDV infection. A co-infection is one in which the individual receives both HBV and HDV at the same time. A superinfection is one in which the individual has a prior infection with HBV, usually a chronic infection, and is then infected with HDV. Such superinfections have a much greater chance of being more extensive and also a greater chance of going on to chronicity.

It was not realized until 1980 that HDV was an infectious agent. Convenient tests for HDV were soon developed and epidemiological information gathered. The initial test was for antibody directed against the delta antigen and then tests were developed for the antigen itself. Now we have much more sensitive tests for the RNA, but such tests are not routinely used.

HDV was first studied among populations in southern Italy. Of course it is only found in situations where HBV is also present, but the converse is not always true. There are geographic populations in which HBV infections are more likely to be associated with HDV. Data indicate that the fraction of HBV infections that are also HDV-associated can range from $<1\%$ to $>10\%$. The high levels have been reported for areas such as the Amazon basin in South America and southern regions of the former Soviet Union. Also, within a geographic population there may be individuals, such as intravenous drug users who share needles, where the fraction is very high, $>70\%$.

Levels of HDV infection have been greatly reduced in recent years. This is in part due to changes in the behavior of susceptible individuals, especially the intravenous drug users, and also due to screening of blood supplies.

In addition, the introduction of widespread immunization against HBV, which simultaneously protects against HDV, will ultimately reduce both the number of chronic HBV carriers and HDV infections.

Clinical Features

The replication of HBV is not directly cytopathic. The liver damage arises because of the involvement of the host immune response to these infections. The same is probably also true for HDV. In addition, there are experimental situations where HDV infections can be directly cytopathic.

In certain geographic areas, such as the Amazon basin, HDV infections can have a very high risk of producing a fulminant hepatitis, sometimes with death in less than 1 week.

Control

Immunization against the natural helper virus, HBV, confers protection against HDV. However, for nonimmunized individuals and especially for those already chronically infected with HBV, the risks remain high.

For an individual infected with HDV, there is no good therapy that directly targets the HDV infection. In one study, treatment with high doses of interferon was associated with some cures. Of course the interferon therapy also attacks the HBV infection.

Recently, antiviral therapies based upon inhibitors of the HBV reverse transcriptase are being directed against HBV infections. One might expect that these therapies would indirectly inhibit cycles of HDV replication, but such has not been the case.

Glossary

Animal reservoir A large animal population serving as a source of virus supply for the transmission of virus(es) to other animals including humans.
Enzootic An epidemiology term describing multiple continuous disease presence in an animal population in a defined geographic region and time period.
Zoonosis Infectious diseases transmissible under natural conditions from vertebrate animals to humans.

Introduction

The initial evidence for the existence of a new form of enterically transmitted viral hepatitis came from serological studies of waterborne epidemics of hepatitis in India in 1980, as cases thought to be hepatitis A were tested negative for antibodies to the hepatitis A virus (HAV). To conform to the standard nomenclature of viral hepatitis, this new form of viral hepatitis was named hepatitis E. In 1983, viral hepatitis E was successfully transmitted to a human volunteer via fecal–oral route with a stool sample collected from a non-A, non-B hepatitis patient, and virus-like particles were visualized by electron microscope in the stool of the infected volunteer. Subsequently, the agent was also successfully transmitted to nonhuman primates. However, the identity of the virus was not known until 1990 when the genomic sequence of the new virus, named hepatitis E virus (HEV), was determined. The recent identification and characterization of animal strains of HEV, swine hepatitis E virus (swine HEV) from pigs in 1997 and avian hepatitis E virus (avian HEV) from chickens in 2001, have broadened the host ranges and diversity of the virus, and also provided two unique homologous animal model systems to study HEV replication and pathogenesis.

Convincing evidence indicates that hepatitis E is a zoonotic disease, and pigs and perhaps other animal species are reservoirs for HEV.

Properties and Structure of Virions

HEV is a symmetrical, icosahedral, spherical virus particle of approximately 32–34 nm in diameter without an envelope (**Figure 1**). The capsid protein encoded by the open reading frame (ORF) 2 gene of HEV is the only known structural protein on the virion. The N-terminal truncated capsid protein, which contains amino acid residues 112–660, can self-assemble into empty virus-like particles when expressed in baculovirus. The buoyant density of HEV virions is reportedly 1.35–1.40 g cm^{-3} in CsCl, and 1.29 g cm^{-3} in potassium tartrate and glycerol. The virion sedimentation coefficient is 183 S. HEV virion is sensitive to low-temperature storage and iodinated disinfectants but is reportedly stable when exposed to trifluorotrichloroethane. HEV virion is more heat labile than is HAV, another enterically transmitted hepatitis virus. HAV was only 50% inactivated at 60 °C for 1 h but was almost totally inactivated at 66 °C. In contrast, HEV was about 50% inactivated at 56 °C and almost totally inactivated (96%) at 60 °C. The fecal–oral route of transmission indicates that HEV is resistant to inactivation by acidic and mild alkaline conditions in the intestinal tract.

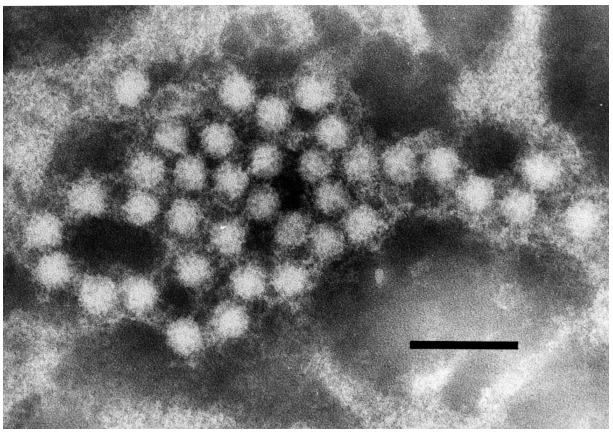

Figure 1 Electron micrograph of 30–35 nm diameter particles of an avian strain of the HEV. The virus particles were detected from a bile sample of a chicken with hepatitis–splenomegaly syndrome. Scale = 100 nm. Reproduced from Haqshenas G, Shivaprasad HL, Woolcock PR, Read DH, and Meng XJ (2001) Genetic identification and characterization of a novel virus related to human hepatitis E virus from chickens with hepatitis–splenomegaly syndrome in the United States. *Journal of General Virology* 82: 2449–2462, with permission from Society for General Microbiology.

Taxonomy and Classification

HEV was initially classified in the family *Caliciviridae* on the basis of its superficial similarity in morphology and genomic organization to caliciviruses. However, subsequent studies revealed that the HEV genome does not share significant sequence homology with caliciviruses, and that the codon usage and genomic organization of HEV are also different from that of caliciviruses. Therefore, in the *Eighth Report of the International Committee on Taxonomy of Viruses* (ICTV), HEV was declassified from the family *Caliciviridae*, and was placed in the sole genus *Hepevirus*. The proposed family name *Hepeviridae* has yet to be officially approved by ICTV.

The species in the genus *Hepevirus* includes the four recognized major genotypes of HEV (**Figure 2**): genotype 1 (primarily Burmese-like Asian strains), genotype 2 (a single Mexican strain), genotype 3 (strains from rare endemic cases in the United States, Japan, and Europe, and swine strains from pigs in industrialized countries), and genotype 4 (variant strains from sporadic cases in Asia, and swine strains from pigs in both developing and industrialized countries). A tentative new species in the genus *Hepevirus* is the recently discovered avian HEV from chickens (**Figure 1**). The nucleotide sequence identity differs by 20–30% between genotypes, and by *c.* 40–50% between avian HEV and mammalian HEVs. Despite the extensive nucleotide sequence variations, however, it appears that there exists a single serotype of HEV.

Genome Organization and Gene Expression

The genome of HEV, which possesses a cap structure at its 5′ end, is a single-stranded, positive-sense RNA molecule of approximately 7.2 kb in length. The viral genome consists of a short 5′ noncoding region (NCR) of approximately 26 bp, three open reading frames (ORFs 1–3), and a 3′ NCR. ORF3 overlaps ORF2, but neither ORF2 nor ORF3 overlaps with ORF1 (**Figure 3**). The ORF1 at the 5′ end encodes viral nonstructural proteins that are involved in viral replication and protein processing.

Functional motifs, characteristic of methyltransferases, papain-like cystein proteases, helicases, and RNA-dependent RNA polymerases (**Figure 3**), were identified in ORF1 based upon sequence analyses and analogy with other single-strand positive-sense RNA viruses. ORF2, located at the 3′ end, encodes the major capsid protein that contains a typical signal peptide sequence, and three potential glycosylation sites. The capsid protein contains the most immunogenic epitope, induces neutralizing antibodies against HEV, and is the target for HEV vaccine development. ORF3 encodes a small

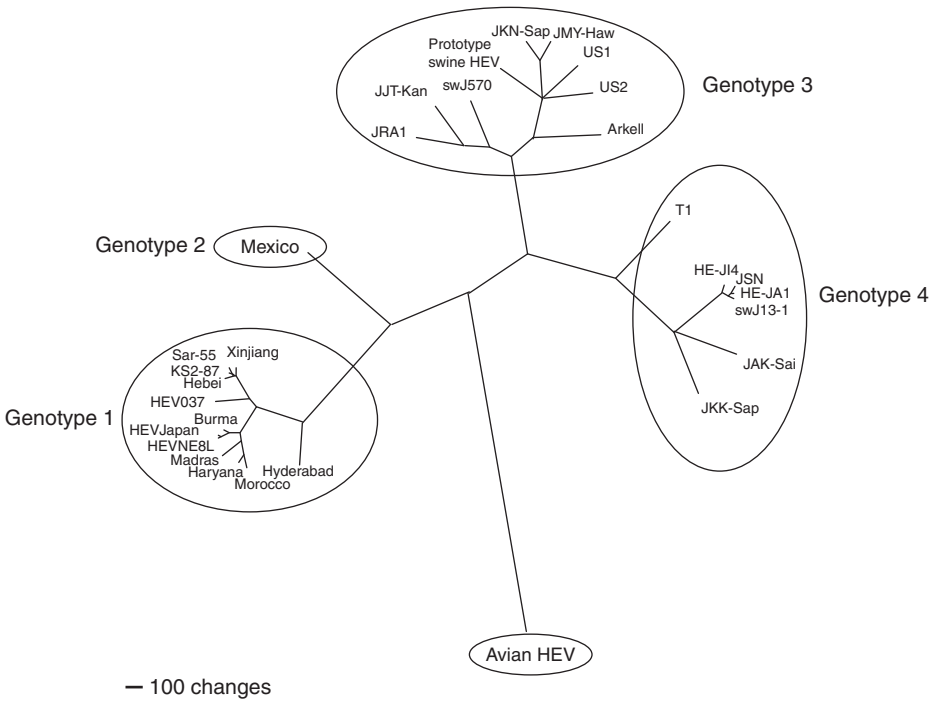

Figure 2 A phylogenetic tree based on the complete genomic sequences of available human, swine, and avian HEV strains. The tree was constructed with the aid of the PAUP program by using heuristic search with 1000 replicates. A scale bar, indicating the number of character state changes, is proportional to the genetic distance. The four recognized major genotypes of HEV are indicated. The avian HEV in a branch distinct from mammalian HEV is tentatively classified as a separate species. Reproduced from Huang FF, Sun ZF, Emerson SU, *et al.* (2004) Determination and analysis of the complete genomic sequence of avian hepatitis E virus (avian HEV) and attempts to infect rhesus monkeys with avian HEV. *Journal of General Virology* 85: 1609–1618, with permission from Society for General Microbiology.

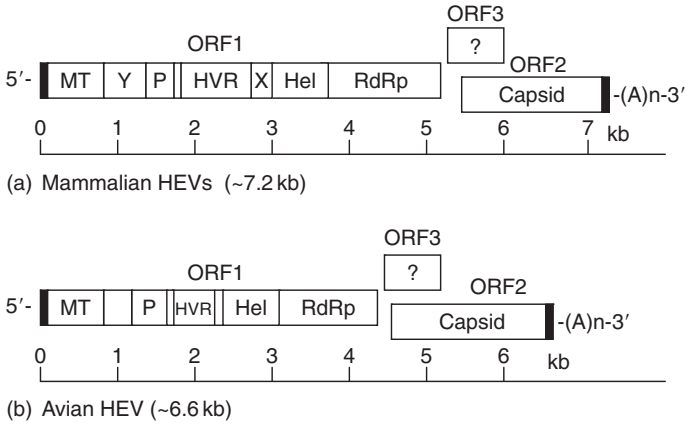

Figure 3 Schematic diagram of the genomic organization of HEV: a short 5′ (solid box at the 5′ end), a 3′ NCR (solid box at the 3′ end), and three ORFs. ORF2 and ORF3 overlap each other but neither overlaps ORF1. ORF1 encodes nonstructural proteins including putative functional domains, ORF2 encodes putative capsid protein, and ORF3 encodes a small protein with unknown function. MT, methytransferase; X, 'X' domain; Y, 'Y' domain; P, a proline-rich domain that may provide flexibility; HVR, a hypervariable region; Hel, helicase; RdRp, RNA-dependent RNA polymerase.

cytoskeleton-associated phosphoprotein. The N-terminus of ORF3 has a cysteine-rich region, binds to HEV RNA, and enters into a complex with the capsid protein. The C-terminal region of the ORF3 protein is a multifunctional domain, and may be involved in HEV virion morphogenesis and viral pathogenesis. Antibodies to ORF3 protein have been detected in some animals (rhesus monkeys and chickens) experimentally infected

with HEV; however, it remains unknown if ORF3 is a structural protein in the virion.

The transcription and translation mechanisms of HEV genes are still poorly understood, largely due to the lack of an efficient cell culture system for the propagation of HEV. By using an *in vitro* HEV replicon system, a bicistronic subgenomic mRNA was identified and found to encode both ORF2 and ORF3 proteins. Subgenomic mRNAs were also detected in infected liver tissues. The ORF3 gene contains a *cis*-reactive element and encodes a protein that is essential for virus infectivity *in vivo*. However, recent studies showed that the expression of ORF3 protein is not required for virus replication, virion assembly, or infection of hepatoma cells *in vitro*. The translation and post-translational processes of the ORF1 polyprotein remain largely unknown. When expressed in baculovirus, the nonstructural ORF1 polyprotein was found to process into smaller proteins that correlate with predicted functional domains in ORF1. However, no processing of the ORF1 polyprotein was detected when it was expressed in bacterial or mammalian expression systems.

Epidemiology

HEV is transmitted primarily through the fecal–oral route, and contaminated water or water supplies are the main sources of infection. Hepatitis E, generally affecting young adults, is an important public health disease in many developing countries of the world where sanitation conditions are poor. Rare epidemics are associated with fecal contamination of water, and are generally restricted in developing countries of Asia and Africa, and in Mexico. Most cases of acute hepatitis E occurred as endemic or sporadic forms worldwide in both industrialized and developing countries. The genotypes 1 and 2 HEV strains are associated with epidemics, whereas genotypes 3 and 4 strains cause sporadic cases of hepatitis E. A unique feature of HEV infections is the high mortality rate, up to 25%, in infected pregnant women, although the mechanism of fulminant hepatitis during pregnancy is still not known.

Seroprevalence of HEV antibodies is age dependent, with the highest rate occurring in young adults of 15–40 years of age. In endemic countries, the seroprevalence rate, generally ranging from 3% to 27%, is much lower than expected, although higher seroprevalence rates have been reported in some endemic countries such as Egypt. Surprisingly, a significant proportion of normal blood donors in the United States (4–36%) and other industrialized countries were tested seropositive for immunoglobulin G (IgG) anti-HEV antibodies, suggesting prior infections with HEV (or an antigenically related agent). The source of seropositivity in individuals from industrialized countries is not clear but a zoonotic origin via direct contact with infected animals or consumption of raw or undercooked animal meats has been suggested.

Swine HEV

The identification and characterization of swine HEV from pigs in the United States lend credence to the zoonosis concept for HEV. Since the initial report in 1997, swine HEV has now been identified from pigs in more than a dozen countries. Thus far, the viruses identified from pigs worldwide belong to either genotype 3 or 4, which both cause sporadic cases of acute hepatitis E. Recently, a genotype-1-like swine HEV was reportedly identified from a pig in Cambodia but independent confirmation of this finding is still lacking. Genetic and phylogenetic analyses of the complete genomic sequences of swine HEV revealed that swine HEV is very closely related, or identical in some cases, to the genotype 3 and 4 strains of human HEV (**Figure 2**). Seroepidemiological studies demonstrated that swine HEV is ubiquitous in pigs in the Midwestern United States, and that about 80–100% of the pigs in commercial farms in the United States were infected. Similar findings were also reported in more than a dozen other developing and industrialized countries, indicating that swine HEV infection in pigs is common worldwide. The ubiquitous nature of swine HEV infection in pigs provides a source of virus supply for zoonotic infection. Swine HEV infection generally occurs in pigs of 2–4 months of age. The infected pigs remain clinically normal, although microscopic evidence of hepatitis has been observed.

Avian HEV

Avian HEV was first isolated and characterized in 2001 from bile samples of chickens with hepatitis–splenomegaly (HS) syndrome in the United States, although a big liver and spleen disease virus (BLSV) with 62% nucleotide sequence identity to HEV (based on a 523 bp genomic region) was reported in 1999 from chickens in Australia. HS syndrome is an emerging disease of layer and broiler breeder chickens in North America characterized by increased mortality and decreased egg production. Dead birds have red fluid or clotted blood in their abdomens, and enlarged livers and spleens. Avian HEV shared *c.* 80% nucleotide sequence identity with the Australian BLSV, suggesting that big liver and spleen disease (BLS) in Australia and HS syndrome in North America are caused by variant strains of the same virus.

Avian HEV is morphologically, genetically, and antigenically related to human HEV. The complete genomic sequence of avian HEV is about 6.6 kb in length (**Figure 3**), which is about 600 bp shorter than that of human and

swine HEVs. Although avian HEV shares only *c.* 50–60% nucleotide sequence identity to mammalian HEVs, the genomic organization, functional motifs, and common antigenic epitopes are conserved between avian and mammalian HEVs (**Figure 3**). Phylogenetic analyses indicated that avian HEV is distinct from mammalian HEV (**Figure 2**) and may represent either a fifth genotype of HEV or a separate species within the genus *Hepevirus*. Like swine HEV, avian HEV infection in chickens is widespread in the United States: *c.* 71% of chicken flocks and 30% of chickens are positive for IgG antibodies to avian HEV. Like human and swine HEVs, avian HEV antibody prevalence is also age dependent: *c.* 17% of chickens younger than 18 weeks are seropositive, as compared to *c.* 36% of adult chickens. Avian HEV isolates recovered from chickens with HS syndrome in the United States displayed 78–100% nucleotide sequence identities to each other, and 56–61% identities to known strains of human and swine HEVs.

Host Range and Cross-Species Infection

Swine HEV has been shown to cross species barriers and infect both rhesus monkey and chimpanzee. Infection of nonhuman primates, the surrogates of man, with swine HEV demonstrated the possibility of human infection with swine HEV. Conversely, genotype 3 human HEV has been shown to infect pigs under experimental conditions. However, attempts to experimentally infect pigs with genotypes 1 and 2 strains of human HEV were unsuccessful. Cross-species infection of HEV has also been reported in other animal species. Lambs were reportedly infected with human HEV isolates. Similarly, Wistar rats were reportedly infected with a human stool suspension containing infectious HEV, although others failed to confirm the rat transmission results. Cross-species infection by avian HEV has also been demonstrated, as avian HEV recovered from a chicken with HS syndrome was able to successfully infect turkeys. However, an attempt to experimentally infect two rhesus monkeys with avian HEV was unsuccessful. Thus, it appears that, unlike swine HEV, avian HEV may not readily infect humans.

There is potentially a wide host range of HEV infection. In addition to swine and chickens, antibodies to HEV have been reportedly detected in several other animal species including rodents, dogs, cats, sheep, goats, cattle, and nonhuman primates, suggesting that these animals have been exposed to HEV (or a related agent) and thus might serve as reservoirs. However, the source of seropositivity in these animal species, with the exception of pigs and chickens, could not be definitively identified since virus was either not recovered from these species or the recovered virus could not be sequenced to confirm its identity. A significant proportion of wild rats caught in different geographic regions of the United States (ranging from 44% to 90%) and other countries tested positive for IgG anti-HEV antibodies. Rodents are frequently found in both urban and rural environments and, thus, could potentially play an important role in HEV transmission. The existence of a wide host range of animal species positive for HEV antibodies further supports the zoonosis concept for HEV.

Pathogenesis and Tissue Tropism

The pathogenesis of HEV is largely unknown. It is believed that HEV enters the host through the fecal–oral route. However, the primary site of HEV replication is not known. In primates and pigs experimentally infected with human and swine HEVs, virus replication in the liver has been demonstrated. It is believed that, after replication in liver, HEV is released to the gallbladder from hepatocytes and then is excreted in feces. In pigs experimentally infected with human and swine HEVs, in addition to the liver, HEV replication was also identified in extrahepatic tissues including small intestine, colon, hepatic, and mesenteric lymph nodes. Although the clinical and pathological significance of these extrahepatic sites of virus replication is not known, it is believed that HEV may first replicate in the gastrointestinal tract after oral ingestion of the virus, and subsequently spreads to the target organ liver via viremia. It has been well documented that pregnancy increases the severity and mortality of the disease. The overall mortality rate caused by HEV in infected pregnant women can reach up to 25%, although, under experimental conditions, fulminant hepatitis E could not be reproduced in infected pregnant rhesus monkeys or infected pregnant sows. Therefore, the mechanism of fulminant hepatitis E in infected pregnant women remains unknown.

Zoonotic Risk

Hepatitis E is now considered a zoonotic disease, and pigs (and possibly other animal species) act as reservoirs. It has been demonstrated that pig handlers such as pig farmers and swine veterinarians in both developing and industrialized countries are at increased risk of HEV infection. For example, swine veterinarians in the United States are 1.51 times (swine HEV antigen, $p = 0.03$) more likely to be positive for HEV antibodies than age- and geography-matched normal blood donors. Also, it has been reported that HEV antibody prevalence in field workers from the Iowa Department of Natural Resources is significantly higher than that in blood donors, suggesting that human populations with occupational exposure to wild animals also have a higher risk of HEV infection. Transmissions of

hepatitis E from a pet cat and a pet pig to human owners were also reported.

As a fecal–orally transmitted disease, waterborne epidemics are the characteristic of hepatitis E outbreaks in humans. Large amounts of viruses are excreted in feces of infected pigs and other animals. Therefore, swine and other animal manure and feces could be a source of contamination of irrigation water or coastal waters with concomitant contamination of produce or shellfish. Strains of HEV of both human and swine origin have been detected in sewage water. Consumption of contaminated shellfish has been implicated in sporadic cases of acute hepatitis E. Sporadic and cluster cases of acute hepatitis E have also been epidemiologically and genetically linked to the consumption of raw or undercooked pig livers. Approximately 2% of the pig livers sold in local grocery stores in Japan and 11% in the United States were tested positive for swine HEV RNA. The contaminating virus in commercial pig livers sold in the grocery stores of the United States remains fully infectious. Most importantly, the virus sequences recovered from pig livers in grocery stores are closely related, or identical in a few cases, to the viruses recovered from human hepatitis E patients in Japan. Recently, a cluster of four cases of acute hepatitis E were definitively linked to the consumption of raw deer meat in two families in Japan. The viral sequence recovered from the leftover frozen deer meat was 99.7–100% identical to the nucleotide sequence of viruses recovered from the four human patients. Family members who ate none or little deer meats were not infected. Taken together, these data provide convincing evidence of zoonotic HEV transmission either via direct contact with animals or animal wastes or via consumption of infected animal meats. Recently, numerous novel strains of HEV genetically closely related to swine HEV have been identified from patients with acute hepatitis E in many countries, suggesting that these novel strains of human HEV may be of swine origin.

Transmission and Natural History

The primary transmission route for HEV is fecal–oral. Feces from infected humans and other animals contain large amounts of viruses and are likely the main source of virus for transmission. However, under experimental conditions, reproduction of HEV infection in nonhuman primates and pigs via the oral route of inoculation has proven to be difficult, even though the animals can be readily infected by HEV via the intravenous route of inoculation. Chickens were successfully infected via the oral route of inoculation with avian HEV. Other route(s) of transmission cannot be ruled out.

The natural history of HEV is not known. The identification of HEV strains from swine and chickens and their demonstrated ability of cross-species infection and the existence of a wide host range of seropositive animals has further complicated the understanding of HEV natural history. Since human-to-human transmission is uncommon for HEV, therefore a speculative scenario is that HEV is constantly circulating among different animal species, and that each species is infected by a unique strain that is enzootic in respective animal species. Some species, but not all, carry HEV strains that are genetically very similar to human HEV and are transmissible to humans. Therefore, HEV can infect humans through direct contact with infected domestic or farm animals or with feces-contaminated water or via consumption of infected raw or undercooked animal meats. If this happens in a developing country, it may result in an endemic or epidemic due to the poor sanitation conditions. However, if this happens in an industrialized country with good sanitation measures, it will occur only as a sporadic case. It will now be important to determine whether there are basic differences in host range or pathogenicity between epidemic or endemic strains in humans and enzootic strains that are mainly circulating in animal species.

Immunity

The immune response to HEV infection, characterized by a transient appearance of immunoglobulin M (IgM) HEV antibodies followed by long-lasting IgG antibodies, appears late during the period of viremia and virus shedding in stool. The HEV capsid protein is immunogenic and induces protective immunity. The capsid proteins between mammalian and avian HEV strains share common antigenic epitopes, and all HEV strains identified thus far appear to belong to a single serotype. Cross-challenge experiments in primates have demonstrated cross-protection following infection with different genotypes of human HEV strains. The cell-mediated immune response against HEV infection is largely unknown.

Prevention and Control

A vaccine against HEV is not yet available. The experimental recombinant HEV vaccines appear to be very promising; however, their efficacies against the emerging strains of HEV including animal strains with zoonotic potential need to be thoroughly evaluated. In the absence of a vaccine, important preventive measures include the practice of good hygiene, and avoiding drinking water of unknown purity or consuming raw or undercooked pig livers. The demonstrated ability of cross-species infection by swine HEV raises a public health concern, especially for high-risk groups such as pig handlers. An effective

measure to prevent potential zoonotic transmission for pig and other animal handlers is to wash hands thoroughly after handling infected animals.

Herpes Simplex Viruses: General Features

L Aurelian, University of Maryland School of Medicine, Baltimore, MD, USA

© 2008 Elsevier Ltd. All rights reserved.

History

The word 'herpes' as applied to spreading, ulcerative skin manifestations is traced to Hippocrates. In 1736, Jean Astruc classified the condition as sexually transmitted. Its infectious nature was demonstrated in 1921, when lesion material was serially transmitted in rabbits. In 1929 Goodpasture concluded that a latent state is established in ganglionic neurons, and in the 1930s it became evident that the manifestation is gingivostomatitis in seronegative subjects and recurrent 'fever blisters' in those who are seropositive. We now know that two distinct viruses preferentially cause facial or genital lesions. A critical advance has been the development of antiviral chemotherapy.

Classification

Herpes simplex virus serotypes 1 and 2 (HSV-1 and HSV-2) are members of the family *Herpesviridae.* They belong to the subfamily *Alphaherpesvirinae* and the genus *Simplexvirus.* Features of the *Alphaherpesvirinae* include a variable host range, relatively short reproductive cycle, rapid spread in culture, efficient destruction of infected cells, and latency establishment in sensory ganglia.

Structure

Virus particles are 150–200 nm in diameter and consist of four components: core, capsid, tegument, and envelope (**Figure 1(b)**). The core contains the 152 kbp linear, double-stranded DNA genome. It has two covalently linked components consisting of unique sequences (U_L and U_S) bracketed by inverted repeats (**Figure 1(a)**). Open reading frames (ORFs) are located within the unique and repeat sequences, the latter in two copies per genome. Some genes (e.g., R1 (large subunit of ribonucleotide reductase) and $\gamma_1$34.5) contain regions with cellular homology, and were presumably captured during evolution.

The capsid is a 100–110 nm protein shell with $T = 16$ icosahedral symmetry (**Figure 1(c)**). The faces and edges of the icosahedron are formed by 150 hexons. The vertices are made by pentons. The triplexes are present in the threefold positions between hexons and between hexons and pentons. One of the 12 vertices is believed to be the portal complex through which the genome enters and leaves the capsid, replacing one of the pentons. Over 30 proteins are in the mature particle, eight of which form the capsids. VP5 forms the bulk of the pentons and hexons. VP26 occupies the outer surfaces of the hexons. VP19C and VP23 form the triplexes, which stabilize the

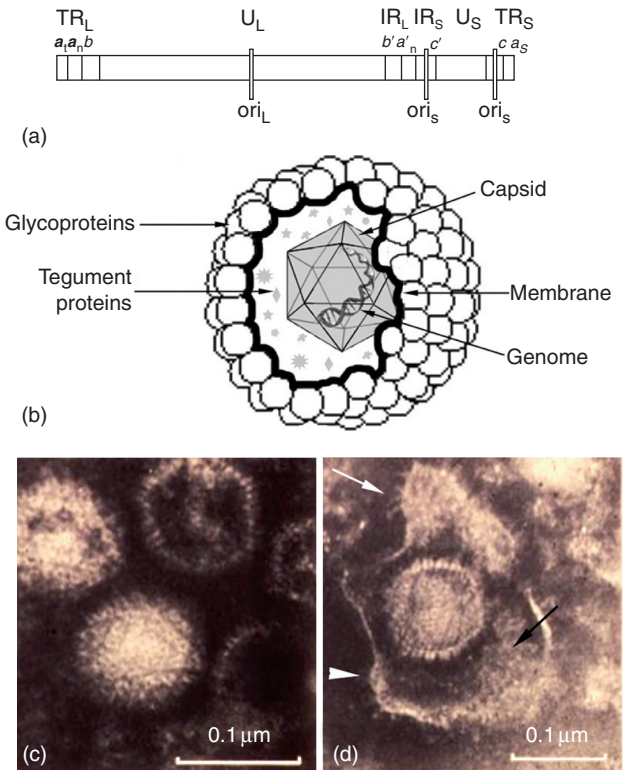

Figure 1 Structure. (a) The HSV genome has two covalently linked components consisting of unique sequences (U_L and U_S) bracketed by inverted repeats (IR_L/TR_L and IR_S/TR_S) and contains three origins of replication (one Ori_L and two Ori_S). (b) The virus particle consists of four components: core, capsid, tegument, and envelope. (c) Negatively stained virus capsids. Capsomers are $9.5 \times 12.5\,nm^2$ (longitudinal section) and evidence a 4 nm in diameter channel that runs from the surface along the long axis. (d) Enveloped virus particle. The capsid is surrounded by an asymmetrical fibrous-like tegument (black arrow). The envelope (arrowhead) is decorated with spikes projecting from its surface that consist of glycoproteins (white arrow).

capsid shell through interactions with adjacent VP5 molecules. The tegument surrounds the capsid. It is asymmetrically distributed and may appear fibrous on negative staining. Tegument proteins are involved in initiating virus replication (e.g., the transactivator VP16) and inhibiting host cell translation (e.g., the virion host shutoff (vhs) protein). The envelope is the outer covering, which is acquired from cellular membranes. It is decorated with spikes that contain viral glycoproteins (**Figure 1(d)**).

Host Range

Humans are the natural host, but HSV also infects experimental animals and embryonated chicken eggs. The animal species, virus type, route of inoculation, and state of immune competence affect the outcome of infection. In the mouse, intracerebral, footpad, intranasal, and intraperitoneal inoculations are used as models of human fatal neurological or visceral disease. Eye infection is used as a model of encephalitic and latent disease. Certain mouse strains (viz., C57BL/6) exhibit natural resistance, while newborn mice are particularly sensitive. Skin infection was described in mice, rabbits, and guinea pigs, the latter providing the best approximation of human recurrent disease. A wide variety of cell lines support HSV growth. Human primary and secondary cultures are generally more sensitive than established nonhuman cell lines and are used for virus isolation.

Virus Replication

The replicative cycle is represented schematically in **Figure 2**.

1. *Entry.* Virus glycoproteins gC and/or gB bind heparan sulfate chains on the cell surface, followed by fusion of the viral envelope with the cell membrane. Fusion requires viral glycoproteins gB, gD, gH, and gL and one cellular entry receptor that binds gD. Receptors include the herpesvirus entry mediator (HVEM), a member of the tumor necrosis factor receptor superfamily, and nectins 1 and 2, which are members of the immunoglobulin superfamily. The same receptor may also initiate endocytosis, in a cell-type specific context. A cellular entry receptor that binds gB was postulated.

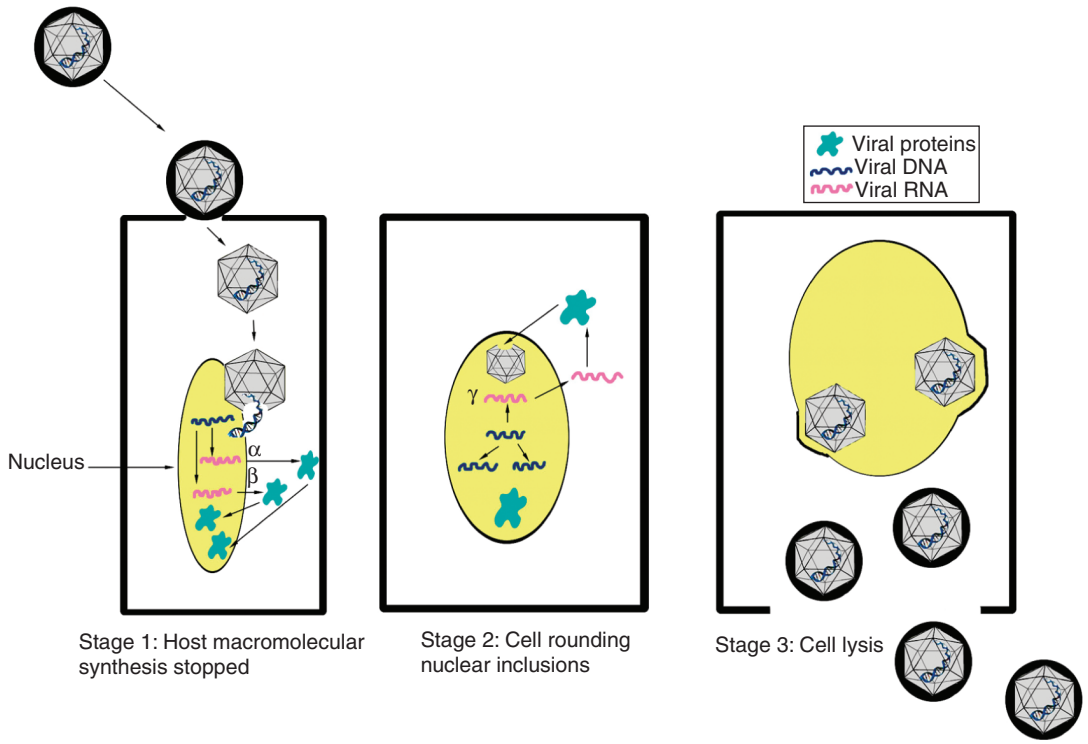

Figure 2 Replicative cycle. Schematic representation includes temporally regulated transcription of IE (α), E (β), and L (γ) genes and the stages of cellular alterations.

2. *Transcription.* Entering capsids dock at the nuclear pore complex and release their genomes. The viral DNA traverses the nuclear pore channel as a condensed, densely packed rod-like structure. In the nucleus, the HSV-1 genomes associate with promyelocytic leukemia protein nuclear bodies (or nuclear domain 10 (ND10)), giving rise to virus replication compartments. The genome encodes up to 84 proteins, and 38 HSV-1 ORFs are essential for virus replication in cell culture. HSV transcripts can have common initiation signals but different termination sites, different initiation sites but co-terminal ends, or differ in their initiation and termination sites but have partially collinear sequences. At least three gene pairs are known to occupy both DNA strands at complementary positions, generating antisense transcripts, the expression of which is mutually exclusive. Only a few HSV mRNAs are spliced (e.g., ICP0).

Three classes of genes are coordinately transcribed and temporally regulated during lytic infection: immediate early (IE), early (E), and late (L) (also known as α, β, and γ, respectively). IE (α) genes (e.g., ICP4, ICP27, ICP0, and ICP22) are transcribed first and play crucial roles in the regulation of productive infection. ICP4 is required for transcription of the E (β) and L (γ) genes. Early after infection, ICP27 co-localizes with ICP4 and has transcriptional and post-transcriptional regulatory activities. Late in infection, it functions in the processing and efficient export of viral mRNAs. ICP0 is not essential, but it is a major transactivator of HSV gene expression and stimulates virus growth, particularly in cells infected at a low multiplicity of infection (moi). ICP22 and its in-frame N-terminal truncation US1.5 are required for virus replication in most cell types. E gene products include enzymes (e.g., thymidine kinase (TK) and DNA polymerase (Pol)), which are required for virus DNA replication. Their expression requires functional IE genes. An exception is R1, which is regulated with IE kinetics. HSV-2 R1 responds to cellular AP-1 transcription factors. L gene expression requires viral DNA synthesis.

The promoters of the IE and R1 genes contain reiterated core enhancer elements (TAATGARAT) that are targeted by VP16 in conjunction with the cellular protein Oct-1 and the transcriptional co-activator HCF-1 in order to mediate transcription. The presence of VP16 is associated with the recruitment of transcription factors (e.g., TFIIB and TFIIH) and the TATA-binding protein (TBP), and assembly of an RNA polymerase II preinitiation complex. Oct-1 is critical for virus replication at low moi.

3. *DNA replication.* Upon reaching the nucleus, the viral genome circularizes and serves as template for DNA replication. DNA replication initiates in an origin-independent manner and continues through an origin-dependent process, perhaps by a rolling-circle and/or homologous recombination-driven mechanism. Homologous recombination may help maintain the integrity of the viral genome through repair of mutated/damaged DNA, and is likely to

contribute to the intratypic molecular diversity of the viral genome. The majority of the replicative intermediates are long concatemers that appear to be generated through sequence replacement or insertion. They contain genomic units with U_L and U_S segments in different orientations that give rise to four possible isomers in equimolar ratios. The biologic relevance of isomerization is unclear. Viral proteins required for DNA replication in cell culture are UL30/UL42, a highly processive heterodimeric DNA polymerase; UL5/UL8/UL52, a heterotrimeric helicase–primase complex; UL29, a single-stranded DNA-binding protein; and UL9, an origin-binding protein that is only required early post infection (pi). Host recombination–repair proteins are also recruited to viral DNA replication sites.

The HSV genome contains three origins of replication with high-affinity binding sites for UL9: a single copy of Ori_L located in the middle of the U_L segment and two copies of Ori_S located in the repeats flanking the U_S segment (**Figure 1**(**a**)). Mutants lacking Ori_L or both copies of Ori_S are replication competent, indicating that Ori_L and Ori_S can compensate for each other. However, differences in their respective functional efficiencies have been reported. Ori_L may be involved in HSV-1 morbidity and mortality and latency reactivation in mice.

4. *Assembly and egress.* Assembly occurs in the nucleus (**Figure 3**(**a**)). The viral genome is inserted into a spherical intermediate capsid (procapsid) by a molecular motor made up of viral proteins UL6 together with UL15 and UL28, which are transiently associated with the capsids, recognize packaging signals on DNA, and cleave replicated concatameric DNA into monomeric units. During packaging, the protein scaffold within the procapsid is cleaved and removed, and the procapsid undergoes morphological changes that result in a more robust and angularized structure. Proteins UL17 and UL25 stabilize capsid-DNA structures. DNA-containing capsids exit the nucleus by budding through the inner and outer nuclear membranes (**Figure 3**(**b**)). This involves the viral protein complex UL31/UL34, which recruits protein kinase (PK) C to the nuclear membrane, thereby causing lamin B phosphorylation and lamina permeabilization.

The mechanism of egress of the alphaherpesviruses has been the subject of a long-standing controversy. According to one model, primary envelopment occurs by budding through the inner nuclear membrane and is followed by transport of primary virions within vesicles from the outer nuclear membrane through the endoplasmic reticulum and secretory Golgi pathway to the cell surface. To account for the lack of identity between primary and mature virions, the second model proposes that enveloped capsids undergo de-envelopment at the outer nuclear membrane and secondary re-envelopment at the *trans*-Golgi network, where they acquire their mature envelope by budding into a cytoplasmic organelle that transports them to the plasma membrane (**Figure 3**(**b**)). Release is by

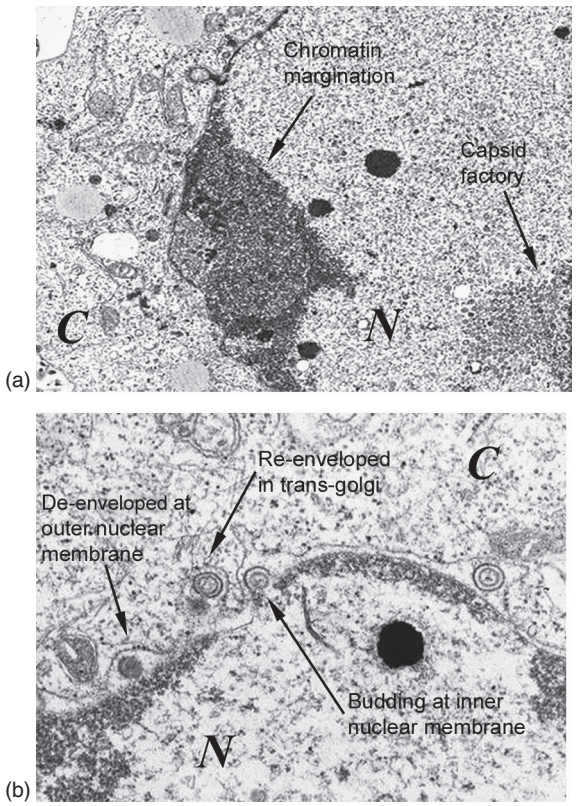

Figure 3 Virus replication. Thin sections of HSV-2-infected cells (12 h after infection) stained with uranyl acetate and lead citrate show nuclear (N) and cytoplasmic (C) compartments. (a) Intranuclear capsids are in different stages of assembly and the nucleus shows chromatin margination. (b) Virion assembly documents budding through the inner nuclear membrane, de-envelopment at the outer nuclear membrane, and re-envelopment in the *trans*-Golgi network. Magnification ×55 700.

exocytosis. During latency reactivation, HSV-1 envelopment likely occurs in neuronal varicosities and growth cones, where the primary site is the *trans*-Golgi network, and traffic/egress is along microtubules. In epithelial cells and neurons, newly assembled virions are directed to specialized cell surface domains (viz., epithelial cell junctions and neuronal synapses) for rapid entry into adjacent connected cells (cell-to-cell spread). Glycoproteins gE/gI bind ligands or receptors at these sites, promoting spread.

5. *Host cell effects.* The IE proteins inhibit cellular DNA synthesis and cause cell cycle arrest. Onset of E gene expression coincides with irreversible shutoff of host cell macromolecular synthesis, which is primarily mediated by the tegument phosphoprotein vhs released into the cytoplasm of the infected cells. Vhs degrades cellular mRNA through an endoribonuclease activity regulated, at least in part, through complexing with VP16. Virus replication is associated with cell rounding, chromatin margination, and the formation of nuclear inclusions (**Figures 2** and **3**).

Serologic Relationships

The HSV-1 and HSV-2 genomes have been sequenced. The genomes share a similar ORF organization, and overall sequence identity in coding region is 83%. Regions of low identity encode glycoprotein gG (used in HSV type-specific serology) and the R1 N-terminal domain, which has PK activity in HSV-2 but not HSV-1. Other biologic differences between HSV-1 and HSV-2 include virus yields in rabbit kidney cells, pock size on the chorioallantoic membrane of embryonated eggs, thermal stability, sensitivity to 5-iododeoxyuridine and interferon (IFN), and neoplastic potential.

Genetics

Epidemiologically unrelated isolates of the same HSV serotype are not identical (intratypic polymorphism). Differences result from base substitutions that may add or eliminate a restriction endonuclease cleavage site or substitute an amino acid, occasional deletions, or variable numbers of repeated sequences at various genome sites. The restriction endonuclease cleavage patterns of a given strain are relatively stable even after many years of serial passage *in vitro*, and may be related to neurovirulence.

Epidemiology and Associated Risks

HSV infects 80% of the adult population globally. Primary HSV-1 infection usually occurs by 5 years of age and is generally asymptomatic. It is estimated that 50 million adults have oral herpes in the USA. A recent cross-sectional survey of the general population in eight European countries revealed intercountry and intracountry differences in age-standardized HSV-1 seroprevalence (52–84%), but a significant proportion of recently screened adolescents in the USA and Europe were HSV-1 seronegative.

The current age-adjusted prevalence of HSV-2 in the USA is 20–25%. Individuals with genital HSV in the USA range between 40 and 60 million (one in five adolescents and adults) and new cases occur at a rate of *c.* 0.5–1 million per year. These estimates may be low, because the disease is not reported and many individuals do not seek medical attention, are misdiagnosed, or shed virus while asymptomatic. Factors that influence acquisition of HSV-2 include gender (women greater than men), race (blacks more than whites), marital status (divorced versus single or married), place of residence (city greater than suburb), and number of sexual partners (higher number has increased risk). Female prostitutes and homosexual men have the highest seroprevalence (75–98%). Women are about 45% more likely than men to be infected with HSV-2. The probability of infection is less than 10% for US women having one partner. It increases to 40%, 62%, and >80% as the number of partners increases to 2–10, 11–50, and >50, respectively. For heterosexual men, these risks are 0, 20%, 35%, and 70% for each of the risk groups, respectively. For homosexual men, the risks are greater than 60% and 90% for those with 11–50 and >50 partners, respectively. HSV-2 infection was also associated with a threefold increased risk of human immunodeficiency virus (HIV) acquisition by meta-analysis calculation of age- and sexual behavior-adjusted relative risks. Recently, HSV-1 became the most common cause of symptomatic first episode anogenital HSV among young people. Among US college students, the proportion of newly diagnosed genital HSV-1 infections increased from 31% in 1993 to 78% in 2001 ($P < 0.001$). HSV-1 was more common in females than males and in persons aged 16–21 than >22.

The major risk to the fetus is maternal primary or initial genital infection, the rate of which is 0.5–10% per year. The incidence of HSV-2 shedding at delivery is 0.01–0.6%, irrespective of past history and time of gestation. Most women whose children are infected (60–80%) are asymptomatic at the time of delivery, and they have neither a past history of genital HSV nor a sexual partner reporting genital infection. The incidence of cervical shedding in asymptomatic pregnant women averages 3%. Clinical diagnosis of genital HSV infection during pregnancy is a significant independent predictor of perinatal HIV transmission. HSV suppression during pregnancy may be a strategy to reduce perinatal HIV transmission.

HSV-induced encephalitis (HSE) is the most common viral encephalitis with an estimated incidence of 2.3 cases per million population per year. The age distribution is biphasic with one peak at 5–30 years of age and a second peak at >50 years of age. HSV-1 accounts for 95% of adult cases and the majority are due to reactivation from latency. HSV-2 does not generally cause encephalitis in adults, but the virus can cause aseptic meningitis, predominantly with primary infection. HSV-2 was isolated from the cerebrospinal fluid in 0.5–3% of patients with aseptic meningitis.

Transmission and Tissue Tropism

HSV is transmitted during close personal contact. The risk of transmission is directly related to virus load. Virus shedding in the saliva was reported in 20% of children 7–24 months old, 18% of those 3–14 years old, 2.7% in those >15 years old, and 2–9% of asymptomatic adults. HSV-1 was isolated from the mouth for 7–10 days after primary infection. Oral secretions from 36–45% of patients examined at prodrome (24–48 h before clinical recurrence)

were HSV-1 positive by polymerase chain reaction (PCR). Genital HSV-1 results from self-inoculation or from oral sexual practices.

Sexual contact is the primary route of HSV-2 transmission. Asymptomatic shedding was reported for the majority of patients. Half of the time it occurs more than 7 days before or after a symptomatic recurrence, and it is believed to be the major cause of transmission. However, cervical lesions are generally unnoticed, and they may be confused with asymptomatic shedding. Most studies of asymptomatic patients used PCR, the sensitivity of which in these subjects is at least four- to fivefold higher than that of virus isolation. When virus titers were measured, they were 100–1000 times higher in clinical lesions than in secretions from asymptomatic subjects, suggesting that transmission due to contact with active lesions is likely to be more efficacious. In discordant couples, 50% of seronegative partners remained seronegative for 16 months of contact, but use of condoms or daily suppressive therapy may be an option to reduce the risk of transmission. Intrapartum transmission accounts for 75–80% of neonatal HSV cases. Approximately 30 babies were identified in the world literature with symptomatic congenital HSV disease. This frequently resulted from ascending infections in women who have had prolonged rupture of membranes before delivery.

In children and young adults, HSE usually results from primary infection by virus entering the central nervous system (CNS) through neurotropic spread by way of the olfactory bulb. The hematogenous route of infection is common in immunosuppressed patients and neonates. Murine studies suggest that gender influences hematogenous HSV-1 infection in the CNS, and apolipoprotein E (ApoE) is involved in HSV-1 colonization of the brain from the blood. HSV infects the skin, eyes, liver, lungs, adrenal glands, pancreas, small and large intestine, CNS, and bone marrow. The trigeminal, vagal, and sacral dorsal root ganglia are the major sites of latent HSV infection.

Pathogenicity

The HSV-1 portal of entry is generally the oropharyngeal mucosa. Following replication at the site of infection, the trigeminal ganglia are invariably colonized (latency). Initial HSV-2 replication is at genital sites with colonization of the sacral ganglia. Animal studies suggest that sex hormones modulate susceptibility to HSV-2, with estradiol, but not progesterone, delaying vaginal pathology. Virus growth in the CNS (after intracerebral inoculation of mice), and its invasion after peripheral inoculation (neurovirulence) were ascribed to several genes, notably TK and $\gamma_1$34.5. The two serotypes have distinct pathogenicity in neurons. HSV-1 induces apoptosis through ICP0-mediated activation of the JNK/c-Jun pathway, and apoptosis is a component of HSE. HSV-2 does not trigger apoptosis in CNS neurons or cause encephalitis in human adults. This is likely due to the PK activity of the HSV-2 R1 protein (also known as ICP10), which is poorly conserved in HSV-1 and overrides apoptotic cascades through activation of survival pathways (viz., Ras/Raf-1/MEK/ERK and PI3-K/Akt) (**Figure 4**).

An unusual aspect of HSV pathogenicity is the infection of stem cells, both epithelial (**Figure 5**(**a**)) and CD34+ bone marrow derived. HSV-2 infection of human cervical cells causes atypia (**Figure 5**(**b**)) and the virus also infects spermatozoa (**Figure 5**(**c**)). Potential risks associated with these infection patterns require better elucidation, particularly as related to stem cells, an area of current research interest.

Clinical Features of Infection

HSV-1 and HSV-2 exhibit similar clinical manifestations. They infect neonates, children, and adults, and produce a wide spectrum of diseases including mucous membrane and skin lesions, ocular, visceral, and CNS disease. The incubation period is 1–26 days (median 6–8 days). Age, gender, host genetic factors, immune competence, associated illnesses, and virulence of the infecting virus strain influence severity.

Most (70–90%) childhood HSV-1 infections are asymptomatic. In children 1–3 years of age, the major manifestion is gingivostomatitis, a serious infection of the gums, tongue, mouth, lip, facial area, and pharynx, often accompanied by high fever, malaise, myalgias, swollen gums, irritability, inability to eat, and cervical lymphadenopathy (**Figure 6**(**d**)). Later in life, the major HSV-1 clinical manifestation is an upper respiratory tract infection, generally pharyngitis, and a mononucleosis-like syndrome. Reactivated HSV-1 is associated with mucosal ulcerations or lesions at the mucocutaneous junction of the lip presenting as small vesicles that last 4–7 days (known as herpes labialis, cold sores, or fever blisters). Other HSV-1 skin diseases include primary herpes dermatitis (a generalized vesicular eruption), eczema herpeticum (usually a manifestation of a primary infection in which the skin is the portal of entry) (**Figure 6**(**e**)), and traumatic herpes (resulting from traumatic skin breaks due to burns or abrasions). Herpetic whitlow is an occupational hazard (dentists, hospital personnel, wrestlers) resulting from infection of broken skin (often on fingers). Herpes folliculitis is a rare HSV-1 manifestation that often presents with lymphocytic folliculitis devoid of epithelial changes characteristic of virus infection. Acute HSV-1 rhinitis is a primary infection of the nose

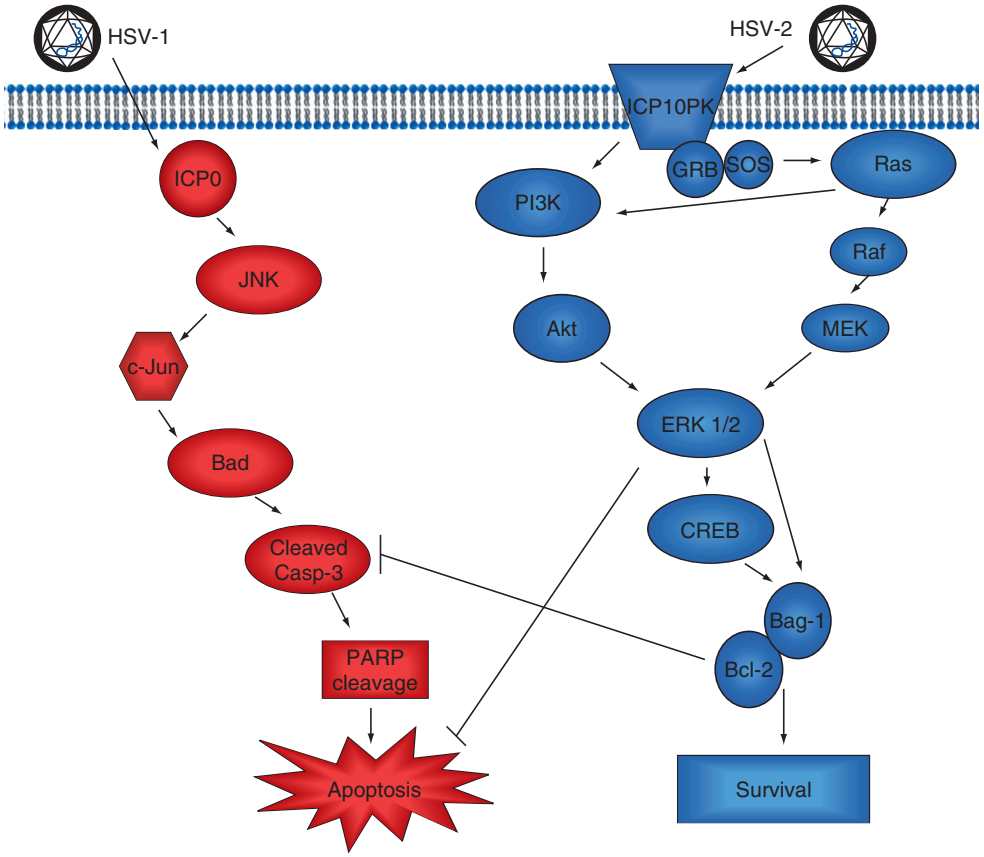

Figure 4 Distinct HSV-1 and HSV-2 pathogenicity. Schematic representation of signaling pathways activated by neuronal cell infection with HSV-1 or HSV-2. HSV-1 activates the pro-apoptotic JNK/c-Jun pathway and triggers apoptosis, likely mediated by the ICP0 protein. HSV-2 activates the MEK/ERK and PI3K/Akt survival pathways and blocks apoptosis, mediated by the PK function of the R1 protein (also known as ICP10).

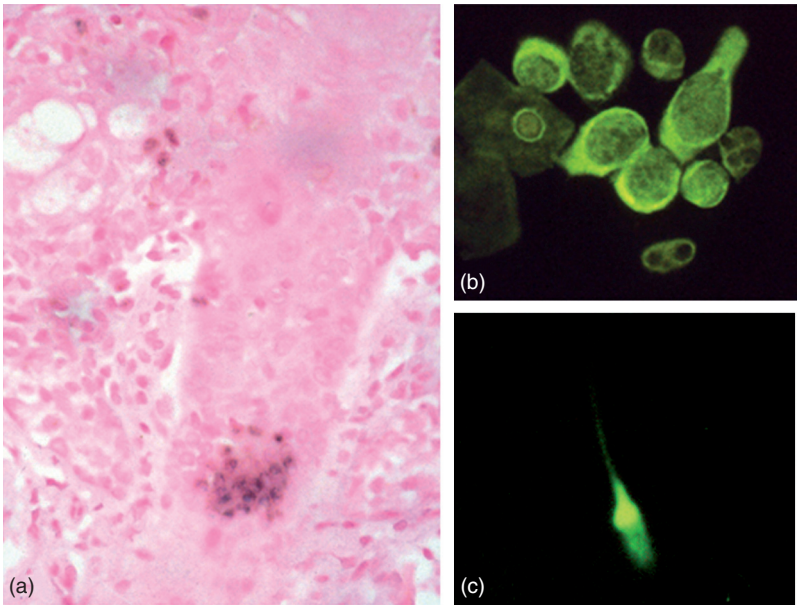

Figure 5 Pathogenicity aspects. Immunohistochemistry and immunofluorescent staining with HSV antibody reveals HSV infection of human epidermal (follicular) stem cells (a), cervical cells (resulting in mild to moderate atypia) (b), and a sperm cell (c).

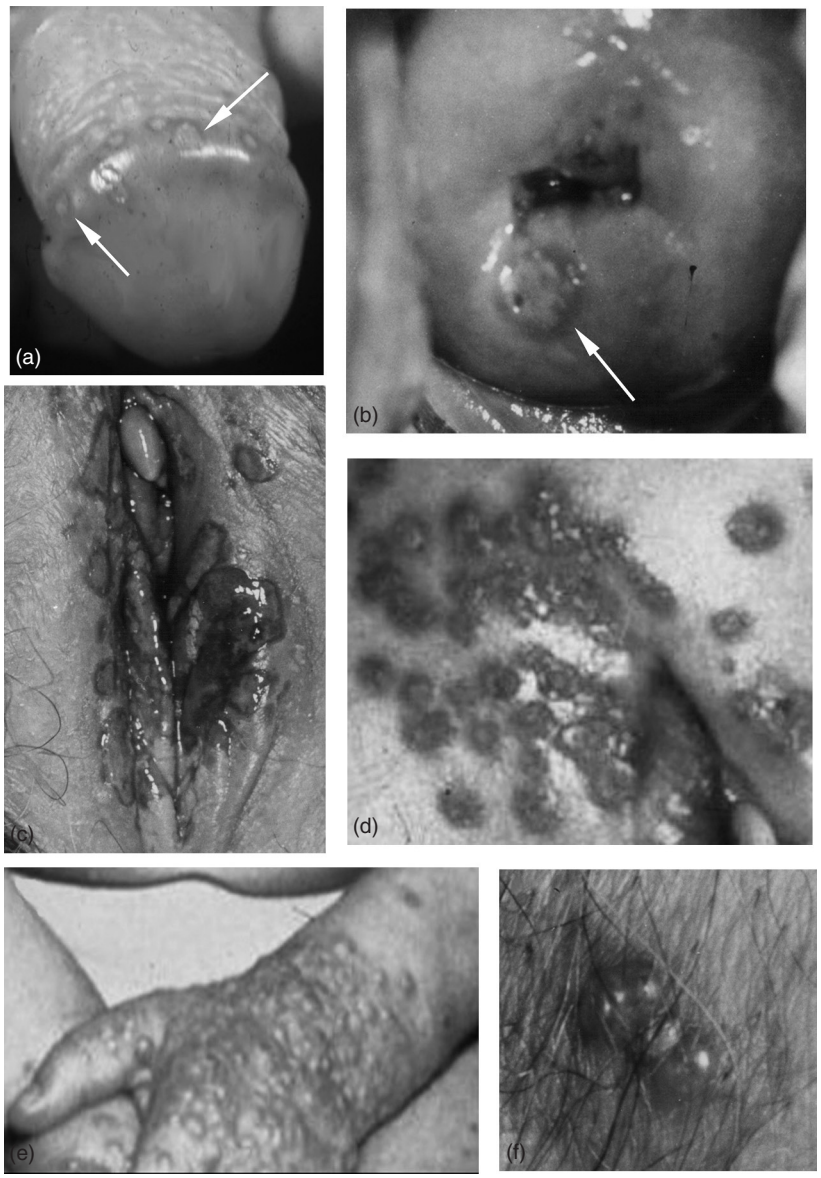

Figure 6 Clinical manifestations. HSV-2 induced lesions of penis (a), cervix (b), and vulva (c, f). Clinical HSV-1 manifestations include gingivostomatitis (d) and eczema herpeticum (e). Arrows in (a) and (b) identify vesicular lesions.

recognized by the appearance of tiny vesicles in the nostrils usually associated with fever and enlarged cervical lymph nodes. HSV-1 infections of the eye can lead to stromal keratitis, one of the leading causes of blindness in the Western world. This disease has a virus-specific T-cell (CD4+) component. Chorioretinitis is a manifestation of disseminated HSV infection that may occur in neonates or in patients with AIDS. HSV-1 accounts for nearly all cases of HSE in adults (and 10–20% of all viral encephalitis cases). Both serotypes can cause encephalitis in infants. With treatment, HSE mortality rates are 15% in newborns and 20% in others. Survivors have neurological sequelae involving impairments in memory, cognition, and personality. Untreated, mortality rates are 60–80%. Genital HSV-1 infections may be less severe and prone to recur than HSV-2 infections.

In females, HSV-2 infection is manifested by vesicles on the mucous membranes of the labia and the vagina (**Figure 6**(**f**)). Severe forms result in ulcers that cover the entire area surrounding the vulva (**Figure 6**(**c**)). Symptoms of primary infection include itching, pain, and lymphadenopathy. Cervical involvement is common, although it generally passes unnoticed (**Figure 6**(**b**)) and the patient is often mistaken for having asymptomatic shedding. Common sites of primary HSV-2 infection in males are the shaft of the penis, the prepuce, and the glans

penis (**Figure 6(a)**). Urethritis is the main local expression accompanied by a watery discharge often resulting in dysuria. Symptomatic urethritis is rare in recurrent disease, but virus can often be cultured from the urethra. The infection is more severe in females than in males and systemic symptoms are more common. They often accompany the appearance of primary lesions and include fever, headache, photophobia, malaise, and generalized myalgias. Dysuria, urinary retention, urgency and frequency, pain, and discharge are also seen. Systemic symptoms are generally not seen in recurrent disease. A prodrome often signals a recurrence. It is characterized by a tingling sensation that may precede the lesions by a few hours to 2 days, could be accompanied by radiating radicular pain, and is related to loss of sodium conductance in neurons that support replication of reactivated virus. Anal and rectal infections are seen primarily in homosexuals, as a result of anal intercourse.

HSV-1- and HSV-2-associated erythema multiforme (HAEM) is a recurrent skin disease that follows reactivation of latent virus and occurs at distal sites. HAEM lesional skin contains HSV DNA fragments (most often comprising the viral Pol gene) that are delivered by migrating infected CD34+ stem cells. Lesion development is initiated by virus gene expression and contains virus-specific and autoimmune components. The virus-specific component consists of a restricted population of Th1 cells (primarily, CD4+ Vβ2) that produce IFN-γ. The autoimmune component is in response to antigens released by lysed/apoptotic virus-infected keratinocytes. A genetic predisposition is implicated.

Immunocompromised adults can develop a severe generalized disease that is occasionally responsible for herpetic hepatitis. HSV pneumonitis accounts for 6–8% of cases of interstitial pneumonia in recipients of bone marrow transplants. Mortality due to HSV pneumonia in immunosuppressed patients is >80%. Generalized HSV with involvement of adrenal glands, pancreas, small and large intestine, and bone marrow was reported in the immunocompromised patient. HSV has also been isolated from 40% of patients with acute respiratory distress syndrome. HSV-1 DNA was recently found by PCR in gastrointestinal sensory neurons and in the geniculate ganglion and adjacent areas, respectively, implicating HSV in recurrent gastrointestinal disorders and Bell's palsy. HSV-1 seropositivity was also associated with myocardial infarction and coronary heart disease in older adults, and with Alzheimer's disease (AD). AD is believed to result from frequent episodes of mild encephalitis and neuronal apoptosis resulting from virus reactivation in individuals homozygous or heterozygous for ApoE4. Virus DNA was detected in the brain from elderly people in some, but not other, studies. Uncommon complications of HSV infection include monoarticular arthritis, adrenal necrosis, idiopathic thrombocytopenia, and glomerulonephritis.

Latency

Following replication in the skin, sensory or autonomic nerve endings are infected by cell-to-cell spread (retrograde transport). Virions, or more likely capsids, are thought to be transported intraxonally to the nerve cell bodies in the ganglia (primarily trigeminal and sacral for HSV-1 and HSV-2, respectively), where viral DNA is maintained as an episome that is largely transcriptionally silent. Human trigeminal ganglia contain approximately 20 viral genome copies per latently infected neuron. Virus isolates obtained at various times from the same patients have different restriction endonuclease patterns, indicating that ganglia can be colonized by multiple HSV strains. Certain stimuli cause virus reactivation with concomitant reverse axonal transport of virus progeny to a peripheral site at or near the portal of entry (anterograde transport) (**Figure 7(a)**). Reactivating stimuli include fever, axonal injury, exposure to ultraviolet irradiation (sunlight), emotional stress, and possibly hormonal irregularities. Development of clinically apparent recurrent lesions is probably influenced by the amount of virus, virus–cell interactions, and the rapidity/efficacy of immune-mediated clearance. In the guinea pig model, latent virus reactivates spontaneously. In other animal models, virus is reactivated by neurectomy, ganglionic trauma, electrical stimulation, epinephrine iontophoresis, cadmium treatment, or ganglia explantation and organ culture.

The mechanism of latency establishment and reactivation is still unclear. One possibility is that they are controlled by cellular factors required for virus replication, such as HCF, which translocates to the nucleus at reactivation. However, the general consensus is that viral genes control latency, although their identity is still controversial. The only HSV transcript abundantly expressed during latency is the 2.0 kbp intron derived from the 8.3 kbp primary latency-associated transcript (LAT). Because LAT overlaps the 3′ end of ICP0, it was assumed to contribute to latency establishment by acting as antisense to ICP0. An alternative hypothesis was that ICP0 splicing and expression are suppressed by the ORF P protein (apparently encoded by a minor LAT). However, both spliced and intron-containing ICP0 transcripts were found in latently infected ganglia, and LAT or ORF P did not increase their levels. Others concluded that LAT promotes efficient latency reactivation. However, mutants lacking LAT were shown to reactivate as well as the wild-type virus. One group has reported the expression of a LAT protein encoded by an ORF within the 2.0 kbp intron, which acts somewhat like ICP0 in that it enhances lytic genes and promotes interaction with cellular transcription factors. Most studies attribute the role of LAT in latency reactivation to its anti-apoptotic activity, which ensures a large pool of latently infected neurons that contribute to efficient virus reactivation. It is thought that LAT

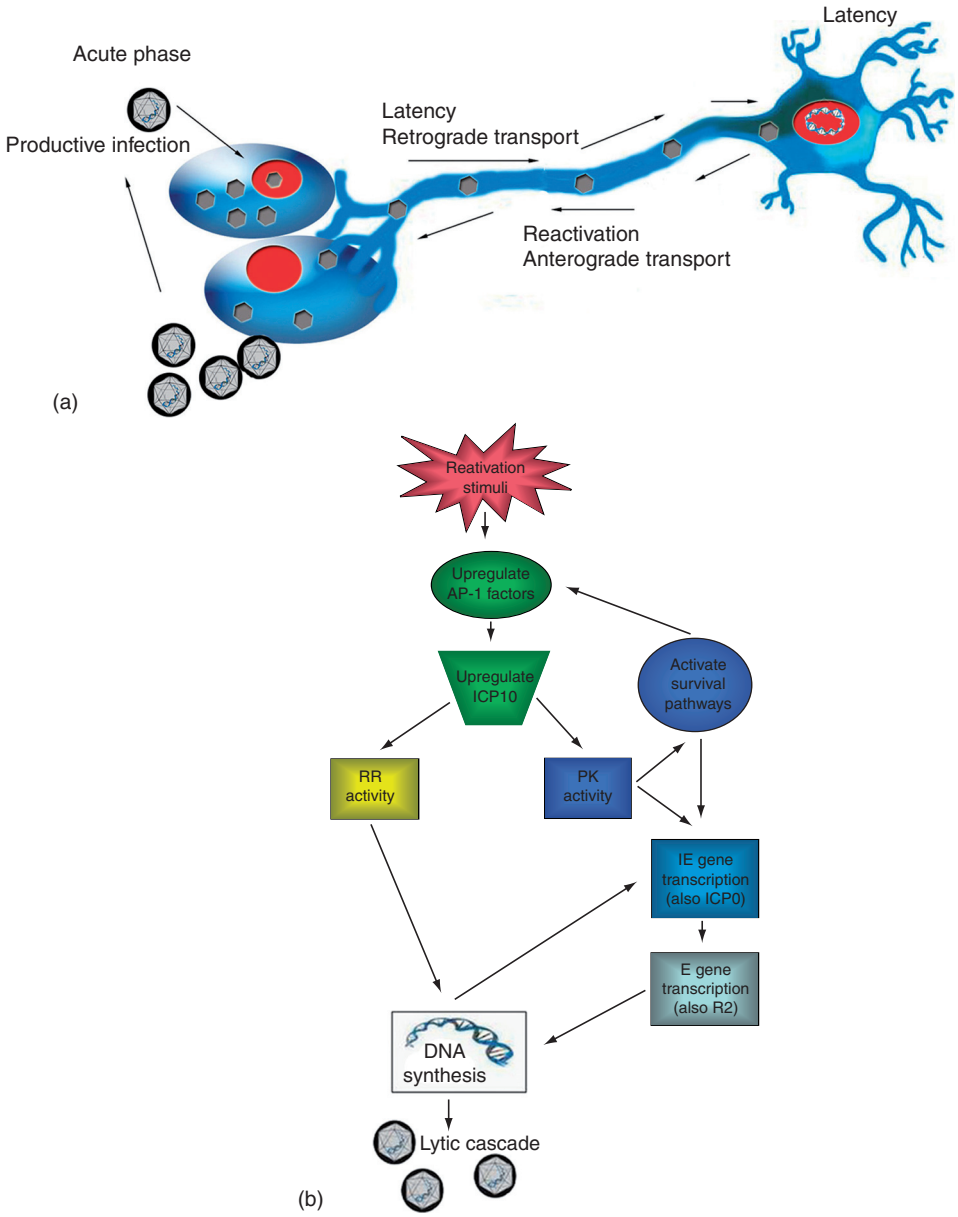

Figure 7 Schematic representation of latency establishment and reactivation. (a) Following replication in the skin, capsids are axonally transported to nerve cell bodies where viral DNA is maintained as a circularized episome. Reactivating stimuli cause reverse axonal transport of virus progeny. (b) Model for involvement of R1 (ICP10) in HSV-2 latency reactivation. Reactivating stimuli upregulate AP-1 factors, thereby causing ICP10 overload. ICP10 supplies the PK activity, which is required for IE gene transcription and a feedback amplification loop through activation of the Ras survival pathway. It also supplies the RR activity that is required for DNA synthesis. The outcome is initiation of the lytic cascade.

counteracts apoptosis induced by corticosteroids, which are upregulated by reactivation-inducing stress stimuli. However, controversy remains. While LAT enhances reactivation in the rabbit eye model, it does not seem to be required in small animal models. LAT anti-apoptotic activity was not studied in neurons, although apoptosis is cell-type specific. LAT anti-apoptotic activity may be unique to certain HSV-1 strains. Apoptosis was also associated with LAT downregulation by stress-induced cAMP early repressors (ICER). The presence of STAT1 response elements in the LAT promoter suggests that cytokines may initiate or contribute to LAT-mediated virus reactivation.

The HSV-2 LAT fails to substitute for its HSV-1 counterpart in promoting latency reactivation, and it does not modulate HSV-2 latency reactivation or its establishment. An HSV-2 mutant deleted in the PK domain of R1 (ICP10) was shown to be significantly impaired in latency establishment/reactivation, and virus reactivation (by ganglia

co-cultivation) was inhibited by an ICP10 antisense oligonucleotide, indicating that ICP10 might be involved in HSV-2 latency. In this model, latency-reactivating stimuli upregulate AP-1 transcription factors, thereby inducing expression of ICP10, which is the only virus protein the basal expression of which is regulated by AP-1. The PK function of ICP10 induces IE gene expression and, thereby, the entire viral transcriptional cascade. It also activates the Ras/MEK/ERK pathway that blocks apoptosis, ensuring a large pool of surviving neurons that contribute to efficient virus reactivation, and provides a feedback amplification loop for ICP10 upregulation The ribonucleotide reductase activity of ICP10 contributes to viral DNA synthesis. The outcome is virus replication (**Figure 7(b)**).

HSV Infection during Pregnancy and Neonatal Disease

Localized genital infection is the most common form during pregnancy, but rare visceral involvement with approximately 50% mortality was reported. Fetal deaths occurred in 50% of cases, although mortality did not correlate with the death of the mother. Maternal primary infection prior to 20 weeks of gestation was associated with spontaneous abortion in 25% of infected women. Fetal infection is generally due to virus shed at the time of delivery. Skin lesions are the most commonly recognized features, but at least 70% of untreated cases have disseminated disease. Neonatal infection is decreased by surgical abdominal delivery when membranes are ruptured for less than 4 h. For women with a past history of genital infection, HSV culture can establish whether virus is shed at the time of delivery.

Pathology and Diagnosis

Histopathologic changes are a combination of virus-induced alterations (cell ballooning, condensed nuclear chromatin, and nuclear degeneration) and associated inflammatory responses. Virus-induced changes are generally within the parabasal and intermediate cells of the epithelium. Multinucleated giant cells are also formed and a clear (vesicular) fluid containing large quantities of virus, cell debris, and inflammatory cells appears between the epidermis and the dermal layer. An intense inflammatory response is seen in dermal structures, particularly in primary infection, and is accompanied by an influx of mononuclear cells, as host defenses are mounted. With healing, the vesicular fluid becomes pustular and, then, scabs. Scarring is uncommon. Similar histopathologic findings are seen in mucous membranes. Perivascular cuffing and areas of hemorrhagic necrosis are also seen in the area of infection, particularly in organs other than skin. In the brain oligodendrocytic involvement, gliosis, and astrocytosis are common. Virus culture is the gold standard for diagnosis, but results require approximately 2 weeks. Accordingly, in severe infections, treatment initiation should not be delayed. The increased sensitivity and rapidity of PCR are desirable for diagnosis of severe infections.

Host Immune Responses

An early nonspecific containment phase (innate immunity) and a later HSV-specific effector phase (adaptive immunity) contribute to protection. Natural killer (NK) cells and rapid production of IFN type I provide a threshold of resistance to HSV-1 infection and were associated with the natural resistance of certain mouse strains. In mice, IFNα/β inhibit the onset of IE gene expression, limit virus spread into the nervous system, and activate NK cells. Dendritic cells (DCs) are required for activation of NK cells and CD4+ and CD8+ T cells in response to HSV-1. Conventional CD11c+CD8α+ DCs are the principal antigen-presenting cells during acute HSV-1 infection. The plasmocytoid CD11c+B220+ DCs secrete large amounts of type I IFN *in vitro* after exposure to HSV-1 and help lymph node DCs to induce HSV-specific cytotoxic T cells (CTLs) optimally during a primary immune response. Various reports have incriminated or refuted the association of HLA with HSV infections.

HSV antibody is first seen on days 5–10 pi and persists indefinitely. Antibody titers are higher in subjects with a history of recurrent disease, reflecting virus reactivation. Antibodies to structural proteins are followed by those directed against gD, gB, ICP4, gE, gG, and gC. IgM and IgG antibodies can be demonstrated at different times pi. In children, antibodies to ICP4 may be predictive of long-term neurologic outcome. Infected newborns produce IgM antibodies (particularly against gD) within the first 3 weeks pi. Transplacentally acquired antibodies do not protect the newborn.

T cells play the major role in recovery from HSV infection. Their development is delayed in newborns (2–4 weeks), presumably explaining the increased sensitivity to disease progression in this age group. Effector mechanisms include: (1) delayed-type hypersensitivity (DTH), an early (days 5–10 pi) HSV-type common response that remains inducible for at least 2 years after infection; (2) effector lymphokines, such as IFN-γ, interleukin 2 (IL-2), and other soluble factors; and (3) CTL. CTL clones are specific for cell surface glycoproteins, primarily gD or gE, and intracellular IE proteins.

Naturally acquired HSV immunity reduces the severity of the disease, but it does not prevent latency establishment, recurrent disease, or reinfection. HSV has developed various mechanisms of immune evasion, notably inhibition of antigen presentation by the MHC class I

complex through binding of the cellular protein that transports antigenic peptides into the endoplasmic reticulum (TAP) by the viral IE protein ICP47 (**Figure 8**). Other immune-evasion mechanisms include resistance to complement attack (mediated by gC), prevention of antibody binding (mediated by gE/gI), and blocking of CD8+ CTL activity through US3-mediated inhibition of caspase activation. HSV-1 also blocks the IFN response at multiple sites, including decreased Jak1 kinase and Stat2, which are associated with IFN signaling. However, the exact role of immune evasion in recurrent disease is unclear. It is believed that reactivated virus circumvents immune inhibition by replicating before immunity is alerted, or by shifting the immunological balance toward tolerance. For example, induction of Th2 cytokines (e.g., IL-10) could downregulate the Th1 antiviral response by inhibiting DC maturation/function. Generation of downregulatory factors, such as prostaglandin E2 (PGE2) and TGFβ, DC infection, and/or induction of T regulatory cells (Tregs) could also be involved. Our longitudinal studies of HSV patients, done approximately 20 years ago, implicated Tregs in the immune downregulation that enables recurrent disease development. Tregs have made a comeback recently and were again implicated in recurrent disease, now in the mouse model.

Neoplastic Transformation

Seroepidemiologic studies have associated HSV-2 infection with an increased risk of human squamous cervical cancer. Current opinion is that HSV-2 is only a co-carcinogen. Notwithstanding, a wealth of experimental evidence indicates that HSV-2 is a tumor virus. It causes neoplastic transformation of immortalized cells (including those of human origin) and causes tumors in animals, both under conditions that interfere with virus replication. Transformation is mediated by R1 (ICP10) PK through activation of the Ras/MEK/ERK pathway, a function that is conserved because it is required for latency reactivation. The HSV-1 R1 gene does not have oncogenic potential, but HSV-1 causes mutagenesis and gene amplification. In humans, HSV-2 can cause severe hyperproliferative lesions that may have an increased risk for neoplastic conversion. We reported the case of a patient with common variable immunodeficiency who presented with hyperproliferative lesions (pseudo-epitheliomatous hyperplasia) caused by an acyclovir-resistant HSV-2 mutant through overexpression of ICP10PK (**Figure 9**).

Therapy and Prevention

A recent critical advance has been the development of antiviral chemotherapy. Agents currently used are acyclovir, valaciclovir, and famciclovir, which have superior oral bioavailability (**Table 1**). Episodic oral therapy speeds healing and resolution of primary and recurrent HSV lesions, but subsequent recurrence rates are not affected. Long-term daily suppressive therapy may reduce the frequency of reactivation in patients with frequent recurrent episodes, but it does not eliminate ganglionic latency and reactivation occurs after therapy is discontinued. Its effect on asymptomatic virus shedding is still unclear. Daily oral administration for 6–12 months appears to be safe, but a potential concern of long-term treatment is that nonreplicating HSV-2 is oncogenic. Intravenous acyclovir is the agent of choice for treatment of neonatal HSV and HSE. These drugs are phosphorylated by the HSV TK at a 10^6-fold faster rate than the cellular enzyme. After additional phosphorylation by cellular enzymes, the triphosphate (active form) blocks viral DNA synthesis by acting as an inhibitor and substrate of viral DNA polymerase, becoming incorporated into the growing DNA chain and causing termination of chain growth. HSV DNA polymerase has a much higher affinity for the

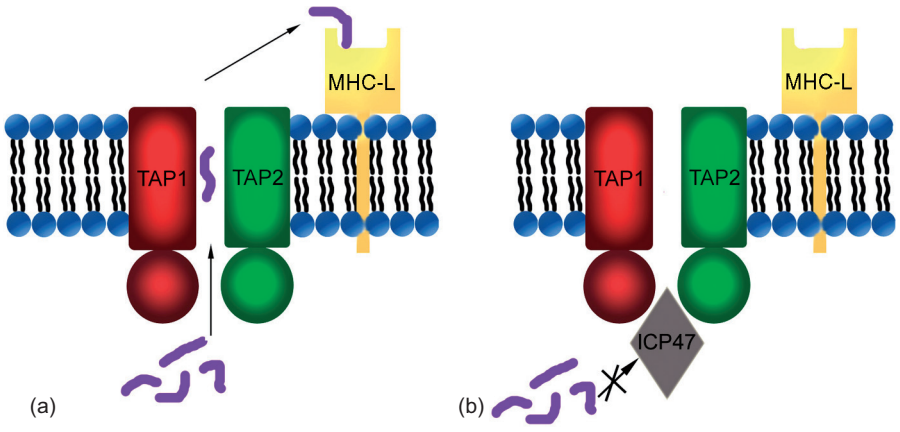

Figure 8 Immune evasion. (a) TAP-mediated transport of antigenic peptides for presentation by MHC class I. (b) ICP47 binds TAP, thereby inhibiting antigen presentation.

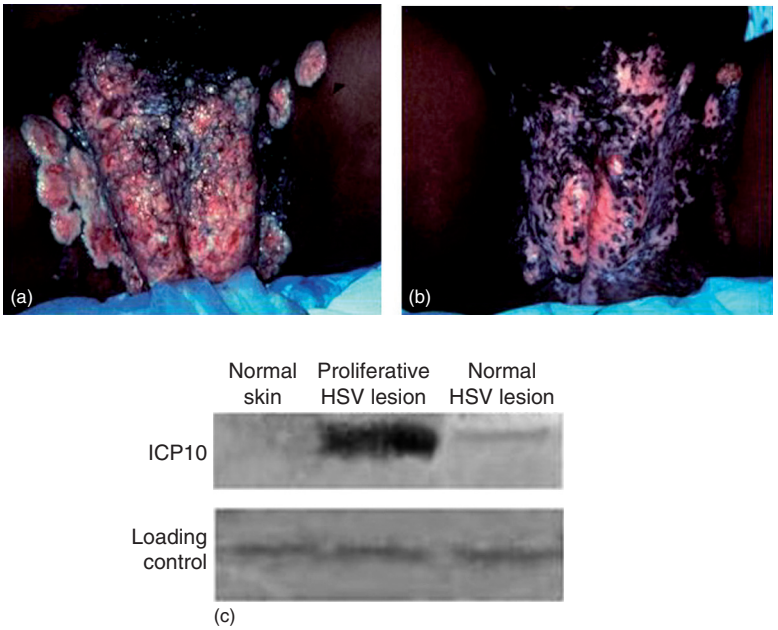

Figure 9 HSV-2 causes human hyperproliferative lesions. Hyperproliferative lesion caused by acyclovir-resistant HSV-2 (a) was treated with intravenous foscarnet (b). The lesion was associated with increased expression of the proliferation-inducing ICP10 protein (c). (a) Reprinted from *Journal of the American Academy of Dermatology*, 37, Beasley KL, Cooley GE, Kao GF, Lowitt MH, Burnett JW, and Aurelian L, Herpes simplex vegetans: Atypical genital herpes infection in a patient with common variable immunodeficiency, 860–863, Copyright (1997), with permission from The American Academy of Dermatology, Inc.

Table 1 CDC treatment recommendations for genital HSV

		Recurrent disease	
	First clinical episode (mg for 7–10 days)	*Episodic (mg × days)*	*Suppressive (mg, daily)*
Acyclovir	400 tid 200 5×/day	400 tid (5 d) 800 bid (5 d) 200 5×/day (5 d)	400 bid
Valaciclovir	1000 bid	500 bid (3–5 d) 1000 qd (5 d)	500 qd 1000 qd
Famciclovir	250 tid	125 bid (5 d)	250 bid up to 1 year

drug than the cellular enzyme. As DNA synthesis is required for the drugs to function, they cannot destroy the virus during latency. Acyclovir resistance emerges with moderate frequency and it crosses to valaciclovir and famciclovir.

Foscarnet and cidofovir are used to treat infections caused by acyclovir-resistant virus. Cidofovir undergoes two stages of phosphorylation, via monophosphate kinase and pyruvate kinase, to form an active metabolite, cidofovir diphosphate (CDVpp), that bears structural similarity to nucleotides and acts as a competitive inhibitor and an alternative substrate for DNA polymerase. Nephrotoxicity is a potential complication with parenteral use of cidofovir, and it should be administered with oral probenecid after prehydration to minimize adverse effects. A topical cidofovir formulation is currently under investigation. Acyclovir-resistant HSV can become sensitive after treatment with cidofovir, suggesting that alternating acyclovir and cidofovir therapies may provide a strategy for managing the emergence of alternating acyclovir-resistant and -sensitive infections.

It is becoming increasingly evident that prevention of HSV infection through vaccination may be an unrealistic goal. A more modest goal has been to reduce the clinical symptoms of primary infection. In two Phase III trials, an HSV-2 gD fragment formulated with a mixture of alum and 3-deacylated monophosphoryl lipid A (3-dMPL) was shown to reduce clinical symptoms of primary HSV-2 infection (approximately 70% efficacy) in women that were HSV-1 and HSV-2 seronegative. Males mounted similar immune responses, but they were not protected and the activity of the vaccine was attributed to the adjuvant used in its composition. Continued research is focusing on HSV-1 recombinants engineered to express immunostimulatory

molecules, such as IL-12, which bridges innate and adaptive immunity.

Another vaccination goal has been to prevent/reduce the frequency of recurrent disease episodes in infected patients (therapeutic vaccine). One such vaccine is an HSV-2 mutant rendered replication incompetent and Th1 polarizing through deletion of ICP10PK. This vaccine caused a 75–90% reduction in the number of guinea pigs with spontaneous recurrent disease and reduced the frequency and duration of recurrent episodes experienced by the rare animals that were not absolutely protected. In Phase I/II clinical trials, the vaccine was tolerated well and recurrences were completely eliminated in 44% of the vaccinated patients at 1 year of follow up. This compares to 13% without recurrences in the placebo group ($p = 0.024$). There was also a significant reduction in the number of episodes relative to the previous year ($p < 0.001$) and in the number of recurrent episodes in the vaccinated relative to the placebo group ($p = 0.04$). Efficacy was gender independent, and was seen in both HSV-1 and HSV-2 seropositive subjects. Virus-specific CD8+ CTL and CD4+ Th1 cells mediated protection.

HSV Vectors and Oncolytic Viruses for Gene Therapy

One vector type, known as an amplicon, consists of a plasmid engineered to contain an HSV-1 origin of replication and packaging site along with a bacterial origin of replication in which a selected therapeutic gene is introduced. Amplicons are packaged by co-transfection with a defective HSV-1 helper virus, giving rise to a mixed population of virus particles that consist of the packaged amplicon and the helper virus. Helper-free amplicons were also developed. Another vector type consists of HSV-1 mutants rendered avirulent through deletion of relevant genes. Therapeutic genes delivered with these vectors limit neuronal death (e.g., Bcl-2), restore energy metabolism (e.g., glucose transporter), or promote neuronal survival (e.g., growth factors). HSV vectors were also developed to deliver short hairpin RNA to inhibit various transcripts (e.g., Aβ precursor). Drawbacks include residual toxicity, loss of immune-evasion mechanisms required for repeat treatment, and the loss of function by surviving neurons. HSV-2, which does not cause encephalitis or apoptosis in the CNS, may be a better candidate for the development of vectors for gene therapy of neurologic disorders. ΔRR, a recently developed growth-compromised and avirulent HSV-2 mutant (even after intracerebral inoculation), delivers the viral anti-apoptotic protein ICP10PK and has been shown to have protective activity in various paradigms of neuronal cell death *in vitro* and in animal models. The surviving neurons retain functional (synaptic) activity.

Oncolytic viruses are promising tools for cancer gene therapy. HSV-1 mutants G207 and MGH1 have double deletions in both copies of the neurovirulence gene $\gamma_1 34.5$ and an insertional mutation in the R1 gene. They are avirulent upon intracerebral inoculation, and were shown to kill CNS tumor cells (e.g., glioma), decrease tumor growth, and prolong survival in tumor-bearing nude mice. Tumor specificity appears to be related to increased MEK activity in tumor as compared to normal cells. Function requires intact T-cell activity. Additional HSV-1-based oncolytic viruses were constructed to express IL-4, GM-CSF, or the CD40 ligand. Others use the glioma-specific nestin promoter to drive $\gamma_1 34.5$ (to increase tumor specificity), or lack ICP47 (to reduce immune evasion). An HSV-2-based oncolytic virus, which is deleted in ICP10PK, was recently shown to eradicate tumors in >80% of breast cancer mouse xenografts. However, mutations may arise in untargeted regions of the viral genome, and their clinical significance is still unclear. Another cancer gene therapy approach (known as suicide) is based on the ability of HSV TK to preferentially activate ganciclovir (GCV), thereby killing tumor cells that contain the TK gene (delivered with an HSV-1, retrovirus, or adenovirus vector) as well as surrounding tumor cells (bystander effect).

Future

Studies of the molecular pathogenesis of HSV neuronal and stem cell infections and the role and modulation of HSV immunity in disease pathogenicity (notably recurrent disease) and protection remain principal goals for future research efforts. Prophylactic and therapeutic vaccines are badly needed. Further research must also focus on the mechanism of latency establishment and virus reactivation, and overcome problems of drug resistance. Risks associated with reinfection, particularly by drug-resistant virus strains, need elucidation. Significant progress may be achieved by developing novel oncolytic viruses, and further research is needed to elucidate the potential of HSV as a vector for gene therapy of neurodegenerative diseases.

The Virion

The Capsid

Like all herpesviruses, herpes simplex virus (HSV) type 1 (HSV-1) and the closely related HSV type 2 (HSV-2) have enveloped, spherical virions. The genome of HSV-1 is densely packaged in a liquid-crystalline, phage-like manner within a 100 nm icosahedral capsid. The capsid comprises 162 capsomeres of 150 hexons and 12 pentons. Hexons contain six molecules of the 155 kDa major capsid protein (VP5 or UL19) with six copies of the vertex protein VP26 (UL35) at the tips. Pentons contain five copies of VP5. Hexons are coordinated in threefold symmetry with a triplex structure made up of two other proteins: one copy of VP19C (UL38) and two copies of VP23 (UL18) per triplex. Small amounts of other viral proteins are also associated with the capsid; these include VP24 (derived from UL26), a maturational protease, and the UL6 gene product. The capsid portal formed from the UL6 gene product is now thought to occupy one of the penton positions, which leaves the capsid with 11 rather than 12 VP5-containing pentons.

The Tegument

The capsid is surrounded by a layer consisting of approximately 20 tegument or matrix proteins. These include the α-*trans* inducing factor (αTIF, VP16, or UL48), and a virion-associated host shutoff function (vhs or UL41).

The Envelope

The trilaminar viral lipid envelope forms the outer surface of the virion. This envelope has a diameter of 170–200 nm, although exact dimensions vary depending upon the method of visualization. The envelope is derived from the host cell nuclear membrane and contains at least 10 virally encoded glycoproteins. One glycoprotein (gG–US4) has sufficient differences in amino acid sequence to serve as a type-specific immune reagent to differentiate HSV-1 and HSV-2. At least four (gL–UL1, gH–UL22, gB–UL26, and gD–US6) are involved in virus penetration into the host cell. The sequence of gB is highly conserved among a broad range of herpesviruses. Another glycoprotein (gC–UL44) facilitates the initial attachment of the virion to glycosaminoglycans (GAGs) on the cell surface. Two others (US7–gI and US8–gE) function together as a heterodimer that binds the Fc region of immunoglobulin G (IgG) and influences cell-to-cell spread of virus.

The Genome

The complete genomic sequences of prototype strains of HSV-1 and HSV-2 are available in standard databases. Homology between HSV-1 strains is >99% for most regions of the genome while overall homology between HSV-1 and HSV-2 approximates 85% within translational reading frames and is significantly less outside them. The HSV-1 genome is shown schematically in **Figure 1**. It is a linear, double-stranded (ds) DNA duplex, 152 000 bp in length, with a base composition of 68% G+C. The genome circularizes upon infection. Because

[†] Deceased

the genome circularizes, the genetic/transcription map is conveniently shown as a circle. The genome contains at least 77 open reading frames (ORFs) translated into funtional proteins. Therefore, the map is complex.

The organization of the genome can be represented as $a_n b U_L b' a'_m c' U_S c a$. The genome is made up of five important regions. These are:

1. The ends of the linear molecules, with the left end comprised of multiple repeats of the 'a' sequence (a_n), which are important in circularization of the viral DNA upon infection and in packaging the DNA in the virion. Variable numbers of the 'a' sequence in inverted form (a'_m) are present internally in the genome.
2. The 9000 bp long inverted repeat (R_L – 'b' region). This region encodes an important immediate early regulatory protein (ICP0), and most of the 'gene' for the latency-associated transcript (LAT), including the promoter. It also encodes the ORF for the ICP34.5 gene, which is important in neurovirulence, and two partially overlapping ORFs antisense to that of ICP34.5, namely ORF-O and ORF-P. Two other short translational reading frames 5′ of the LAT cap site, termed ORF-X and ORF-Y, are also present, but have unknown functions.
3. The long unique region (U_L), which is 108 000 bp long, and encodes at least 58 distinct proteins. It contains an origin of DNA replication (ori_L) and genes encoding DNA replication enzymes, including the DNA polymerase. A number of capsid proteins and glycoproteins are encoded in U_L as well as many other proteins.
4. The 6600 bp short inverted repeats (R_S – 'c' region) encode the very important immediate early transcriptional activator, ICP4. R_S also encodes another origin of DNA replication (ori_S) and the promoters for two other immediate early genes.
5. The 13 000 bp short unique region (U_S) contains 13 ORFs, a number of which encode glycoproteins important in viral host range and response to host defense.

The arrangement of the inverted repeat elements allows the unique regions of the viral genome to invert relative to each other into four 'isomers': prototype (P), inversion of U_L relative to U_S (I_L), inversion of U_S relative to U_L (I_S), and inversion of both U_L and U_S (I_{LS}). Inversion is facilitated by the 'a' sequence elements noted above.

Viral Replication

Entry

Initial association of HSV with a host cell is mediated by the association with the envelope glycoproteins gB (UL27) and gC (UL44) and glycosamminoglycans (GAGs), such as heparin sulfate, on the cell surface. Virus internalization involves the mediation of four essential glycoproteins, gB (UL27), gH (UL22), gD (US6), and gL (UL1). In many cells, this is mediated by interaction of gD with a cellular surface protein named the herpesvirus entry mediator (HVEM). HVEM is a member of the TFN/NGF family of proteins. Other cellular surface proteins may also function in a similar capacity since some cells lacking this receptor still allow efficient viral entry. Following entry, HSV exists as a de-enveloped virion in the cytoplasm. This particle must then be transported to the nucleus by a process that requires the cell microtubule machinery, and then the viral DNA released into the nucleus (uncoating). The details of these processes are poorly understood.

Transcription and DNA Replication

Once in the nucleus, the viral DNA becomes available for transcription by host RNA polymerase II into mRNAs. The viral genome is accompanied into the nucleus by the VP16 or αTIF protein (UL48), which functions in enhancing immediate early viral transcription via cellular transcription factors. Gene expression occurs in three phases – immediate early or α (the first phase), early or β (which requires the immediate early protein ICP4), and late or γ (which requires the immediate early proteins ICP4 and ICP27 and viral DNA replication for maximal expression). DNA replication has a significant influence on viral gene expression. Early expression is reduced following the start of DNA replication, while late genes begin to be expressed at high levels. Immunofluorescence studies show that DNA replication occurs at discrete sites or replication compartments in the nucleus. Many of the early proteins are involved in viral DNA replication. Some of these early proteins, such as the two-subunit DNA polymerase and the three-subunit helicase–primase, participate directly in DNA synthesis, while others, such as thymidine kinase and the two-subunit ribonucleotide reductase, are involved indirectly by increasing the pools of deoxynucleoside triphosphates.

RNA Export, Translation, and Post-Translational Processing

HSV mRNAs are capped at the 5′ end and processed to form the 3′ end by polyadenylation, but the majority of viral transcripts do not undergo splicing. HSV transcripts are exported to the cytoplasm using the cellular TAP/NXF1 mRNA export pathway, and this process is facilitated by the HSV immediate early protein ICP27, which binds to viral RNAs as well as to the TAP/NXF1 receptor. HSV mRNA is translated on polyribosome structures using the host translational machinery.

Extensive proteolytic processing of HSV proteins does not occur, but the maturation of the capsid absolutely

requires the activity of the maturational protease encoded by the UL26 gene product. Many viral proteins are extensively phosphorylated, including the immediate early regulatory proteins ICP4, ICP0, and ICP27, as well as a number of structural proteins. Other modifications such as arginine methylation of ICP27 have also been described. The precise role of such post-translational modifications upon the function of these proteins has not been well characterized.

Assembly and Release

Following DNA replication in the nucleus, the completed viral genomes are packaged into preformed capsids as the scaffolding proteins (the products of UL26.5 and the 3′ portion of UL26) are displaced. This assembly process entails several proteins that comprise the DNA encapsidation/cleavage machinery. The packaging process also involves the 'a' sequence at the other end of the genome-sized DNA fragment, leading to cleavage of the growing DNA chain and resulting in encapsidation of a full-length genome. Assembly is accompanied by a major change in capsid structure (maturation), which entails the action of the UL26 viral protease. This is followed by a very complicated process of egress. While there is controversy on how this process occurs, in the currently favored model, the nucleocapsid first buds through the inner nuclear membrane acquiring an envelope. The virion then enters the cytoplasm by fusing with the outer nuclear membrane, thereby losing its initial envelope. Subsequently, it becomes re-enveloped by budding into intracellular membranous compartments and proceeds through the cytoplasm. Whatever the exact mechanism, infectious virus can be recovered from cells many hours before cellular disintegration and release of virions into the extracellular medium. Virus spread by cell to cell contact and/or cell fusion is probably an important feature of the pathogenesis of infection in the host and can be readily observed with infections in cultured cells.

Viral Transcripts and Proteins

Each viral protein is expressed from its own independently regulated transcript. The viral transcription map is included in **Figure 1**. Independent starts of overlapping transcripts, (rare) splicing, and temporally differentiated polyadenylation site utilization result in the number of independent transcripts expressed exceeding 100.

General Properties of Transcripts and Promoters

Generally, the ORFs of HSV-1 are expressed as unique, intronless mRNA molecules that are controlled by temporal class-specific promoters. Nested, partially overlapping transcripts, each encoding a unique ORF but utilizing a shared polyadenylation site, are common (e.g., transcripts encoding UL24, UL25, and UL26 and those encoding US5, US6, and US7). Some complementary reading frames also exist, such as the mRNAs encoding ORF-P and ORF-O with that encoding ICP34.5 and transcripts encoding reading frames complementary to UL43.

Most HSV promoters are recognizable as eukaryotic RNA polymerase II promoters with obvious 'TATA' box homologies 20–30 nucleotides (nt) 5′ of the mRNA cap sites. The *cis*-acting elements mediating transcription of immediate early (α) transcripts include upstream enhancer elements at sites distal to and extending to several hundred nucleotides upstream of the cap sites, as well as several transcription factor binding sites located within the region from −120 to −50. The enhancers contain multiple copies of a 'TAATGARAT' sequence, which interacts with cellular transcription factors of the POU family (notably, Oct-1). Enhancement of transcription occurs through the action of virion-associated tegument protein VP16 or αTIF (UL48), which is a powerful transcriptional activator. The *cis*-acting elements mediating transcription of early (β) promoters include several transcription factor binding sites and the TATA box at −30, but the 'TAATGARAT' enhancer elements are not present. Leaky-late (βγ) and late transcript (γ) promoters contain critical sequence elements mediating full levels of transcription at or near the cap site, and at least some contain transcription factor binding sites in the proximal part of the leader sequence downstream of the start site of transcription. HSV-1 promoters representing the temporal classes of productive infection are shown in **Figure 2**.

Nomenclature of Proteins

The proteins encoded by HSV-1, their functions (if known), and the locations of their coding regions on the genome are given in **Table 1**.

Currently accepted protein nomenclature is a mix of historic and systematic systems. Proteins encoded in the repeats and a number of other proteins of well-established function are referred to by their historic or functional names. Proteins encoded by ORFs in the U_L and U_S regions are often referred to by the location of the ORF. Both nomenclatures are used in **Table 1**.

Functional Classification of Proteins

Regulatory proteins

The cascade of viral gene expression begins with the expression of immediate early or α proteins. There are five immediate early genes and their expression is highly activated by the action of VP16 or αTIF (UL48), which interacts with cellular transcription factors, Oct1 and

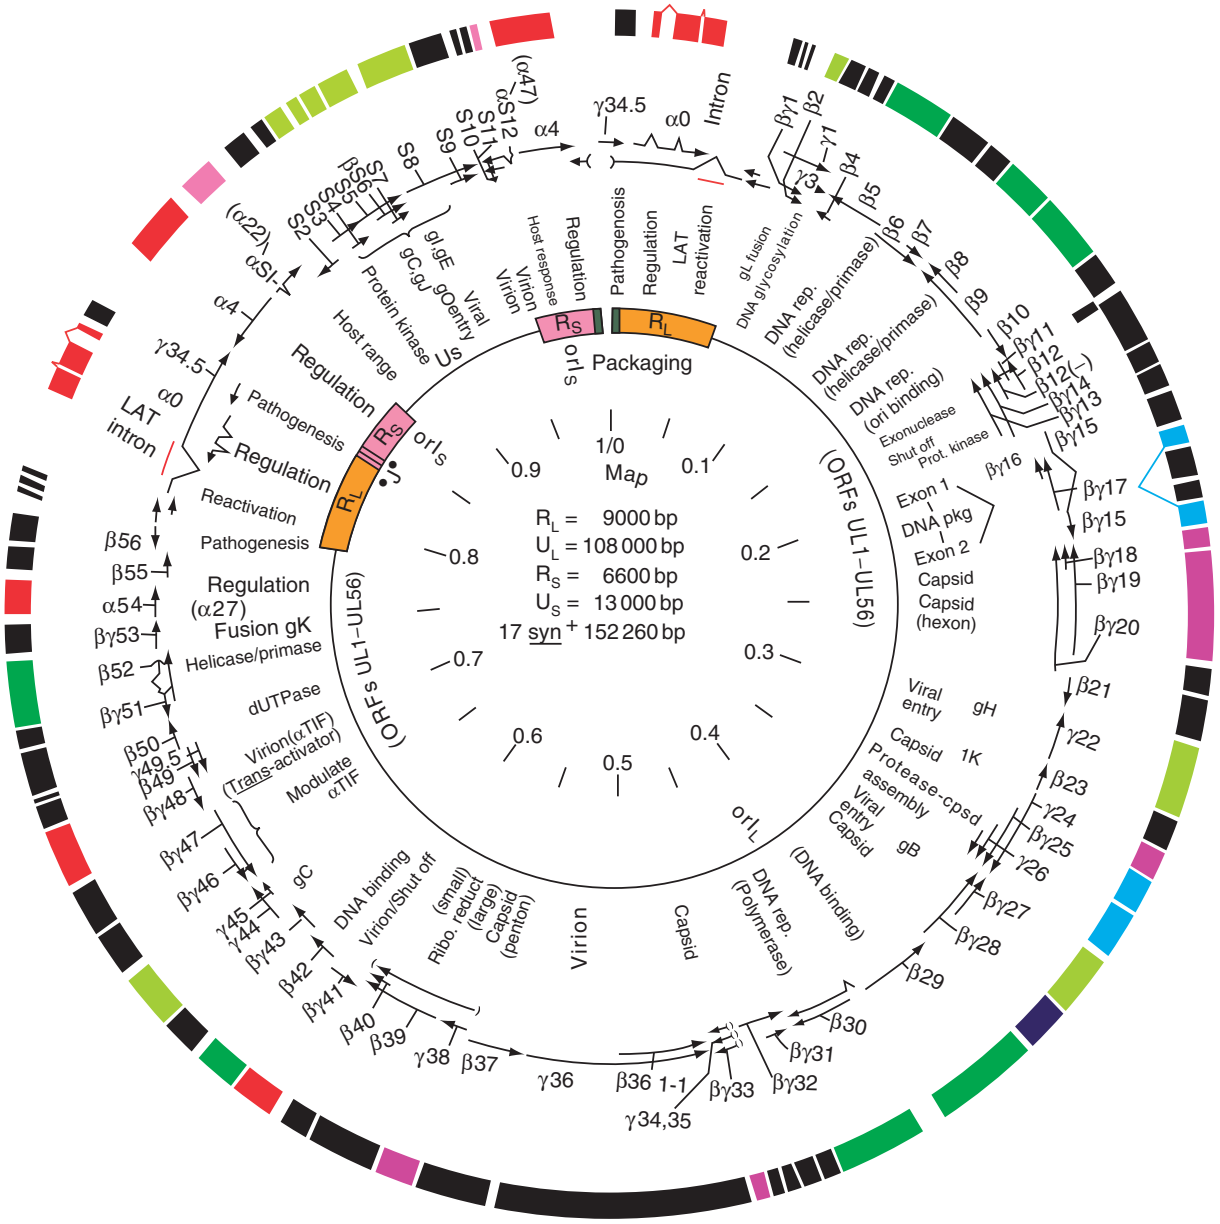

Figure 1 The genetic and transcriptional map of HSV-1 (strain 17*syn*$^+$). The map is shown as a circle to indicate the fact that the linear genome circularizes upon infection. ORFs predicted from sequence data are named numerically according to their position on the viral genome, and transcripts expressing all or part of them are indicated with the arrowheads showing the transcription termination/polyadenylation sites. Known kinetic classes of transcripts are indicated; the LATs in the R_L regions are the only transcripts expressed during latent infection. Also shown are the location of the origins of replication and the 'a' sequences at the genome ends which are involved in encapsidation. In addition, and where known, the functions of individual genes are shown. In the literature, gene names sometimes contain a subscript (e.g., U_L19 rather than UL19).

HCF. The resulting complex binds to the 'TAATGARAT' sequences upstream of immediate early gene promoters. Three of the five immediate early genes, ICP4, ICP0, and ICP27, have roles in regulating viral gene expression at the level of transcription. ICP4 is a transcriptional activator that is required for the transcription of early and late viral mRNAs. Multiple phosphorylated forms of the protein have been identified in the infected cell. ICP4 apparently stabilizes the formation of the transcription initiation complexes at the TATA box of viral promoters.

The essential ICP27 protein is multifunctional, acting at both the transcriptional and post-transcriptional levels to regulate viral and cellular gene expression. Different functional domains of ICP27 are required for its activities, which include recruiting cellular RNA polymerase II to sites of viral DNA, inhibiting cellular splicing, promoting

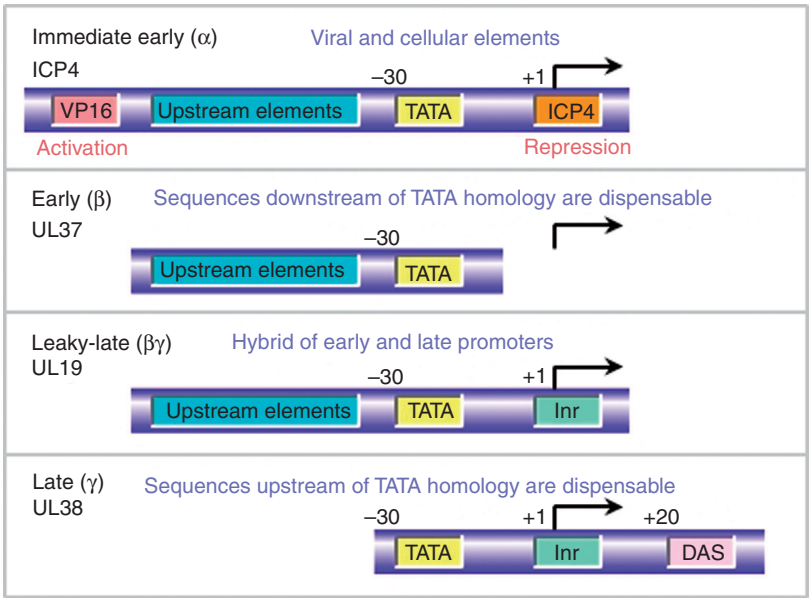

Figure 2 The architecture of HSV promoters. Features of the promoters controlling representative members of the kinetic classes of viral transcripts expressed during productive infection are shown. Inr, initiator element; DAS, downstream activator sequence.

export of viral intronless mRNAs, and enhancing translation of viral transcripts. ICP27 interacts with myriad cellular and viral proteins, and it binds to viral RNAs. ICP27 is phosphorylated and methylated on some arginine residues, and these modifications presumably help regulate its various activities.

ICP0 is also a multifunctional protein that is, first and foremost, a transcriptional activator. ICP0 appears to play a central role in regulating whether HSV infection goes into the lytic phase or the virus becomes latent. ICP0 is a member of the family of E3 ubiquitin ligase enzymes that have a so-called RING finger zinc-binding domain. This domain confers on ICP0 the ability to induce the proteasome-dependent degradation of a number of cellular proteins. This process results in multiple consequences, including the disruption of cellular nuclear substructures known as ND10 or PML nuclear bodies. ICP0 interacts with or forms complexes with a large number of proteins. It also undergoes extensive post-translational modification, including phosphorylation by viral and cellular kinases, and ubiquitination. The phosphorylation status of ICP0 alters as infection progresses, suggesting that the change in ICP0 localization from nuclear to predominantly cytoplasmic at later times of infection may in part be regulated by phosphorylation.

DNA replication proteins

Seven early proteins are required for the formation of the viral DNA replication complex: The DNA polymerase (UL30) functions in a complex with UL42, a processivity factor. The ori binding protein (UL9) binds to the critical core sequence 'GTTCGCAC' in ori_S and may function as a dimer. Equimolar amounts of proteins UL5, UL8, and UL52 make up the helicase–primase complex; and ICP8 (UL29), the major single-stranded DNA-binding protein functions in a manner analogous to phage T_4 gene 32 protein in keeping the replication fork open.

A number of other early proteins are involved in genome replication by altering the pool of deoxyribonucleoside precursors and for repair and proofreading functions. These include thymidine kinase (UL23), the large and small subunits of ribonucleotide reductase (UL39 and UL40), and deoxyuridine triphosphatase (UL50). An enzyme with a potential repair function is uracil-DNA glycosylase (UL2).

Structural proteins

More than 30 HSV late proteins are associated with mature virions. These include five capsid proteins, of which VP5 is the major capsid protein. A large number of tegument proteins and 10 or more glycoproteins are also found in mature virions.

Capsid assembly can be readily accomplished both *in vitro* and in insect cells with proteins expressed from a panel of recombinant baculoviruses expressing the four principal capsid proteins (UL19–VP5, UL38–VP19C, UL18–VP23, and UL35–VP26), the scaffolding protein (UL26.5), and the maturational protease (UL26). Other proteins have been implicated genetically in the capsid assembly process, but are dispensable in minimal *in vitro* systems.

Packaging of the viral DNA into the mature capsid requires a large number of viral proteins, including UL6, UL15, UL17, UL25, UL28, UL32, and UL33. The protein encoded by UL15, in conjunction with that encoded by UL28, may function as a terminase, cleaving

Table 1 Genetic functions encoded by HSV-1

Location	*Name*	*Function*
R_L	'a'	*cis* genome cleavage, packaging signal
	ICP34.5	RL1, neurovirulence, inhibits cellular apoptosis
	ORF-O	Modulates ICP0, ICP22 – inhibits splicing
	ORF-P	Modulates ICP4
	ICP0	RL2 (α0, IE1) immediate early *trans*-activator, E3 ubiquitin ligase, disrupts nuclear ND10 structures
	LAT-intron	Stable accumulation in nuclei of latently infected neurons
	LAT	*c*. 600 nt in 5′ region facilitates reactivation
	ORF-X	Unknown
	ORF-Y	Unknown
U_L	UL1	gL, essential glycoprotein that functions as a heterodimer with gH – involved in viral entry
	UL2	Uracil DNA glycosylase, DNA repair
	UL3	Nuclear protein
	UL4	Nuclear protein
	UL5	Part of helicase–primase complex, essential for DNA replication
	UL6	Capsid portal protein, capsid maturation, DNA packaging in capsid
	UL7	Unknown, dispensable in cell culture
	UL8	Part of helicase–primase complex, essential for DNA replication
	UL9	Ori-binding protein, essential for DNA replication
	UL10	gM, glycoprotein of unknown function
	UL11	Tegument protein, capsid egress, and envelopment
	UL12	Alkaline exonuclease, DNA packaging (?), capsid egress
	UL12.5	C-terminal 2/3 of UL12, expressed by separate mRNA – specific function unknown
	UL13	VP18.8, tegument-associated protein kinase
	UL14	Unknown
	UL15	DNA packaging, spliced mRNA, exons flank UL16 and UL17
	UL16	Tegument protein
	UL17	Cleavage and packaging of DNA
	UL18	VP23, capsid protein, triplex
	UL19	VP5, major capsid protein, hexon
	UL20	Membrane-associated, virion egress
	UL21	Tegument protein, auxiliary virion maturation function (?)
	UL22	gH, glycoprotein involved in viral entry as heterodimer with gL
	UL23	TK, thymidine kinase
	UL24	Nuclear protein
	UL25	Tegument protein, capsid maturation, DNA packaging
	UL26	VP24 (N-terminal half), protease, minor scaffolding protein (C-terminal half)
	UL26.5	Scaffolding protein
	UL27	gB, glycoprotein required for virus entry, mediates binding through interaction with GAGs in plasma membrane
	UL28	ICP18.5, capsid maturation, DNA packaging
	UL29	ICP8, single-stranded DNA-binding protein, essential for DNA replication
	ori_L	Origin of DNA replication
	UL30	DNA polymerase
	UL31	Nuclear lamina protein involved in nuclear egress
	UL32	Capsid maturation, DNA packaging
	UL33	Capsid maturation, DNA packaging
	UL34	Nuclear membrane protein involved in nuclear egress
	UL35	VP26, capsid protein
	UL36	VP1/2, tegument protein
	UL37	Tegument phosphoprotein
	UL38	VP19C, capsid protein, triplex
	UL39	Large subunit of ribonucleotide reductase
	UL40	Small subunit of ribonucleotide reductase
	UL41	vhs, virion host shutoff protein, degrades mRNA
	UL42	Polymerase accessory protein, essential for DNA replication
	UL43	Multiple membrane spanning protein
	UL43.5	Antisense to UL43
	UL44	gC, glycoprotein involved in initial stages of virion-cell association with GAGs, complement binding protein
	UL45	Membrane associated
	UL46	VP11/12, tegument associated

Continued

Table 1 Continued

Location	*Name*	*Function*
	UL47	VP13/14, tegument associated
	UL48	αTIF, VP16, virion-associated transcriptional activator, enhances immediate early transcription
	UL49	VP22, tegument protein
	UL49.5	Membrane protein associated with gM, glycosylated in other herpesviruses (gN) but not in HSV-1
	UL50	dUTPase, nucleotide pool metabolism
	UL51	Unknown
	UL52	Part of helicase–primase complex, essential for DNA replication
	UL53	gK, glycoprotein involved in virion egress
	UL54	ICP27, immediate early regulatory protein, multifunctional regulator, inhibits splicing, mediates viral RNA export, enhances translation initiation
	UL55	Unknown
	UL56	Tegument protein, affects pathogenesis
R_L		See R_L above
	R_L/R_S junction	Joint region, site of inversions of long and short segments, contains 'a' sequences
R_S	LAT-poly(A) site	Polyadenylation site for the primary latency associated transcript and the transcripts encoding ORF-O and ORF-P
	ICP4	RS1, essential immediate early transactivator, required for early and late gene expression
	ori_S	Origin of DNA replication
U_S	ICP22	US1, nonessential immediate early protein, affects host range
	US2	Unknown
	US3	Tegument-associated protein kinase, phosphorylates UL34 and US9
	US4	gG, glycoprotein of unknown function
	US5	gJ, glycoprotein of unknown function
	US6	gD, glycoprotein involved in virus infectivity and entry, binds HVEM
	US7	gI, glycoprotein, which as heterodimer with gE binds IgG-Fc and influences cell-to-cell spread of virus
	US8	gE, glycoprotein, which as heterodimer with gI binds IgG-Fc and influences cell-to-cell spread of virus
	US8.5	Nucleolar protein
	US9	Tegument-associated phosphoprotein (type II membrane protein)
	US10	Tegument-associated protein
	US11	Tegument-associated phosphoprotein, RNA binding, post-transcriptional regulation
	US12	ICP47, immediate early protein, inhibits major histocompatibility complex type 1 antigen presentation in human and private cells

genome-sized fragments from the growing concatemeric replication complex. The UL15–UL28 complex also appears to mediate the initial entry of viral DNA into the capsid, that is, it serves a 'docking' function. The alkaline exonuclease gene (UL12) also plays a role in DNA packaging.

Proteins involved in pathogenesis and cytopathology

After the onset of viral DNA synthesis, a large fraction of the viral genome is represented in abundant amounts of complementary mRNA that can form stable dsRNAs, which serve to activate protein kinase R (PKR). Activated PKR phosphorylates the α subunit of the translation initiation factor 2 (eIF-2α), which shuts off protein synthesis. To combat this response, HSV encodes a protein named $\gamma_1$34.5 (ICP34.5), which binds phosphatase 1α and redirects it to dephosphorylate eIF-2α, thereby preventing the shutoff of protein synthesis by activated PKR. One of the immediate early proteins, ICP47, appears to have a role in modulating host response to infection by specifically interfering with the presentation of viral antigens on the surface of infected cells by major histocompatibility complex class I (MHC-I), precluding immune surveillance by $CD8^+$ T lymphocytes at the very onset of infection.

A number of the envelope glycoproteins found in the intact virion appear to have a significant role in controlling host response. The complex of glycoproteins gE (US9) and gI (US8) functions as an IgG Fc receptor blocking the presentation of this region of the antibody molecule and precluding activation of the complement cascade. In addition, gC (UL44) binds several components of the complement complex, and viruses with mutations in gD (US6) display altered pathogenesis in mice.

Other viral gene products also have a role in cytopathology and pathogenesis. While dispensable for productive infection in some cells, the immediate early protein ICP22 is required for HSV replication in others – perhaps by mediating the expression of a set of late transcripts. Viruses lacking thymidine kinase (UL23) have significantly altered pathogenic patterns in experimental animals while certain mutations in the DNA polymerase gene (UL30) have altered patterns of neurovirulence.

Viral mutants defective in the virion host-shutoff protein (vhs; UL41) also have altered virulence in mice.

Latent Infection

HSV-1 latency is characterized by the persistence of viral genomes as episomes in the nuclei of sensory neurons. During latency, lytic functions are repressed and only one region of the genome is transcribed abundantly: the region encoding the LATs. The LAT domain is transcriptionally complex, and while the predominant species that accumulates during latency is a 2.0 kb stable intron, other RNA species are transcribed from this region of the genome, including a number of lytic or acute-phase transcripts. The LAT promoter (**Figure 3**) has not been characterized in quite as much detail as those promoters controlling productive cycle transcripts. It appears to have a number of regulatory elements important in neuronal expression over extended periods of time.

Latent infection with HSV can be viewed as having three separable phases: establishment, maintenance, and reactivation. In the establishment phase, the virus must enter a sensory neuron, and, following entry, there must be a profound restriction of viral gene expression so that the cytopathic results of productive infection do not occur. Thus, productive cycle genes are quiescent transcriptionally and functionally and only LAT is expressed. The maintenance of the HSV genome in latently infected neurons requires no viral gene expression apart from the LATs. Latent HSV genomes are harbored within the nucleus of a nondividing sensory neuron and do not need to replicate. HSV DNA is maintained as a nucleosomal, circular episome in latent infections and low levels of genome replication might occur or be necessary for the establishment or maintenance of a latent infection from which virus can be efficiently reactivated.

Reactivation of HSV results in the appearance of infectious virus at the site of entry in the host. Expression of only a 350 bp region of LAT near its 5′ end is both necessary and sufficient to facilitate reactivation in several animal models. Whatever the specific mechanism for this facilitation, it does not involve expression of a protein; rather, the active region appears to function by a *cis*-acting mechanism, the details of which are currently obscure. The process of reactivation is triggered by stress as well as other signals that may transiently lead to increased transcriptional activity in the harboring neuron, which may achieve a threshold that leads to lytic infection. The latency and reactivation cycle is shown in **Figure 4**.

Latent Phase Transcripts

Latently infected neurons represent 1–10% of the total neurons in the ganglia. In some neurons, an 8.5 kb polyadenylated primary LAT is expressed, which extends through the joint region (across the 'a' sequences) to a polyadenylation signal next to that of the ICP4 gene. The primary LAT is extensively processed, forming a stable 2 kb poly(A-) intron in lariat form, which accumulates in the latently infected neuronal nucleus. The mechanism by which LATs contribute to the establishment of and reactivation from latency has not been elucidated; in part, this is because LAT mutants behave somewhat differently in the different animal models used to study HSV latency. Because LAT does not become translated into protein, the RNA is believed to be the regulatory factor. It has been proposed that LAT may function as an antisense RNA or a small interfering RNA (siRNA). Future studies will reveal whether these possibilities are involved.

Future Trends

HSV possesses a number of features that will make it a continuing research model in the future. Among the most obvious are: (1) the neurotropism of the virus, along with the ability to generate recombinants containing foreign

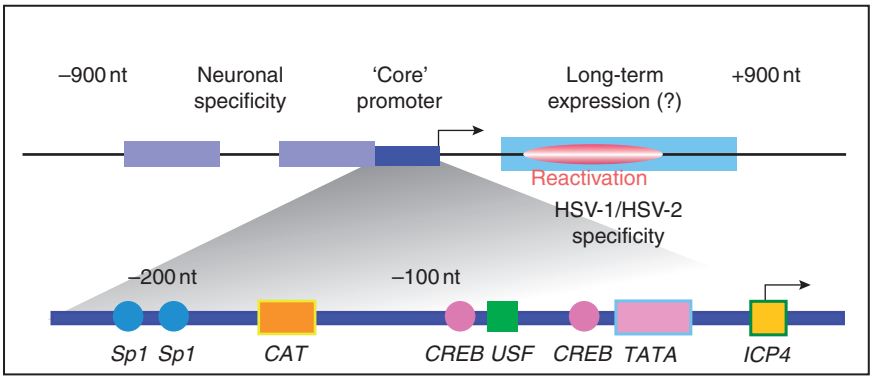

Figure 3 The architecture of the HSV LAT promoter. The transcriptional initiation site (arrow) and binding sites for transcriptional factors are shown in the expansion of the 'core' promoter.

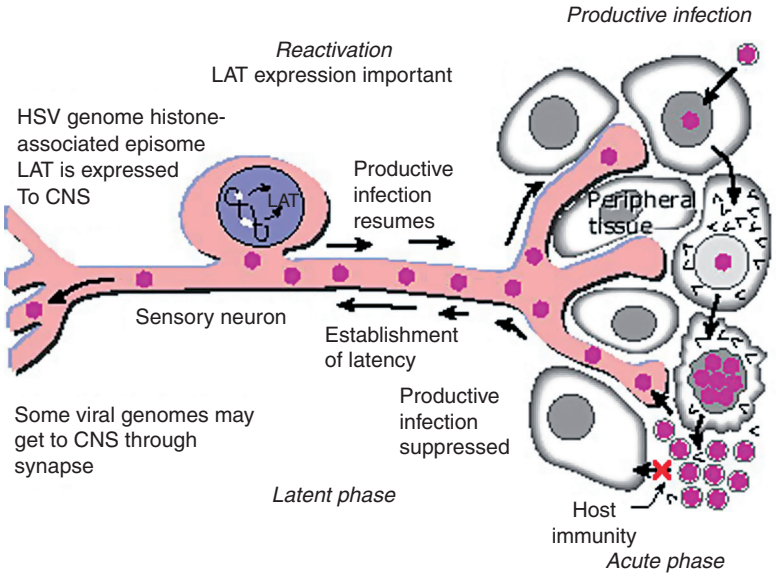

Figure 4 Schematic representation of HSV latent infection and reactivation. CNS, central nervous system.

genes, recommends HSV as a vector for introducing specific genes into neural tissue; (2) the fact that replication of HSV is restricted in terminally differentiated neurons suggests its potential as a therapeutic agent against neural tumors, and several studies have suggested real promise; (3) the abundance of viral genes dedicated to the efficient replication of viral DNA in the productive cycle provides a number of potential targets for antiviral chemotherapy; and (4) the number of multifunctional viral proteins that interact with many different cellular proteins makes HSV a useful model for detailed analysis of specific aspects of eukaryotic gene expression and cellular functions.

Herpesviruses of Birds

Introduction

A large number of herpesviruses are found in avian host species of several different orders. Similar to their mammalian counterparts, they generally have a relatively narrow host range *in vitro* and *in vivo*. At present, only the gallid herpesviruses (GaHV-1, GaHV-2, and GaHV-3), meleagrid herpesvirus 1 (MeHV-1; also referred to as herpesvirus of turkeys, HVT), and psittacid herpesvirus 1 (PsHV-1) have been classified taxonomically by the International Committee on Taxonomy of Viruses (ICTV) as members of the *Alphaherpesvirinae* subfamily. Genomic sequences have been reported for all of these alphaherpesviruses and deposited in the GenBank sequence

database. Avian beta- or gammaherpesviruses have not been identified.

Taxonomically unclassified herpesviruses have been discovered in a wide variety of avian hosts; including the bald eagle (acciptrid herpesvirus 1, AcHV-1), duck (anatid herpesvirus 1, AnHV-1), black stork (ciconiid herpesvirus 1, CiHV-1), pigeon (columbid herpesvirus 1, CoHV-1), falcon (falconid herpesvirus 1, FaHV-1), crane (gruid herpesvirus 1, GrHV-1), bobwhite quail (perdicid herpesvirus 1, PdHV-1), cormorant (phalacrocoracid herpesvirus 1, PhHV-1), black-footed penguin (sphenicid herpesvirus 1, SpHV-1), and owl (strigid herpesvirus 1, StHV-1). Of these viruses, only AnHV-1 causes a known disease, duck virus enteritis (DVE), which accounts for significant economic losses. DVE, also referred to as duck plague, is a highly contagious acute disease of ducks, geese, and swans, and is characterized by hemorrhagic lesions in the blood vessels, gastrointestinal mucosa, and lymphoid tissues. The clinical symptoms of DVE are unspecific, and often mortality is the first observation in infected waterfowl flocks. Morbidity and mortality in domestic ducks may range from 5% to 100%.

Gallid herpesvirus 1 (GaHV-1), frequently referred to as infectious laryngotracheitis virus (ILTV), belongs to the type species of the genus *Iltovirus* and is the causative agent of a highly contagious, acute respiratory tract disease of domestic fowl termed infectious laryngotracheitis (ILT). ILT causes considerable economic losses to the poultry industry worldwide owing to mortality and decreased egg production associated with the disease. Epizootic forms of ILT are characterized clinically by severe respiratory symptoms such as dyspnea and hemorrhagic expectorations, and are generally associated with high mortality (5–70%). Enzootic infections, predominantly those occurring in poultry flocks of developed countries, are associated with mild symptoms (nasal discharge, conjunctivitis, and decreased egg production) or subclinical symptoms. Modified-live vaccines against ILTV infections are available, but their use is commonly restricted to areas where ILT is enzootic. However, most of the current modified-live virus vaccines have residual virulence, and several ILT outbreaks have been attributed to reversions of the ILTV vaccine strains to a virulent phenotype.

ILTV is the only virus allocated to the genus *Iltovirus*. However, recent genomic information indicates clearly an affiliation of PsHV-1 with this genus. PsHV-1 causes Pacheco's disease, a generally fatal disease of psittacine birds characterized by acute onset and massive necrotizing lesions of the crop, intestines, pancreas, and liver. Parrot species from multiple geographic regions are highly susceptible to Pacheco's disease. However, captive parrots such as macaws, Amazon parrots, and cockatoos account for the majority of clinical cases of Pacheco's disease; hence, the disease is of great concern to pet traders and exotic bird breeders worldwide. An association of subclinical PsHV-1 infections with mucosal papillomatosis in neotropical (Central and South American) parrots has been reported, but causality has not yet been demonstrated. Recently, genomic DNA of a novel psittacine alphaherpesvirus has been amplified from mucosal and cutaneous papillomas of African grey parrots. This virus is related to, but phylogenetically distinct from, PsHV-1, and has been designated psittacid herpesvirus 2 (PsHV-2).

Gallid herpesvirus 2 (GaHV-2) or Marek's disease virus (MDV) is the etiologic agent of Marek's disease (MD), an economically important, neoplastic, and neuropathic disease of chickens. MDV is highly infectious and routinely causes >90% morbidity and mortality in susceptible, unvaccinated animal populations. MD manifests as various clinical syndromes of varying severity. Of these, T-cell lymphoproliferative syndromes, including fowl paralysis (classic MD) and fatal MD lymphoma (acute MD), are most frequently associated with the disease. However, infections of chickens with the most recent clade of MDV strains are characterized by massive inflammatory brain lesions that are clinically manifested as transient paralysis and/or peracute death. Owing to its biological features, namely its lymphotropism and oncogenic potential, MDV was long thought to be related to Epstein–Barr virus, a lymphomagenic gammaherpesvirus. However, based on its genomic organization, MDV was reclassified as an alphaherpesvirus; thus, MDV is genetically more closely related to herpes simplex virus 1 (HSV-1) and varicella-zoster virus (VZV) (**Figure 1**). MDV belongs to the type species of the genus *Mardivirus*, into which two other closely related but distinct species have been grouped, represented by gallid herpesvirus 3 (GaHV-3) and MeHV-1 (HVT). Although the three viruses are closely related, only MDV causes MD while GaHV-3 and HVT are nonpathogenic. Therefore, the old nomenclature referring to GaHV-3 and HVT as MDV (serotypes) 2 and 3 is misleading and should be avoided.

Control of MDV-caused syndromes by vaccination was started in the late 1960s using an attenuated MDV strain (HPRS-16att) or the nonpathogenic HVT. Because MDV field strains are evidently evolving toward greater virulence in the face of vaccination, combination vaccines consisting of HVT and GaHV-3 or an attenuated MDV strain (CVI988-Rispens) are currently used to immunize chickens against the latest clade of MDV strains. Based on their ability to cause breaks of vaccinal immunity, MDV strains are subdivided into four different pathotypes: mildly virulent (m), virulent (v), very virulent (vv), and very virulent plus (vv+).

History

ILT was first described in 1925 as tracheolaryngitis, and shortly thereafter its viral etiology was demonstrated. The term infectious laryngotracheitis was adopted in 1931

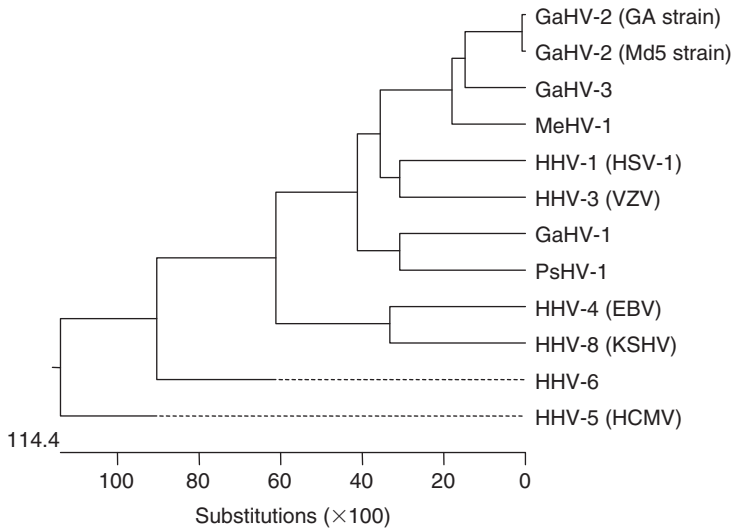

Figure 1 Genetic relationship of avian herpesviruses. A ClustalV-based comparison of the amino acid sequences of the DNA polymerase proteins of the viruses is shown. Human herpesviruses 5 (human cytomegalovirus) and 6, representatives of the *Betaherpesvirinae*, were chosen as outgroups. It is evident that the two representatives of the *Iltovirus* genus, GaHV-1 (ILTV) and PsHV-1 are closely related, as are the three members of the genus *Mardivirus*, GaHV-2 (MDV), GaHV-3, and MeHV-1 (HVT). These results also indicate independent evolution of *Alphaherpesvirinae* (GaHV-1 and GaHV-2) within one bird species (*Gallus gallus*). EBV, Epstein–Barr virus; HCMV, human cytomegalovirus; HHV, human herpesvirus; HSV-1, herpes simplex virus type 1; KSHV, Kaposi's sarcoma-associated herpesvirus; VZV, varicella-zoster virus.

by the Special Committee on Poultry Diseases of the American Veterinary Medical Association. ILT was the first major viral avian disease against which an effective vaccine was developed, being achieved in the 1930s by Hudson and Beaudette at Cornell University. Pacheco's disease was first recognized by Pacheco and Bier in the late 1920s in Brazil, but was not seen again until the 1970s, when outbreaks of the disease occurred in wild-caught neotropical parrots and a psittacine herpesvirus was identified as the etiologic agent.

The first account of MD dates from 1907, when József Marek (after whom the disease was named in 1960), a preeminent clinician and pathologist at the Royal Hungarian Veterinary School in Budapest, reported a generalized neuritis interstitialis or polyneuritis in four adult cockerels, which were affected by paralysis of the limbs and wings. Marek's detailed histological examination revealed that the sciatic nerve and areas of the spinal cord of the affected birds were infiltrated by mononuclear cells, an observation that is still made today after infection with most MDV strains. In the late 1920s, Pappenheimer and colleagues at Rockefeller University recognized the lymphoproliferative character of MD, and proposed that polyneuritis and visceral lymphoma were manifestations of the same disease. The identification of a highly cell-associated herpesvirus as the etiological agent of MD in the late 1960s by Churchill and colleagues led to the development of vaccines that achieved unparalleled success in preventing the disease, and provided the first example of immune prophylaxis against a cancer induced by an oncogenic virus.

Host Range and Virus Propagation

Like most avian herpesviruses, ILTV exhibits a very narrow host range. The chicken is the primary natural host, but pheasants and peafowl have also been reported to be susceptible. Turkeys have been shown to be susceptible to infection under experimental conditions, but other avian species are probably refractory. Embryonated chicken eggs are also susceptible, and can be used to propagate the virus. Chorioallantoic membrane (CAM) plaques resulting from necrosis and proliferative tissue reactions can be observed as early as 2 days post inoculation (pi). The virus can also be propagated in a variety of primary avian cell cultures, including chicken embryo liver cells (CELCs), chicken embryo kidney cells (CEKCs), and chicken kidney cells (CKCs). In addition, a permanent chicken cell line (LMH) derived from a chemically induced liver tumor was shown to permit replication of cell culture-adapted ILTV. Viral cytopathology *in vitro*, characterized by the formation of syncytia and nuclear inclusion bodies, can be observed as early as 4–6 h pi.

PsHV-1 infects a broad spectrum of psittacine species. In addition, it has been isolated from a superb starling, and some evidence suggests that other passerine species, such as the common cardinal, zebra finch, and canary, are also susceptible to PsHV-1 infections. Embryonated chicken eggs and primary chicken embryo cells (CECs) derived from 10- to 12-day-old chicken embryos are used for virus propagation *in vitro*.

MDV infections and MD-like symptoms have been observed in quail, turkeys, and pheasants, but the chicken

is considered the natural host of MDV. Primary chicken cells (CKCs and CECs) or duck embryo fibroblasts (DEFs) are used routinely to propagate the virus *in vitro*. However, for primary isolation and propagation of low-passage MDV isolates, the use of CKC or DEF is recommended to retain wild-type properties of the virus. Permanent avian cell lines such as OU2, DF-1, and QM7 allow only low level or abortive MDV replication. On permissive cells, MDV-induced plaques ($\leq$1 mm in diameter) develop very slowly (in 5–14 days pi) on primary isolation and 3–7 days pi after cell culture adaptation. In addition, 1-day-old chicks can be used for primary isolation and propagation of MDV *in vivo*.

Morphology

All herpesvirus particles share a complex and characteristic multilayered structure in which the nucleocapsid containing the viral DNA is separated from the envelope by a proteinaceous layer called the tegument. While both MDV and ILTV capsids have a diameter of approximately 125 nm, the incorporation of highly variable amounts of tegument into ILTV virions results in diameters of enveloped ILTV particles that vary between 195 and 350 nm. In contrast, enveloped MDV particles have a diameter of 150–160 nm. The morphologies of GaHV-3 and HVT closely resemble that of MDV, but, in thin sections, HVT capsids commonly show a characteristic cross-shaped appearance. The morphology of PsHV-1 has not been studied in detail, but typical herpesvirus particles have been visualized.

Genetics

The genomes of herpesviruses are linear, double-stranded DNA molecules that range in size from approximately 120 to 300 kbp. A total of six different genome organizations, referred to as classes A through F, are distinguished in the *Herpesviridae*, and only class D and E genomes are found in the *Alphaherpesvirinae*. ILTV and PsHV-1 have class D genomes and the three members of the *Mardivirus* genus (MDV, GaHV-3, and HVT) have class E genomes. Class D genomes consist of two unique sequence regions (unique-long, U_L; unique-short, U_S) with inverted repeats (internal repeat, IR; terminal repeat, TR) flanking U_S. Class E genomes consist of U_L and U_S, each bracketed by inverted internal (IR_L, IR_S) and terminal repeats (TR_L, TR_S).

The ILTV genome sequence, as assembled from 14 overlapping genome fragments from different virus strains, is approximately 147 kbp in length and has a G+C content of 48.2%. The PsHV-1 genome is 163 kbp in length and has a nucleotide composition of 61% G+C. ILTV and PsHV-1 contain 76 and 73 protein-coding open reading frames (ORFs), respectively, and the majority of these ORFs exhibit significant homologies to genes of the prototypic alphaherpesvirus, HSV-1. However, ILTV and PsHV-1 exhibit several unusual structural features, for example, a large internal inversion of the region within U_L containing genes UL22 to UL44 (a suffix is sometimes used in gene name, e.g., U_L 22). Also, U_L in both viruses contains a unique cluster of five ORFs (designated A to E) that do not share significant sequence similarity with known viral or cellular genes. The function of these ORFs is unknown, but they have been shown to be dispensable for ILTV replication *in vitro*. Another striking feature is the localization of the UL47 gene, which encodes a tegument protein and is usually localized in the U_L region of alphaherpesvirus genomes. UL47 is absent from the corresponding position in the ILTV and PsHV-1 genomes, but both viruses are still predicted to encode a homolog of UL47 (ILTV: UL47; PsHV-1: sORF1) in U_S.

One major structural difference between the closely related viruses ILTV and PsHV-1 can be found in the inverted repeat regions of the genomes. The ILTV repeats are considerably (18.5%) shorter than those of PsHV-1, and each harbors three genes: ICP4, US10, and sORF4/3. In contrast, ICP4 is the only gene located in the PsHV-1 repeat, and the US10 and sORF4/3 genes are located in U_S. Moreover, PsHV-1 U_L contains a homolog of UL16, an ORF that is conserved throughout the herpesvirus subfamilies but is absent from the ILTV genome, having presumably been lost during evolution. Conversely, ILTV U_L contains the UL48 gene and ILTV-specific UL0 gene, neither of which is found in the PsHV-1 genome.

The complete genomic sequences of representatives of all three species in the genus *Mardivirus* have been determined. The gene contents and linear arrangements of the genomes of MDV, GaHV-3, and HVT are similar in general, but vary considerably with regard to G+C content and size. Whereas the ~180 kbp MDV genome has a G+C content of 44.1%, the ~165 kbp GaHV-3 genome has a nucleotide composition of 53.6% G+C; the ~160 kbp HVT genome has a G+C content in between these two values (47.2%). A total of 103 (MDV), 102 (GaHV-3), and 99 (HVT) genes have been clearly identified in the mardivirus genomes. The majority of these genes are homologous to genes encoded by other alphaherpesviruses, but genus- and species-specific genes are also present.

Most of the differences between the three mardiviruses concern the TR_L and IR_L regions. In pathogenic MDV, they harbor a unique cluster of three species-specific genes, which are designated vTR, vIL-8, and meq. vTR, which encodes a viral homolog of telomerase RNA (vTR), exhibits 88% sequence identity to chicken telomerase RNA, and was presumably pirated from the chicken genome. The vIL-8 ORF encodes a CXC chemokine (viral interleukin-8, vIL-8) of 18–20 kDa in size, which functions as a chemoattractant for chicken mononuclear cells. The meq

gene encodes the 339-residue oncoprotein Meq (MDV EcoRI Q), a transcriptional regulator that is characterized by an N-terminal bZIP domain and a proline-rich C-terminal transactivation domain.

In addition, a genus-specific ORF (pp38), which is located in the junctions between the U_L and the adjacent repeat regions of all three mardivirus genomes, encodes a pp38 phosphoprotein of variable size dependent on the virus and the phosphorylation status of the protein. Another mardivirus-specific ORF, vLIP, is located in U_L in close proximity to pp38, and encodes a 120 kDa N-glycosylated protein, a portion of which shows significant similarity to the α/β hydrolase fold of pancreatic lipases and was thus termed viral lipase (vLIP). The HVT-specific vN-13 ORF encodes a 19 kDa protein (vN-13) that exhibits 63.7% amino acid sequence identity to cellular N-13, an anti-apoptotic member of the Bcl-2 family. While Bcl-2-like sequences have been identified in several gammaherpesviruses, HVT is the only alphaherpesvirus that encodes a Bcl-2 homolog.

One striking feature of all three mardiviruses is the presence of heterogenic telomeric repeat sequences at the genome termini. Interestingly, similar telomeric repeat sequences have been identified in the genomes of two betaherpesviruses, human herpesviruses 6 and 7 (HHV-6 and HHV-7), and one gammaherpesvirus, equid herpesvirus 2 (EHV-2). The structural or functional significance of these telomeric repeats is unknown, but they might be responsible for genome integration and maintenance of virus genomes in latently infected (tumor) cells.

Pathobiology

Pathogenesis, Clinical Features, and Pathology of Iltovirus Infections

ILTV is readily transmitted from infected to susceptible chickens, and virus shedding and spread mainly occur via the respiratory and ocular routes. Early cytolytic replication of ILTV in the epithelia of the upper respiratory tract results in syncytia formation and subsequent desquamation. Following the acute phase of infection, which lasts for approximately 6–8 days, ILTV establishes latency in the central nervous system (CNS), in particular in trigeminal ganglia. No clear evidence exists for a viremic phase in the course of lytic infection, latency, or reactivation. Sporadic reactivations from the latent state are usually asymptomatic, but generally lead to productive replication in the upper respiratory tract and virus shedding, which can result in infection of susceptible contact animals. The severity of clinical symptoms of ILT depends on the virulence of a particular ILTV strain or isolate, and mortality rates range from 0% to 70%. Severe epizootic forms of ILT are characterized clinically by marked dyspnea and hemorrhagic expectorations. Clinical signs of the milder, enzootic forms include nasal discharge, conjunctivitis, sinusitis, gasping, and decreased egg production. The incubation period of ILT ranges from 6 to 12 days. Pathomorphological alterations may be found in the conjunctiva and throughout the respiratory tract, but are most consistently detected in the larynx and trachea. Typical gross lesions include mucoid to hemorrhagic tracheitis, conjunctivitis, infraorbital sinusitis, and necrotizing bronchitis. However, in the case of the mild enzootic forms of ILT, conjunctivitis and sinusitis are often the only detectable gross lesions. Microscopic lesions include epithelial syncytia, desquamation, and submucosal edema. Eosinophilic intranuclear inclusion bodies in epithelial cells are detectable from day 1 to 5 pi, but disappear as desquamation of infected epithelial cells progresses.

Similar to ILTV, PsHV-1 is shed from the upper respiratory tract but also in the feces of infected parrots. Transmission of the virus occurs by direct contact between infected and susceptible animals or indirectly by contact with contaminated fomites or environmental contamination. The target sites for primary lytic viral replication and the establishment of latency are unknown. The systemic character of Pacheco's disease strongly argues for a viremic phase of infection during which the virus disseminates into multiple organ sites. Anorexia, depression, diarrhea, nasal discharge, and ataxia are among the most common clinical signs of the disease, but a variety of symptoms may be observed, largely depending on which organ system is affected. However, the majority of diseased animals die peracutely, that is, before the onset of clinical symptoms. Latently infected parrots that survive the disease play an important epidemiological role as asymptomatic virus carriers and shedders. The incubation time of Pacheco's disease ranges from 3 to 14 days. Gross pathological lesions are unspecific and may be found in a multitude of organ systems, including the respiratory and gastrointestinal tract, liver, and CNS. Microscopically, Pacheco's disease is characterized by a necrotizing hepatitis with minimal associated inflammation and the presence of intranuclear inclusion bodies (Cowdry type A).

Pathogenesis, Clinical Features, and Pathology of MD

MDV shed from the skin and associated with feathers and dander is highly infectious and can persist for extended periods in the environment. Transmission of the virus occurs by inhalation, either through direct contact or through virus present in dust and dander. In the current model of MDV pathogenesis, phagocytic cells in the lower respiratory tract become infected either directly or after an initial round of replication in epithelial cells. Within 24 h of uptake, the virus is detectable in the primary and secondary lymphoid organs such as thymus, bursa of Fabricius, and spleen. Following primary productive replication, which takes place in B-lymphocytes, the virus

infects activated $CD4^+$ lymphyocytes, and, rarely, $CD4^-CD8^-$ T-cells or $CD8^+$ T-cells. Infected $CD4^+$ T-cells serve as the target for the establishment of MDV latency and are also the means of virus dissemination within an infected animal. Besides epithelial layers in visceral organs, MDV enters the feather follicle epithelium, where cell-free infectious virus is assembled and released into the environment.

In latently infected T-cells, viral DNA is commonly integrated into the cellular genome. MDV is one of the few herpesviruses that achieve genome maintenance during the quiescent stage of infection through this mechanism, the details of which are entirely enigmatic. It is well known that latency is a prerequisite for oncogenic transformation by MDV, but only small subsets of latently infected T-cells become ultimately transformed and proliferate to generate tumors. Depending on the virulence of the virus strain and the susceptibility of the chicken population, mortality rates range from 0% to >90%. Clinical and pathological signs of MD vary according to the specific syndrome. The leading symptom of the classical form of the disease (fowl paralysis) is flaccid or spastic paralysis of the limbs and/or wings caused by lymphoproliferative peripheral nerve lesions. Chickens affected by MD lymphoma (acute MD) generally exhibit unspecific symptoms such as weight loss, anorexia, depression, and ruffled plumage, but (transient) paralysis may also be seen. Unlike the classic form of paralysis, transient paralysis is caused by inflammatory lesions of the CNS and peripheral nervous system. Most v and vv MDV strains induce MD lymphoma and/or (transient) paralysis in susceptible chicken lines. Recent outbreaks of MD caused by vv+ MDV strains are characterized clinically by transient paralysis, a massive rash affecting mainly the extremities, and/or peracute death.

Enlarged peripheral nerves and lymphomatous lesions are the most frequently observed gross pathological findings in MD. Lymphomatous lesions can develop as early as 14 days after infection and generally manifest as diffuse infiltrations and/or solid lymphomas, which affect a variety of organs, including the viscera (heart, liver, spleen, kidney, gonads, adrenal gland, etc.), skeletal muscle, and skin. Two main peripheral nerve pathologies are described: neoplastic proliferation that sometimes involves secondary demyelination (type A) and primary inflammatory cell-mediated demyelination (type B). MD lymphomas are cytologically complex and essentially comprised of lymphocytes and macrophages. MD tumors mainly consist of T-cells, but only a minority of these are transformed, the majority representing immune T-cells that try to contain the neoplasm.

Tumors induced by avian retroviruses represent a differential diagnosis for MDV-induced tumors, but onset of disease is delayed and nerve lesions are generally absent. Histologically, intranuclear inclusions are always absent from retrovirus-infected cells. A hallmark of MDV-transformed cells is expression of the viral oncoprotein Meq, and upregulation of the Hodgkin's antigen, CD30, has also been reported.

Prevention and Control

Control of Iltovirus Infections

ILTV-infected chickens produce peak virus-neutralizing antibody titers around 21 days post infection or vaccination. ILTV-neutralizing antibodies decline over the following months, but remain detectable for years. Although the detection of ILTV-specific antibodies by virus neutralization test is an important means of serological diagnosis, neutralizing antibody titers do not reflect the immune status of infected chickens or vaccinees, as immunity against ILT largely rests on local and cell-mediated immune response in the upper respiratory tract. Maternal antibodies to ILTV are transmitted to the chicken embryo via the egg yolk, but do not confer passive immunity against ILT or interfere with vaccination. For many years, modified-live virus (MLV) vaccines have been used to immunize chickens against ILT. They are administered via the intraocular route and for rapid mass vaccination via the drinking water or aerosolization. Immunization of chickens with attenuated ILTV vaccine strains results in latently infected carrier animals and spread of vaccine virus to nonvaccinates. However, spread to nonvaccinates results in consecutive bird-to-bird passages during which the vaccine virus may revert to a virulent phenotype. Therefore, the use of ILTV MLV vaccines has commonly been restricted to areas where infectious laryngotracheitis is enzootic. Experimental inactivated whole-virus vaccines and subunit preparations containing affinity-purified immunogenic ILTV glycoproteins were tested successfully as an immune prophylactic alternative to MLV vaccines. However, due to high costs of production and individual administration, the practical use of these vaccines in the field is debatable. Thus, the generation of MLV vaccines based on genetically engineered ILTV strains appears to be a more promising approach to the development of safe and efficacious ILTV vaccination protocols for the future.

Immune prophylaxis against Pacheco's disease is available in the form of an inactivated vaccine that is administered subcutaneously or intramuscularly. However, the vaccine is only protective against certain PsHV-1 serotypes, and its administration has been associated with adverse side effects, including granuloma formation and paralysis. Treatment with antiherpetic nucleoside analogues such as acyclovir can be used for pro- and metaphylactic measures in aviaries affected by Pacheco's disease. Strict quarantine protocols together with diagnostic screenings and isolation of birds that have been exposed to PsHV-1 are the most effective control measures for parrot breeding facilities and pet stores.

Control of MD

MD is controlled worldwide by vaccination of 18-day-old embryos *in ovo* or 1-day-old chickens by subcutaneous/intramuscular injection into the neck. Vaccine practices, however, vary between countries and, for example, broilers usually remain unvaccinated in Europe whereas all chickens are vaccinated in the USA. These different vaccine regimens exist largely because of differences in the production practices of broilers, which live longer in the Americas to produce carcasses with higher body mass as preferred by the consumer. Prior to the introduction of vaccines against MD in the late 1960s and early 1970s, the disease had an economically devastating impact on the poultry industry, and mortality rates reached as high as 30–60%. All MD vaccines used today are MLV preparations, and some of them have been used for almost 40 years. The first vaccines were based on HVT isolate FC126 (used mainly in the USA) and on HPRS16att (Europe), a formerly virulent strain that was rendered nonpathogenic by serial passage in cultured cells. Shortly after the introduction of vaccination in Europe, a naturally avirulent MDV strain, CVI988, was isolated, which has formed the basis of the MDV-based vaccines that are currently in use worldwide.

It became evident early on that MD vaccination is able to reduce and delay tumor development, but does not induce sterile immunity, which leads to a situation where constant evolutionary pressure is on field viruses to adapt to, and ultimately escape, vaccination. Consistent with this hypothesis, new MDV strains have been isolated that are able to break vaccine protection provided by HVT. The appearance of new, more virulent strains led to the introduction of so-called bivalent vaccines consisting of HVT and GaHV-3 strain SB-1. The latter was isolated from chickens, is completely avirulent, and is closely related genetically and antigenically to HVT and MDV. The bivalent vaccine was able to protect against more virulent (vv) viruses, but in the early 1990s even more virulent (vv+) MDV strains began to emerge. Most recently, repeated vaccinations using various combinations of vaccines (HVT + GaHV-3, HVT + MDV, MDV alone) are employed mainly in the USA to keep MD in check.

With the threat of new, even more virulent strains breaking through the current vaccination protocols, the development of novel vaccines is a huge challenge to the scientific community. Next to the efficacy of the vaccine preparations, the production process of vaccines in primary chicken embryo cultures is a major problem. The cost of producing these vaccines is high for several reasons, most notably the maintenance of pathogen-free chicken flocks, and approaches to find alternatives have been undertaken. The availability of infectious clones of various MDV strains and of HVT holds promise for a novel generation of rationally designed and efficacious vaccines.

Herpesviruses of Horses

D J O'Callaghan, Louisiana State University Health Sciences Center, Shreveport, LA, USA
N Osterrieder, Cornell University, Ithaca, NY, USA

History

The first disease attributed to an equine herpesvirus (EHV), the agent that is now referred to as equid herpesvirus 1 (EHV-1, equine abortion virus; equine rhinopneumonitis virus), was documented at the University of Kentucky Agricultural Experiment Station in Lexington, KY. EHV-1 was first shown to be associated with spontaneous abortions in pregnant mares in 1932. In 1941, equine abortions were found to be associated with

mild respiratory disease with clinical signs similar to those associated with equine influenza virus infections. EHV-1 was also shown to be the etiological agent of epizootic respiratory disease in young horses. Based on these investigations, the disease was termed viral rhinopneumonitis, and the agent was called equine rhinopneumonitis virus. In the 1980s, however, the two disease manifestations, viral abortion and viral rhinopneumonitis, were shown to be caused by two closely related but clearly distinct viruses now classified as EHV-1 (equine abortion virus) and EHV-4 (equine rhinopneumonitis virus).

Equid herpesvirus 2 (EHV-2) was first isolated from horses in 1963. The cytopathology caused by this virus closely resembled that of cytomegalovirus infections, which were first described in 1921 in humans. EHV-2 is a ubiquitous, slow-growing virus that infects horses at a very young age (<2 years) and establishes a lifelong chronic infection such that the horse becomes a continuous shedder of the virus. To date, no major disease has been attributed to EHV-2. However, an association of EHV-2 with chronic throat infections (the 'lumpy bumpies') or recurrent eye disease has been established by some investigators, although the causal relationships have not been proved unequivocally. Also, EHV-2 may be a cofactor in EHV-1 and/or EHV-4 infections in that it is able to modulate EHV-1 and EHV-4 replication by immunosuppression, causing general malaise, or by modulation of EHV-1 gene expression through EHV-2-specific transcriptional transactivators.

Equid herpesvirus 3 (EHV-3; equine coital exanthema virus, ECE virus) was first isolated independently in 1968 in Canada, Australia, and the USA. EHV-3 is the etiological agent of equine coital exanthema, a generally mild genital infection of mares and stallions that is transmitted venereally and has been largely eradicated.

Equid herpesvirus 4 (EHV-4) is associated mainly with respiratory disease and has also been associated occasionally with equine abortions. On the other hand, EHV-1 is associated primarily with equine abortions, but frequently causes respiratory disease in young animals, highly fatal neurological disease, fulminating neonatal pneumonitis, and, very rarely, an exanthematous condition involving the external genitalia of the mare.

Equid herpesvirus 5 (EHV-5) is closely related to EHV-2 and no information on possible disease(s) caused by this virus is currently available.

Equid herpesvirus 9 (EHV-9), previously referred to as gazelle herpesvirus 1, was described very recently. It has been shown to be closely related to EHV-1 (and asinine herpesvirus 1) and exhibits a broad host range *in vivo*. While clinical signs in horses seem to be relatively mild, EHV-9 can cause lethal encephalitides in other animals, such as gazelles and goats.

Taxonomy and Classification

Eight of the nine EHVs have been classified as species in the family *Herpesviridae*. The species names are *Equid herpesvirus 1* through *Equid herpesvirus 9*, with the exception of *Equid herpesvirus 6*, which is not yet in existence as EHV-6 has not yet been fully assigned to a species. EHV-6, EHV-7, and EHV-8 are donkey herpesviruses that are also referred to as asinine herpesviruses 1, 2, and 3, respectively, and will not be discussed in detail in this article. The morphology of all six members is typical of the herpesviruses in that they are enveloped, contain an icosadeltahedral capsid, and have a proteinaceous coat, the so-called tegument, which surrounds the nucleocapsid. EHVs are composed of six distinct species: (1) EHV-1 is the major equine pathogen causing fetal abortions, respiratory illness, and neurological disease; (2) EHV-2 (and perhaps EHV-5) establish mainly asymptomatic, long-term persistent infections; (3) EHV-3 is the causative agent of mild progenital exanthema; (4) EHV-4 is a major respiratory pathogen that differs significantly from EHV-1 at the DNA level and is associated occasionally with equine abortions; and (5) EHV-9 can cause mostly subclinical encephalitides in horses, while infections of other hosts are often lethal. In the latter respect, EHV-9 possesses biological properties very akin to an alphaherpesvirus of pigs, pseudorabies virus (PRV). EHV-1, EHV-3, EHV-4, and EHV-9 are members of subfamily *Alphaherpesvirinae*, genus *Varicellovirus*. EHV-2 and EHV-5 are members of subfamily *Gammaherpesvirinae*, genus *Rhadinovirus*.

Geographic and Seasonal Distribution

EHV-1 and EHV-4 are distributed worldwide, and infections can occur year-round. Over the past 30 years in the USA, EHV-1 'abortion storms' have occurred in many areas. Major outbreaks have also been reported in Australia and England. Due to the nature of the disease manifestation, viral abortions caused by EHV-1 exhibit a seasonal cumulation in the spring on broodmare farms, whereas EHV-1 and EHV-4 infections of the upper respiratory tract (rhinopneumonitis), as well as the neurological form of EHV-1 disease, are observed mainly on race tracks and after crowding of large numbers of animals.

EHV-2 has also been isolated in many countries, including England, Switzerland, Germany, the USA, and South Africa. The existence of the closely related EHV-5 was described for England and Australia. More thorough studies, however, have led to the assumption that both EHV-2 and EHV-5 are distributed worldwide.

To date, EHV-3 has been isolated in five countries: Germany, USA, Australia, Canada, and England. EHV-9 so far has only been described in captive gazelles in Japan, although zoo animals in other parts of the world have been shown to harbor antibodies against the agent.

Host Range and Virus Propagation

Although the horse is the natural host of the EHVs, a variety of animals and tissue culture systems can be used to propagate the viruses. Regarding the major equine pathogen, EHV-1, experimental animals include Syrian hamsters and baby hamsters, chick embryos, baby mice and adult mice, and kittens. Primary tissue culture systems used to propagate EHV-1 include cells from a variety of equine tissues such as fetal lung, dermis, spleen, and kidney, as well as cells from domestic cats, dogs, hamsters, rabbits, mice, sheep, and swine. In the laboratory, permanent tissue culture systems commonly used to cultivate EHV-1 include primate HeLa, Vero, and CV-1 cells, rabbit kidney (RK) cells, mouse L–M cells, and equine NBL-6 and Edmin337 cells.

The host range for EHV-2, EHV-3, EHV-4, and EHV-5 is more restrictive than that for EHV-1. Except for RK cells and primary cat cells, EHV-2 and EHV-5 growth appears to be restricted to cells of equine origin. The host range for EHV-3 and EHV-4 is limited to cells of equine origin, although Vero cell culture-adapted EHV-4 strains have been described. EHV-9 is a notable exception of the rule of narrow host range of EHVs *in vivo*. As mentioned above, this virus was first isolated from an outbreak of fatal encephalitis in zoo gazelles and was later characterized in detail and shown to be most closely related to EHV-1. EHV-9 has a wide host range *in vivo* and *in vitro*.

Genetics

All six EHVs contain a linear, double-stranded DNA genome ranging between 140 and 184 kbp. The reported sizes of the genome are: EHV-1, 150 kbp; EHV-2, 184 kbp; EHV-3, 144 kbp; EHV-4, 145 kbp; and EHV-5, 179 kbp. The size of the EHV-9 genome has not yet been determined, but is likely to be close to that of EHV-1. The genomes of EHV-1, EHV-3, EHV-4, and probably EHV-9 exist in two isomeric forms, since the short region (S) can invert relative to the fixed orientation of the unique long region (U_L). The S region is composed of a central segment of unique sequences (U_S) bracketed by a pair of inverted sequences (IRs). In the case of the Kentucky A (KyA) tissue culture-adapted strain of EHV-1, each IR is 12.8 kbp. In contrast, the genomes of EHV-2 and EHV-5 exist as one isomer and are comprised of a large (149 kbp) central segment of unique sequences that is bracketed by a pair of direct repeat sequences. Each of the terminal direct repeat segments is 18 kbp, and the total genome size is 179–184 kbp. Other characteristics of the genomes are shown in **Table 1**.

There are varying degrees of homology at the DNA level among the six EHVs. The sequences shared by EHV-1, EHV-3, EHV-4, and EHV-9 appear to be arranged collinearly and are dispersed throughout the genome. EHV-1 and EHV-4 exhibit 55–84% identity at the DNA level and are antigenically very closely related, and antibodies can cross-neutralize. Levels of identity between EHV-1 and EHV-9 are even higher than those between EHV-1 and EHV-4. EHV-1 and EHV-2 show negligible identity, as do EHV-2 and EHV-3. EHV-1 and EHV-3 exhibit approximately 10% identity at the DNA level. Lastly, EHV-2 and EHV-5 show approximately 60% identity at both the DNA and protein levels.

The cloning of the genomes of a number of EHV-1 strains, among them the attenuated KyA and pathogenic RacL11 strains, as bacterial artificial chromosomes (BACs) has been achieved. These clones are infectious and provide a basis for rapid and efficient mutagenesis of the EHV-1 genome in prokaryotic cells. A variety of recombinant viruses that lack nonessential genes or portions of an essential gene have been generated and used in experiments to elucidate the functions of these genes in virus replication and/or pathogenesis.

Genome Structure

The entire genomes of EHV-1 strains, Ab4 and V592, EHV-4 strain NS80567, and EHV-2 strain 86/67 have been sequenced. The EHV-1 strain Ab4 genome is 150 224 bp in size, while that of EHV-4 is 145 597 bp. Both genomes contain 76 open reading frames (ORFs) potentially encoding proteins, with 4 duplicated in

Table 1 Properties of equine herpesvirus genomes

Member	*Subfamily*	*Isomers*	*S value*	*G+C content*	*Clinical manifestations*
EHV-1	Alpha	2	49–55	56%	Abortion, respiratory infection, paralysis
EHV-2	Gamma	1	61.8	57%	Chronic throat infection; perhaps recurrent eye infection
EHV-3	Alpha	2	55.4	66%	Equine coital exanthema
EHV-4	Alpha	2	ND[a]	50%	Respiratory infections
EHV-5	Gamma	1	ND	ND	Not known; possibly pneumonia
EHV-9	Alpha	2	ND	ND	Mild infections in horses; encephalitis in other animals (e.g., gazelles and goats)

[a]ND, not determined.

repeated regions in EHV-1 and -3 in EHV-4, giving a total of 80 ORFs in EHV-1 and -79 in EHV-4. The 63 ORFs in the U_L region are arranged colinearly between EHV-1 and EHV-4 and with those of herpes simplex virus (HSV) and varicella-zoster virus (VZV). Several genes mapping within IR and U_S of the S region differ in arrangement from those of other alphaherpesviruses. In addition, EHV-1 and EHV-4 contain a limited number of unique genes that are present in neither HSV-1 nor VZV and which might represent the viruses' gene repertoire involved in determining host specificity.

Each identical IR of the S region of the KyA tissue culture-adapted strain of EHV-1 is composed of 12 777 nucleotides. Six genes and the origin of DNA replication (ORI) have been mapped to IR: (1) the IR1 gene (gene 64) is an immediate-early (IE) gene encoding a spliced 6.0 kbp mRNA and a major phosphoprotein (1487 amino acid residues) with an apparent molecular mass of 203 kDa; (2) the IR2 gene is an early gene that is embedded within the IR1 gene, and its 4.4 kbp mRNA encodes a 130 kDa polypeptide (1165 amino acid residues) – the protein product of the IR2 gene represents a truncated form of the IE polypeptide; (3) the IR3 gene is a delayed-early gene encoding a 0.9 kbp mRNA that overlaps the IE promoter region on the opposite DNA strand; (4) the EHV-1 ORI maps downstream of IR3 and exhibits 60% identity to the corresponding ORI of HSV-1 and HSV-2; (5) the IR4 gene (gene 65) is a homolog of the ICP22 gene of HSV-1 and is differentially regulated to encode a 1.4 kbp early mRNA and a 1.7 kbp late mRNA; (6) the IR5 gene (gene 66) is a homolog of the US10 gene of HSV-1; and (7) the EHV-1 unique IR6 gene (gene 67) is a 'very early' gene encoding a 1.2 kbp mRNA and a 31/33 kDa phosphoprotein that has been shown to be a capsid constituent and a major determinant of virulence in some EHV-1 strains.

Additional EHV-1 genes in the S region map in the U_S segment and include homologs of the HSV-1 US2 gene, the protein kinase gene, the US9 gene, and genes that encode the glycoproteins (g) gG, gD, gI, and gE. In addition, a unique gene (EUS4 or gene 71) was mapped in U_S. This gene encodes a highly O-glycosylated protein referred to as gp2. Some size variations of gp2 were documented for EHV-1 strains KyA, Ab4, RacL11, and an EUS4 gp2 null mutant was apathogenic in a murine model of EHV-1 infection. Replacement of the truncated EUS4 gene of the apathogenic KyA strain with the EUS4 gene of the pathogenic RacL11 strain, which encodes the full size gp2 of 791 amino acid residues, resulted in a 'transfer' of pathogenic properties, indicating that gp2 is a major determinant of virulence. While gD is essential for virus replication in cultured cells, gI and gE are not, but do play a role in virulence. Restoration of the gI and gE sequences to a gI/gE deletion mutant or to vaccine strain KyA, which has an attenuated phenotype, restores virulence in the equine and murine models of infection.

Functional analyses of genes encoded in U_L have also been performed. Among the genes investigated are those encoding thymidine kinase, gB, gC, and gM, which show strong homology to their HSV-1 and VZV counterparts. Functional homology between HSV-1 and EHV-1 genes has been demonstrated for gM and gB.

The genomic sequences of EHV-2 and EHV-4 have been determined, but intensive research on gene functions has not yet been performed. Nothing is known about EHV-3 or EHV-9 gene functions.

Replication

The receptor for EHV-1 entry has not been identified, but recent studies showed that the virus utilizes a unique entry receptor, as it efficiently entered and replicated in cells that lack the entry receptors HveA, HveB, and HveC used for entry by other alphaherpesviruses, such as HSV-1, HSV-2, and PRV. As with other alphaherpesviruses, EHV-1 entry is mediated by gD.

The genes of the tissue culture-adapted KyA strain of EHV-1 are regulated at the transcriptional and translational levels in a temporal fashion, and three kinetic classes of genes designated IE, early, and late have been described (see **Table 2**). The sole IE gene (IR1) maps in both IR segments and gives rise to a spliced 6.0 kbp

Table 2 Regulatory genes of EHV-1

Gene	*Temporal class*	*Gene product*	*Function in replication*
IE (gene 64)	Immediate early	1487 aa[a]	Transactivates early genes and activates some late genes
IR4 (gene 65)	Early	293 aa	Enhances IE protein DNA-binding and binds TBP
UL5 (gene 5)	Early	470 aa	Binds the IE protein, TFIIB, and TBP
EICP0 (gene 63)	Early	419 aa	Promiscuous transactivator, which antagonizes IE protein function; binds IE protein, TFIIB, TBP
IR2	Early	1165 aa	Dominant negative regulator, which blocks IE protein binding to promoters
IR3	Early	0.9 kb RNA	Antisense to IE mRNA; possible precursor of microRNA
ETIF (gene 12)	Late	479 aa	Transactivates the IE promoter; essential for virus egress

[a]aa, amino acid residues in the primary translation product.

mRNA. Multiple IE polypeptide species have been observed, and the major IE protein (IE1, 203 kDa) is a nuclear-localized phosphoprotein that is capable of transactivating other viral genes and autoregulating its own transcription. The transactivation domain (residues 3–89), the DNA-binding domain (residues 422–597), and the nuclear localization domain (PPAPKRRV; residues 963–970) of the IE protein have been mapped. Recent studies have revealed that the IE protein harbors domains for binding general transcription factors, such as TFIIB and TATA-binding protein (TBP), and thus serves to promote the formation of pre-initiation complexes that mediate viral transcription.

Following IE polypeptide synthesis, approximately 45 early transcripts can be detected. Four of the early proteins serve as regulatory proteins and are designated IR4 (EICP22), UL5 (EICP27), EICP0 (UL63), and IR2. The IR4 protein interacts physically with the IE protein and serves to enhance the DNA binding of the IE protein to its target sequence (ATCGT) present within the promoters of EHV-1 genes characterized to date. The IR4 protein also binds to TBP and is present at viral early promoters in association with the IE protein and TBP. These interactions explain the synergistic effect on the transactivation of viral genes mediated by the IE and IR4 proteins. The EHV-1 UL5 protein exhibits limited identity to HSV-1 ICP27, and is essential for virus replication in cell culture. It acts synergistically with either the IE protein or the EICP0 early regulatory protein to activate expression of both early and late viral gene expression. This early regulatory protein also interacts physically with both the IE protein and TBP, and serves to enhance formation of transcriptional complexes on viral promoters. The third early regulatory protein is EICP0, which is a powerful and promiscuous transactivator that can independently activate expression of viral genes of all three temporal classes. Ironically, EICP0 cannot activate its own promoter, possibly due to a 28 bp negative regulatory element that maps at nucleotides (nt) −204 to −177 within the EICP0 promoter. The EICP0 protein binds to the IE protein and to cellular TFIIB and TBP, but is not a DNA-binding protein. The EICP0 and IE proteins have an antagonistic relationship that may result from their physical interaction in the nucleus and/or from competition for binding to TFIIB and TBP. Both viral proteins bind to the same domain in TFIIB. Deletion of the EICP0 gene greatly impairs virus replication and severely retards late gene expression, suggesting that this regulatory protein is important in the switch from early to late transcription. The fourth early regulatory protein is the IR2 protein, which is a truncated form of the IE protein lacking its essential transactivation and serine-rich domains. The IR2 protein serves a negative regulatory role as it downregulates viral gene expression by acting as a dominant negative protein that blocks IE protein binding to viral promoters and/or by squelching the limited supply of TFIIB and TBP. In addition to these four early auxiliary regulatory proteins, the EHV-1 unique IR3 gene contributes a regulatory role as it encodes a small transcript that is antisense to a portion of the IE transcript. In transient transfection assays, the IR3 transcript downregulates IE gene expression and is only minimally expressed as a protein. Initial studies suggest that the IR3 transcript is processed to a microRNA, and this indicates that the IR3 gene may use novel mechanisms to downregulate IE gene expression at late times of infection.

Early gene expression is followed by viral DNA replication and the production of approximately 29 late transcripts has been detected. Although these transcripts have been positioned on the viral genome, only a small number of protein products have been identified and characterized (see above).

Viral DNA replication initiates at approximately 4 h post infection and requires the virus-encoded DNA polymerase. DNA replication is thought to occur by the rolling circle mechanism whereby long concatemers of the viral genome are generated, cleaved, and then packaged into the maturing virions. The UL15 homolog of HSV-1, one of the two spliced EHV-1 genes known to date, appears to be essentially involved in the generation of unit length genomes and their packaging into mature capsids. Sequences at the L terminus of the EHV-1 genome are composed of direct repeats (DR1 = 18 bp and DR4 = 16 bp) as well as unique sequences (Uc = 60 bp), while sequences at the terminus of the S region contain a 54 bp region designated Ub. Thus, the sequence arrangement at the concatameric junction following replication of the EHV-1 genome is Ub-DR1-Uc-DR4, which represents a functional cleavage/packaging signal, similar, but not identical, to that of HSV-1.

The start of viral DNA synthesis initiates late gene expression and the synthesis of the late regulatory protein EHV transinducing factor (ETIF), a counterpart to the alpha-transinducing factor of HSV-1. This 60 kDa protein is multifunctional and plays at least three roles in EHV-1 replication. First, ETIF is present in several molecular sizes in the tegument and contributes to overall virion structure. Second, after virus entry and uncoating, ETIF serves to transactivate the IE promoter by binding to cellular factors that mediate its association with the TAATGARATT sequence at nt−630 to −620 in the IE promoter. This transactivation function to initiate viral gene programming is important but not essential, as EHV-1 DNA is infectious and virus progeny are produced in cells transfected with plasmids carrying the EHV-1 genome. The activation of a viral promoter by ETIF is specific for the IE promoter as ETIF has not been shown

to transactivate any early or late promoter tested to date. Recent experiments with an ETIF-deleted virus and an ETIF-complementing cell line revealed a third function for ETIF, and one that is essential for virus replication. Ultrastructural studies of cells infected with ETIF-deleted virus showed a marked defect in secondary envelopment of viral nucleocapsids at cytoplasmic membranes, such that few enveloped virions are produced. Thus, this transactivator protein also plays a key role in secondary envelopment.

Three different EHV-1 capsid species have been identified and probably correspond to the forms found in HSV-1, which are designated type A, B, and C capsids. The EHV-1 capsid species were designated: (1) L capsids, which appear to be empty; (2) I capsids which possess an electron-lucent, immature core structure in the shape of a cross; and (3) H capsids, which contain an electron-dense, mature core. All three capsids appear at approximately 6 h post infection. I capsids are believed to be a major precursor in the formation of mature capsids. The major capsid protein has an apparent size of 148 kDa, and other structural proteins have also been identified. As reported for other herpesviruses, EHV-1 maturation occurs by interaction of mature nucleocapsids with the inner portion of the nuclear membrane resulting in the formation of enveloped particles. As noted above, recent studies with ETIF-deleted EHV-1 support the model of the sequential envelopment/de-envelopment/re-envelopment pathway for egress of EHV-1 from the cell.

Infectious EHV-1 particles contain an envelope whose protein component is composed mainly of glycoproteins. To date, 12 EHV-1 glycoproteins have been identified and an association of gB, gC, gD, gG, gH, gL, gM, gp2, and the tegument protein VP13/14 with purified virions has been demonstrated. The glycoproteins have been shown in other alphaherpesviruses to be involved in virus binding, virus penetration, and cell-to-cell spread of infection. In the case of EHV-1, these functions were confirmed for gB, gD, gM, and gp2, and the latter two proteins were shown to be nonessential for virus growth. In contrast, gB- or gD-deleted EHV-1 mutants are unable to grow in cell culture. The defect in replication of gB- and gD-negative viruses is caused by an entry defect and the inability to spread from infected to uninfected cells. Detailed functional analyses for the other glycoproteins have not been performed, but are now facilitated by the use of engineered virus mutants produced by targeted gene deletion or disruption using infectious DNA clones of the virus. Even less is known for proteins that make up the third component of the mature virion, the tegument. Only one protein that is related to an HSV-1 tegument protein has been analyzed in detail. As discussed above, recent studies have shown that ETIF is essential for virus maturation and egress.

Defective Interfering Particles and Persistent Infection

EHV-1, EHV-2, and EHV-5 have been shown to mediate persistent infection. In the case of EHV-1, defective interfering particles (DIPs) have been shown to initiate and maintain this outcome. EHV-1 DIPs have been generated *in vivo* in the Syrian hamster model, and therefore may be relevant during EHV-1 infection of the natural host. DIPs are replication defective and require standard EHV-1 as a helper. The overwhelming majority of EHV-1 DNA sequences are absent from DIPs. The packaged DIP DNA molecule is a concatamer of EHV-1 sequences ranging in size from 5.9 to 7.3 kbp, repeated head to tail until it is approximately the size of the standard viral genome. DNA sequencing has revealed that sequences from three regions of the EHV-1 genome are conserved in DIPs: (1) the L terminus, including genes UL3, UL4 and the 3′ portion of UL5; (2) the junction between U_L and the internal IR; and (3) the central portion of IR, including ORI and the 5′ portion of gene IR4. The UL3 and UL4 genes in DIP genomes are 100% identical to those of infectious virus, but their functions in virus replication remain to be elucidated. The DIP genome also contains a perfectly conserved cleavage/packaging signal. The sequences at the L terminus and IR are joined by a homologous recombination event mediated by a conserved 8 bp sequence present at both the L terminus and within the IR4 gene to generate a unique ORF present only in DIPs. This ORF is expressed as a 31 kDa 'hybrid protein' comprising the N-terminal 196 amino acid residues of the IR4 protein (the homolog of HSV-1 ICP22) linked in frame to the C-terminal 68 amino acids of the UL5 protein (the homolog of HSV-1 ICP27). Unique to EHV-1 persistently infected cells (not detected in EHV-1 cytolytic infection) is a 2.2 kbp transcript that maps to the U_L/IR junction and is antisense to the IE mRNA. Interestingly, this transcript exhibits significant homology to the latency associated transcripts of HSV-1, which appear to be associated with HSV-1 reactivation rather than establishment of latency.

Lastly, in EHV-1 persistently infected cells, transcription of certain viral genes appears delayed compared with cytolytically infected cells. Recent findings reveal that expression of the 31 kDa IR4/UL5 hybrid protein downregulates expression of specific EHV-1 promoters. Moreover, altered forms of the EHV-1 IE polypeptides have been observed only in persistently infected cells. Taken together, these studies indicate that altered or aberrant viral regulatory mechanisms may be involved in establishing or maintaining persistent infection. Ongoing studies with recombinant forms of the DIP genome indicate that the hybrid gene is not essential for DIP replication, but is important in the ability of EHV-1 DIPs to establish persistent infection.

Evolution

The six EHVs are biologically distinct. Initial DNA sequence analyses have revealed that genes identified to date are collinearly arranged in the genomes of EHV-1, EHV-3, and EHV-4, all of which possess a two-isomer genomic structure. Evolutionary relationships have become more apparent now that EHV-1, EHV-2, and EHV-4 have been sequenced and data on EHV-5 sequences and genomic organization are available. It is clear that EHV-1, EHV-4, and EHV-9 are closely related and may have arisen from the same ancestor. The same is true for EHV-2 and EHV-5. However, it is not possible to determine precise details of the EHV ancestor since additional sequence data (especially on EHV-3) are not available.

Serological Relationship and Variability

The six EHVs share certain antigens, but are antigenically distinct. EHV-1, EHV-4, and EHV-9 are closely related antigenically, such that cross-neutralizing antibodies are generated. Also, EHV-2 and EHV-5 are closely related. Almost no data are available on the relationship of EHV-3 to other members of the EHVs. However, all of the EHVs are believed to share complement-fixing antigens.

Epidemiology

Rhinopneumonitis caused by EHV-1 and EHV-4 is spread by direct or indirect contact (ingestion and inhalation). The viruses are most commonly shed in nasal droplets for up to 3 weeks after initial infection and are present in large amounts in aborted fetuses and the placenta.

EHV-1 infection can also result in spontaneous abortions in pregnant mares. Horses are most susceptible to EHV-1 infection between the eighth and eleventh months of pregnancy. The peak incidence is in the ninth and tenth months, at which time approximately 70% of abortions occur.

EHV-2 and EHV-5 have been isolated from the respiratory tract, kidneys, spleen, testicles, genital tract, and rectum. Once infected, the horse is a lifelong carrier and excreter of the virus. The exact modes of spread of EHV-2 and EHV-5 are unknown.

EHV-3 causes a mild coital exanthema that is spread by genital contact and – rarely – the respiratory route. An EHV-3 infection is usually cleared after 14 days and is not associated with equine abortions.

Transmission and Tissue Tropism

EHV-1, EHV-4, and EHV-9 are spread mainly by nasal discharge. EHV-2 and EHV-5 establish a chronic infection and may be spread by the respiratory route. EHV-3 is spread by genital contact. EHV-1 has a wide host range *in vitro* as described above, while EHV-4 is more limited. EHV-2, EHV-3, and EHV-5 are restricted mainly to cells of equine origin.

Pathogenicity

EHV-1 and EHV-4 cause rhinopneumonitis, which is often transient and mild but can be complicated by secondary bacterial infections and become more severe and long lasting. EHV-1 is also associated with spontaneous abortions as well as neurological disease. Although EHV-1 and EHV-4 respiratory infections are clinically indistinguishable, their pathogenesis is quite different. EHV-1 infection results in a systemic viremia that can lead to abortion and/or neurological disease. Alternatively, EHV-4 infection usually remains restricted to tissues of the upper respiratory tract. EHV-2 and also EHV-5 infections are acquired horizontally early in life usually by inhalation. EHV-2 and EHV-5 establish a chronic lifelong infection in peripheral blood mononuclear cells. EHV-3 causes an acute coital exanthema in both the mare and the stallion, and infection remains localized to the genitalia.

Clinical Features of Infection

EHV-1 and EHV-4 cause outbreaks of upper respiratory disease ('common cold') in young horses (mainly EHV-4 in adult horses) with no previous exposure to the viruses. Infection is characterized by a short incubation time (<1 day) followed by fever (39–41 °C), which can last between 1 and 4 days, sometimes with a second spike approximately 1 week after the primary pyrexia, and animals suffer from serous nasal discharge and congestion of the nasal mucosa and conjuctiva. Less frequently, one can detect a transitory period of anorexia, enlargement of the submandibular lymph nodes, and edematous swelling of the lower parts of the body and the extremities. An initial leukopenia is followed by leukocytosis before the temperature falls. Recovery is usually uneventful and occurs within 1 week. Older horses show few or no clinical signs, although increased sensitivity is seen in stressed horses. Death is not uncommon from natural acquired infection resulting in neurological disease.

Equine abortions induced by EHV-1 usually occur late in gestation (8–11 months). The foals are usually born dead, but, if alive, often succumb to pneumonia within the first few days. Clinical signs of neurological disease caused by EHV-1 are highly variable and include head pressing, ataxia, and paralysis with complete recumbence.

Both EHV-1 and EHV-4 have been isolated from the central nervous system (CNS) of infected horses, but EHV-1 is by far the leading cause of EHV-induced neurological disease. The virus strains do not invade the extravascular nervous tissue and are not neurotropic *per se*. Rather, the virus spreads from the respiratory tract to the CNS via infected leukocytes and infects endothelial cells of the blood vessels supplying the spinal cord. While the neurological form of the disease is usually lethal, some horses have fully recovered from it with no permanent neurological sequelae.

The roles of EHV-2 and EHV-5 in clinical disease are virtually unknown. However, the viruses have been associated occasionally with chronic throat infections and have been isolated from the respiratory tract of horses with respiratory disease.

An incubation period as long as 10 days can be observed following natural infection with EHV-3. The initial lesions are small (1–2 mm), raised, reddened papules. The lesions then progress rapidly to the pustular form, and there is a general reddening of the vaginal mucosa in the mare. The number of lesions increases in the first few days, and by day six, many of the lesions form ulcers up to 20 mm in diameter and 5 mm deep. Lesions can also be seen on the vulva, perineal skin, as well as on the penis and prepuce of the stallion. The disease is usually mild, with temperature, pulse, appetite, and respiration remaining close to normal. The severity of the disease can be increased by secondary bacterial infections; however, uneventful cases are usually cleared within 2 weeks. Lastly, EHV-3 is not abortigenic and does not lead to infertility.

Infections with EHV-9 lead to encephalitis in horses, but, more severely, in other species as well. Among the susceptible hosts are gazelles and goats, and also carnivores such as dogs and cats.

Pathology and Histopathology

Respiratory disease caused by EHV-1 and EHV-4 results in inflammation, congestion, and sometimes necrosis of the tissues of the upper respiratory tract. Extensive swelling of the nasal mucosa may occur and, in later stages, the lungs may become involved. One can find typical herpesvirus inclusion bodies in the nuclei of the respiratory epithelium. The respiratory infection can become more serious if followed by a secondary bacterial infection, which may lead to bacterial pneumonia.

Fetuses that are aborted as a consequence of EHV-1 infection present with widespread hemorrhages and edema, as well as a yellowish discoloration of the fetal conjunctiva and splenomegaly – if virus is transmitted from mother to animal. However, abortions without infection of the fetus also occur, and the pathogenesis in the uterine vasculature largely resembles that of the vasculitis observed in the neurological form of the disease. The classic histopathology includes the presence of eosinophilic intranuclear inclusion bodies in various organs of the aborted fetuses. Gross pathological and histopathological alterations are sometimes not as obvious, and only sensitive methods (virus isolation or PCR) are able to confirm the EHV-1 abortion. Classically, features associated with EHV-1-induced abortions differ in those fetuses aborted during the first 6 months of gestation as compared with those aborted after 6 months. Those before 6 months present with widespread cell necrosis and inclusion bodies in the liver and lung. Those after 6 months exhibit jaundice, subcutaneous edema, excessive pleural fluid, pulmonary edema, splenomegaly, and necrosis of the liver.

In experimental EHV-1 infections, a severe hepatitis is observed following intraperitoneal infection of the Syrian hamster, and a model of respiratory infection is also available in the hamster. Intranasal infection of mice with EHV-1 results in respiratory disease and subsequent cell-associated viremia, thus serving as a model that somewhat mimics the disease in equines. The murine model of EHV-1 infection is widely used in virulence and immunogenicity studies. Recent studies with a library of EHV-1 mutants reveal the importance of full-size gp2 in respiratory disease. DNA-array analyses of lung tissues confirmed earlier findings from RNase protection assays and showed that the massive influx of inflammatory cells into the lung is preceded by 2–13-fold increases in >30 inflammatory genes. Expression of these genes increased as early as 8–12 h post infection, and they encode major cytokines and chemokines, including interleukin-1β (IL-1β), IL-6, tumor necrosis factor alpha, macrophage inflammatory protein 1α (MIP-1α), MIP-1β, and MIP-2. Future investigations should give insight into specific domains of gp2 that activate this constellation of inflammatory genes and the signal transduction pathways that are involved.

EHV-2 (and also EHV-5) infection becomes widespread throughout the body, and the viruses have been isolated from a variety of tissues. The infected animal becomes a lifelong carrier, and the viruses remain highly cell associated.

Tissues affected following an infection with EHV-3 include the vaginal and vestibular mucosa, penis, prepuce, and the skin of the perineal region. One of the characteristics of an infection with EHV-3 is the sloughing of the surface epithelial cells. On occasion, the skin of the lips and mucus membranes of the respiratory tract may become involved, but the exanthema is usually mild.

Immune Response

Neutralizing antibodies are detected in the serum soon after an EHV-1 or EHV-4 infection. The antibodies can first be

detected from a week following infection and are most abundant after several weeks. However, the immunity is short lived, in that horses can be re-infected and exhibit respiratory symptoms just 3 months after the initial infection. Multiple exposures to either EHV-1 or EHV-4 will result in the development of neutralizing, cross-reactive antibodies. However, cell-mediated immune responses are likely to be primarily responsible for induction of a sustainable immunity.

Immunity to EHV-2, EHV-3, and EHV-5 is poorly understood. However, virtually all horses have antibodies to EHV-2 and EHV-5, confirming the general apathogenicity of these viruses.

Prevention and Control

A number of vaccine approaches are followed to combat EHV-1 infections; among them are modified live vaccines (e.g., Rhinomune and Prevaccinol), inactivated vaccines (e.g., Pneumabort K and Prestige), inactivated combination vaccines, which – among others – also contain EHV-4 (e.g., Innovator, Resequin, and Duvaxyn1,4), and subunit vaccines also covering both viruses (e.g., Cavalon IR). Unfortunately, many EHV vaccines cause undesirable side effects in the form of massive local reactions while not affording acceptable levels of protection, especially when inactivated combination vaccines are considered. All vaccines are given repeatedly to pregnant mares usually in the third, fifth, seventh, and ninth months of pregnancy, since, to ensure protection, a good level of population immunity is imperative. To protect against viral rhinopneumonitis outbreaks, the vaccine is usually given to all horses every 3–6 months. There is considerable ongoing discussion as to proper vaccination against the neurological disease, which has become more prevalent during past years. Recent studies seem to suggest that modified live virus vaccines are superior, especially to multivalent inactivated vaccines, with respect to duration of fever, virus excretion from the nasal mucosa, and development of neurological symptoms. These studies, however, need to be corroborated by further comparative studies and/or larger numbers of animals in experimental groups.

Clinical management often involves the use of antibiotics to prevent severe bacterial complications following the viral rhinopneumonitis. Control of EHV-1 and EHV-4 infections involves isolation and quarantine of infected horses (for at least 3 weeks) and sound hygiene for prevention of viral infection, since the viruses are highly contagious. Quarantine procedures are required more often with EHV-1 infections, since EHV-1 can lead to more serious diseases of the CNS. Since many of the EHV vaccines provide unacceptable levels of protection, the first step in the prevention and control of EHV-1 and EHV-4 infections involves specific management practices and adequate day-to-day care of the animals. The viruses can be spread easily in contaminated feed and water. In addition, minimizing stress and close contact of large groups of horses can prevent the spread of disease.

Future Perspectives

Considerable progress in unraveling the nucleotide sequences of EHV-1, EHV-2, EHV-4, and EHV-5 has been made during recent years, and EHV-1, EHV-2, and EHV-4 have been entirely sequenced. With this information in hand, it will be possible to pursue studies on gene expression and on those proteins that are involved in virulence of EHV. These studies will in turn open the possibility for a rational design of anti-EHV vaccines, especially against the most important pathogens, EHV-1 and EHV-4. These goals may be achieved by the use of viral deletion mutants that carry targeted gene deletions, which is greatly facilitated by the advent of a number of infectious DNA clones during the past years. Using novel molecular approaches, a better understanding of EHV biology will be possible and in the future will open new perspectives in the understanding of diseases caused by EHVs.

Herpesviruses: Discovery

B Ehlers, Robert Koch-Institut, Berlin, Germany

History of Herpesvirus Discovery

Diseases caused by herpesviruses have been known since ancient times, but it was not until the beginning of the twentieth century that the viruses causing these diseases were detected. Human alphaherpesviruses (members of subfamily *Alphaherpesvirinae*) such as herpes simplex virus (HSV) and varicella-zoster virus (VZV) were the first to be propagated in cell culture and visualized by electron microscopy. Later, betaherpesviruses (members of subfamily *Betaherpesvirinae*) such as human cytomegalovirus (HCMV) and gammaherpesviruses (members of subfamily *Gammaherpesvirinae*) such as Epstein–Barr virus (EBV) were discovered and studied in detail. EBV was the first herpesvirus whose genome was cloned in bacteria and completely sequenced. In the middle of the last decade of the twentieth century, the complete genome sequences of roughly 40 herpesvirus species had accumulated in public databases. These human and animal herpesviruses had previously all been cultured, and their physical, morphological, and antigenic characteristics had been studied. This was a cumbersome process and usually carried out only with viruses causing important diseases.

For the primary characterization of uncultured viruses, alternative, more-straightforward approaches were needed. Immunological cross-reaction and nucleic acid hybridization were the first tools used for the detection of unknown viruses closely related to known species. Later, nonspecific amplification methods were developed that detected nucleic acids of unknown DNA and RNA viruses directly in clinical samples. Expression libraries of genomic DNA or cDNA were screened immunologically with sera from patients infected with the putative etiologic agent. Then subtractive approaches were developed to isolate sequences in one DNA sample that were absent from another, and one of these, representational difference analysis, led to the discovery of human herpesvirus 8 (HHV-8; also known as Kaposi's sarcoma-associated herpesvirus). Although very powerful, these nonspecific amplification methods are most appropriate for the detection of agents in defined samples from diseased individuals where a microbiologic etiology is strongly indicated. They are too laborious for broad screening of large sample numbers.

In 1988, Mack and Sninsky were the first to describe a polymerase chain reaction (PCR)-based method for the identification of uncharacterized viruses related to known virus groups, using degenerate primers (a pool of all the possible combinations of sequences that could code for a given amino acid sequence). Later, and following the same principles, a PCR method for the universal detection of herpesvirus genomes was published by VanDevanter and co-workers. Despite its restriction to herpesviruses, this method was a hallmark because it had the potential to detect virtually all vertebrate herpesviruses by a straightforward approach. Since then, nearly all novel herpesviruses have been discovered with the help of this method (in its original version or with modifications), and many were found in individuals lacking a recognized disease history.

Panherpes PCR with Degenerate Primers

The method is based on the fact that herpesvirus genomes contain highly conserved genes, which are present in all because they code for proteins essential for viral growth. One of the most conserved is the herpesvirus DNA polymerase (DPOL) gene. Investigators aligned the DPOL genes of all herpesviruses for which sequence data were available, in order to identify short blocks of greatest amino acid identity that encode domains essential for DPOL function. This procedure allowed the design of

five degenerate primers that were used in a nested PCR – three primers in the first round and two primers in the second round (**Figure 1**). The region amplified in between the primers displayed a lower degree of conservation. This allowed investigators to assess (1) whether the detected herpesvirus was known or novel, and (2) to which herpesvirus subfamily the novel species could be assigned. In some cases, even a tentative assignment to a virus genus was possible.

The primers are degenerate in their 3′ part and nondegenerate in their 5′ part. As an example, the sense primer (TGV) of the second round is shown in **Figure 2**. The degenerate 3′ part enables it to bind universally to the DPOL gene of higher vertebrate herpesviruses in the first PCR cycle. The nondegeneracy of the 5′ part ensures amplification efficiency in subsequent cycles. The product amplified in the second round has a length of ~210–235 bp, depending on the virus. Only HCMV and chimpanzee cytomegalovirus, as well as some herpesviruses of insectivoral shrews, give rise to significantly larger amplification products of >300 bp (**Figure 3**).

Several variations of the original method were subsequently published, using (1) deoxyinosine-substituted primers, (2) a nondegenerate consensus sequence as 5′-part of the primer (also called consensus-degenerate hybrid oligonucleotide primers (CODEHOPs)), or (3) other conserved primer binding sites in the DPOL gene. Also, targeting of other highly conserved herpesvirus genes such as the glycoprotein B (gB) gene or the terminase gene was attempted. Degenerate consensus primers were also used to amplify a larger number of conserved genes ($n = 8$) of a novel porcine herpesvirus (porcine lymphotropic herpesvirus 3, PLHV-3). These sequence 'islands' were then connected with the help of long-distance PCR to yield a contiguous sequence of ~100 kbp (accession AY170316). This is the longest part of a herpesvirus genome of unknown sequence ever determined directly from primary virus-positive organ material solely through PCR (i.e., without virus cultivation).

How Many Herpesviruses Have Been Discovered?

Since the publication of these methods, the number of novel herpesviruses discovered has risen very fast. Prior to writing this article, more than 200 potential herpesvirus species had been detected, belonging to more than 20 mammalian orders (**Table 1**). These are many more than currently accepted by the International Committee on Taxonomy of Viruses (ICTV), which lists some 120 herpesvirus species (VIIIth Report). Sequences of more than 160 herpesviruses are available under the taxonomy browser of the NCBI, most detected by DPOL consensus primers. In addition, sequences indicating the existence of more than 100 additional herpesvirus species, not yet available in public databases, await publication. By combining all the data currently available, a total of approximately 300 detected

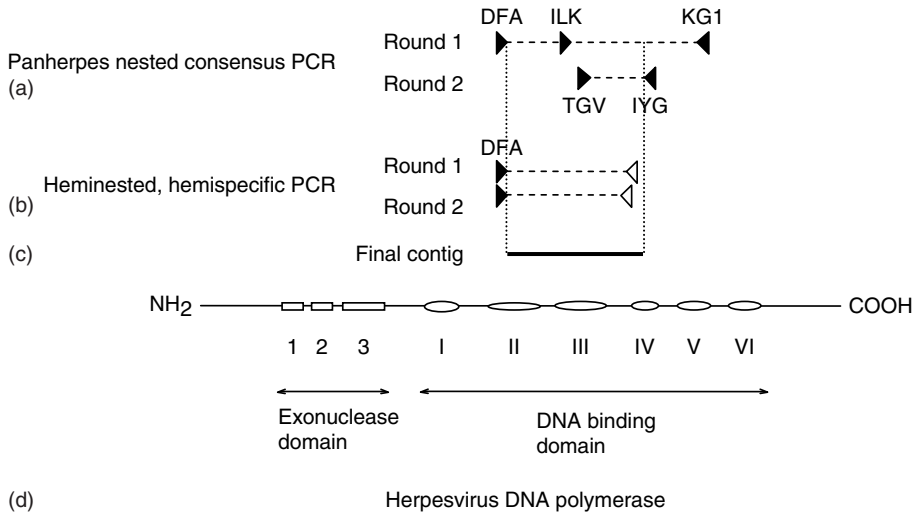

Figure 1 Panherpes consensus PCR with degenerate primers. Schematic diagram of the PCR strategy. (a) Initially, panherpes-nested PCR with degenerate and deoxyinosine-substituted primers (black triangles) is performed for amplification of novel herpesvirus DPOL sequences. In the first round, the sense primers DFA and ILK are combined with the antisense primer KG1. In the second round, the sense primer TGV and the antisense primer IYG are used. (b) Subsequent heminested PCR with the degenerate sense primer DFA and two virus-specific antisense primers (open triangles). The exact position of the virus-specific antisense primers is slightly different for each individual DPOL sequence but is always located between primers TGV and IYG. (c) The final contig is represented by the solid line (450–480 bp, without primer-binding sites). (d) The DPOL gene is shown schematically. Highly conserved, functionally important regions are represented by boxes and ovals, respectively, and numbered.

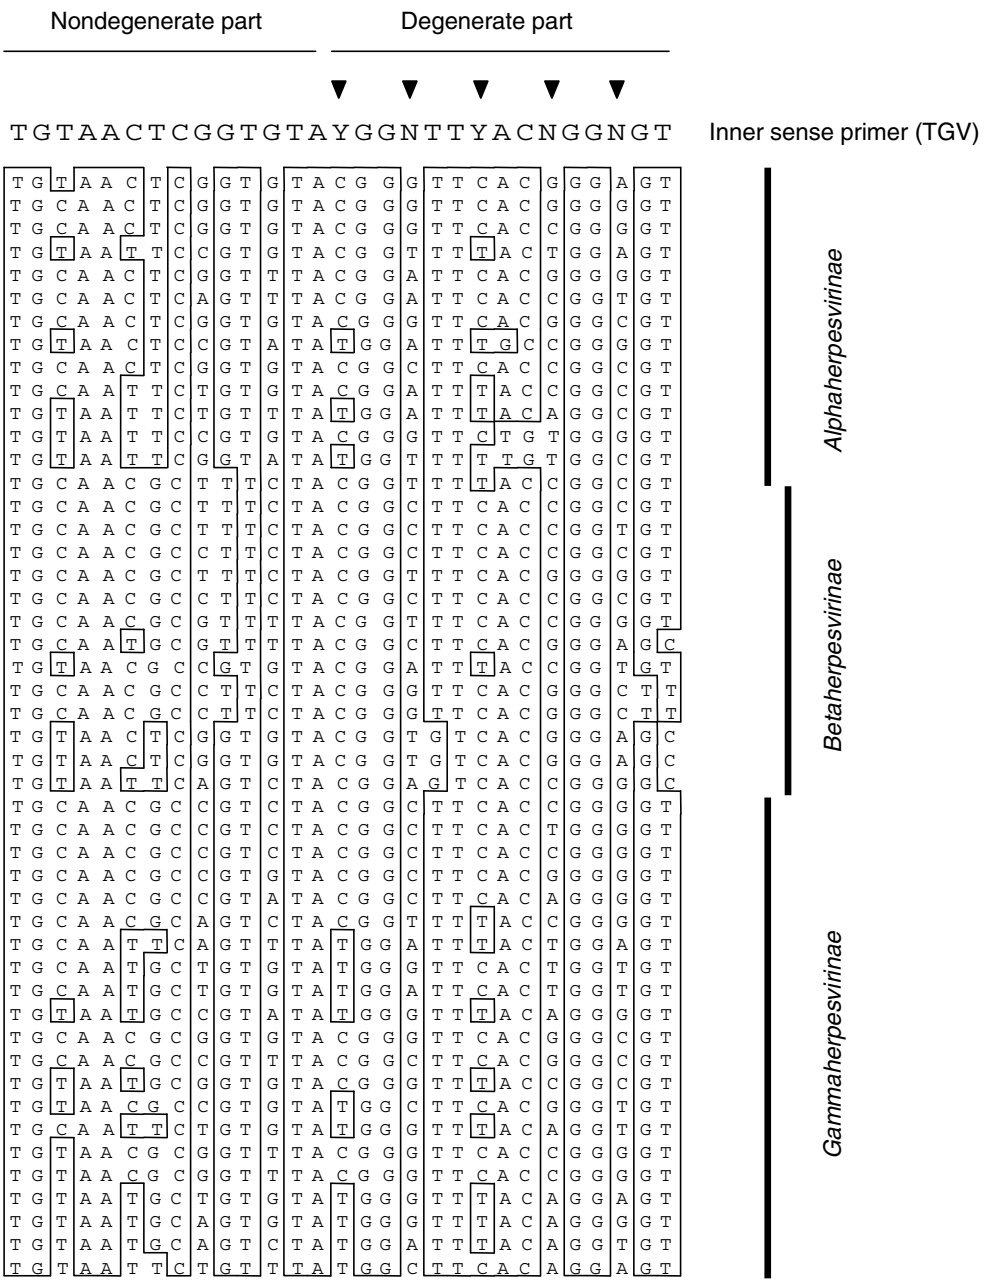

Figure 2 Primer-binding site of the inner sense primer of the panherpes consensus PCR. An alignment is shown of the binding regions of the inner sense primer (TGV) in alpha-, beta-, and gammaherpesviruses. Above, the TGV primer is shown, originally designed by VanDevanter and co-workers. In its degenerate part, the primer does not match perfectly the sequences of some alpha- and betaherpesviruses. Nonetheless, the DPOL sequences of these viruses are amplifiable by panherpes consensus PCR.

herpesvirus species can be presumed, the vast majority infecting a broad spectrum of mammalian hosts such as primates, elephants, ungulates, rodents, dolphins, carnivores, insectivores, manatees, and bats. Herpesviruses have also been found by consensus primer PCR in non-mammalian hosts such as reptiles, birds, and fishes (**Table 1**). Even a mollusk (Pacific oyster) has been shown to host a herpesvirus. The fact that herpesviruses are not yet known for many animal hosts is most probably due to lack of investigation.

Most of the novel viruses from which newly detected sequences originate have never been isolated or propagated in tissue culture, and a large number probably never will. On the other hand, some of the herpesviruses that were cultured in the premolecular era and classified formally have never been characterized genetically and are

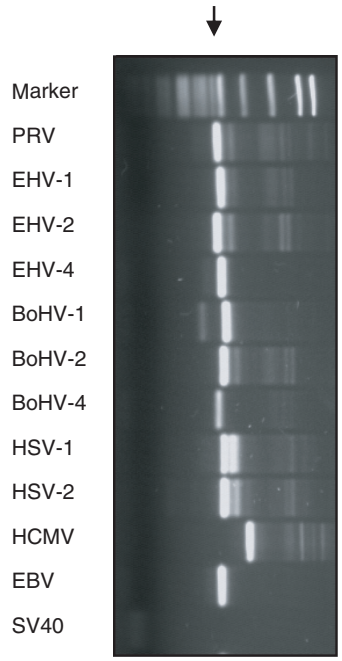

Figure 3 Amplified fragments obtained by panherpes consensus PCR. Partial DPOL sequences were amplified from various herpesviruses: porcine (PRV), equine (EHV-1, EHV-2, and EHV-4), bovine (BoHV-1, BoHV-2, and BoHV-4), and human (HSV-1, HSV-2, HCMV, and EBV). The arrow marks the amplified fragments, most of which have a length of ~230 bp. Note the considerably larger band (310 bp) obtained by amplification of HCMV. DNA of the polyomavirus SV40 was used as a negative control.

no longer available. Therefore, some of the new PCR sequences may represent rediscovery of a herpesvirus whose existence was reported many years earlier.

The mammalian herpesviruses may all be assigned to one of the subfamilies *Alpha-*, *Beta-*, and *Gammaherpesvirinae*, and many mammals host one or more herpesviruses from each subfamily. Humans, for example, are infected by three alpha-, three beta-, and two gammaherpesviruses (HSV-1, HSV-2, VZV, HCMV, human herpesviruses 6 and 7, EBV, and HHV-8, respectively). Other host species apparently lack herpesviruses of a certain subfamily (**Table 1**). For example, in dogs, birds, and reptiles, only alphaherpesviruses have been found, but no beta- or gammaherpesviruses. In Equidae and Bovidae, alpha- and gammaherpesviruses have been found, but no betaherpesviruses. These 'blind spots' may be due to evolutionary developments; that is, some herpesvirus species may have existed but died out later, or have never developed in certain host lineages. On the other hand, certain herpesvirus species may be low in prevalence, replicate to low titers and reside in narrow ecological niches with few or no pathological consequences, which would make their detection difficult. In addition, panherpes consensus PCR may be inefficient in detecting certain sequences because of insufficient primer binding. The latter could be due to the fact that the DPOL consensus primers were originally designed on the basis of a limited set of complete DPOL genes. This selection of genes may have been too small to ensure that the primers do not encounter mismatches in their binding sites within certain herpesvirus genomes. For example, betaherpesviruses are more heterogeneous in their DPOL sequences than alpha- or gammaherpesviruses, and some currently available sequences reveal mismatches with the consensus primers. Therefore, the sensitivity of the PCR may be suboptimal for some betaherpesviruses. Inclusion of novel DPOL sequences as a basis for redesign of current panherpes PCR systems may improve their universality and enable the discovery of additional herpesviruses that otherwise might remain undetected.

It is a common phenomenon that hosts are infected with more than one herpesvirus. The detection of all herpesviruses present in such samples is a technical challenge. Panherpes consensus PCR usually favors the amplification of one viral sequence and concurrently neglects others. This is a result of different binding efficiencies of the degenerate primers to each viral genome and the genome copy number of each virus in the sample. One solution for this problem is to design degenerate primers with a more limited spectrum of detection. These can be derived from less-conserved sites in the DPOL gene or from other, less well-conserved genes. For example, the gB gene allows the derivation of subfamily-specific or genus-specific degenerate primers only. Thus, samples which are positive for gammaherpesviruses in the panherpes DPOL PCR can be additionally screened with betaherpesvirus-specific gB primers. Such detection strategies often reveal the presence of several herpesviruses in a given sample, and this has resulted in the discovery of previously unknown herpesvirus sequences in primates and perissodactyls (odd-toed ungulates such as horse, zebra, and donkey).

Tentative Classification of Novel Herpesvirus Sequences

According to ICTV, "related herpesviruses are classified as distinct species if (a) their nucleotide sequences differ in a readily assayable and distinctive manner across the entire genome and (b) they occupy different ecological niches by virtue of their distinct epidemiology and pathogenesis or their distinct natural hosts." These requirements are only very rudimentarily fulfilled after determination of a short partial DPOL sequence from a primary sample. However, it is possible to make an initial attempt tentatively to classify the new virus entity.

It is a general rule (with some important exceptions such as herpes B virus and pseudorabies virus (PRV)) that

Table 1 Herpesviruses amplified through consensus PCR and their hosts

	Perciformes	Tilapia larvae	1			

herpesviruses are specific for their hosts. Thus, related, albeit distinct, herpesvirus sequences from different hosts can be assigned as originating from distinct herpesvirus species. In line with this, analysis of the novel sequence is primarily performed by pairwise and multiple alignment with sequences of known and classified viruses.

When a more detailed view is desired, phylogenetic tree construction is performed. The most reliable phylogenetic trees are constructed with the proteins encoded by sets of conserved herpesvirus genes. This requires the determination of the complete genome sequence of the novel species in question (or at least a considerable part of it). For noncultured herpesviruses and with the amplification techniques presently at hand, this is either impossible or at least very time consuming. As a compromise, the short DPOL sequence, amplified with panherpes consensus PCR, is extended by many investigators in an upstream direction. The final contiguous sequence extends from the outer degenerate sense primer to the inner degenerate antisense primer (450 to >700 bp; the length depends on the virus) (**Figure 1**).

This DPOL region is sufficient for a first attempt to construct a phylogenetic tree in order to (1) identify the closest relatives among the herpesviruses already sequenced, and (2) classify tentatively the virus from which the novel sequence originated. As an example, a phylogenetic tree of all HHV-8-related gammaherpesviruses, for which sequences >450 bp are available, is shown in **Figure 4**. The tree contains 63 distinct sequences and reveals that a large group of Old World primate rhadinoviruses (RHVs) exists, and that this can be divided into two subgroups. One subgroup contains a human RHV (HHV-8), but a human member of the other subgroup has not been identified. Furthermore,

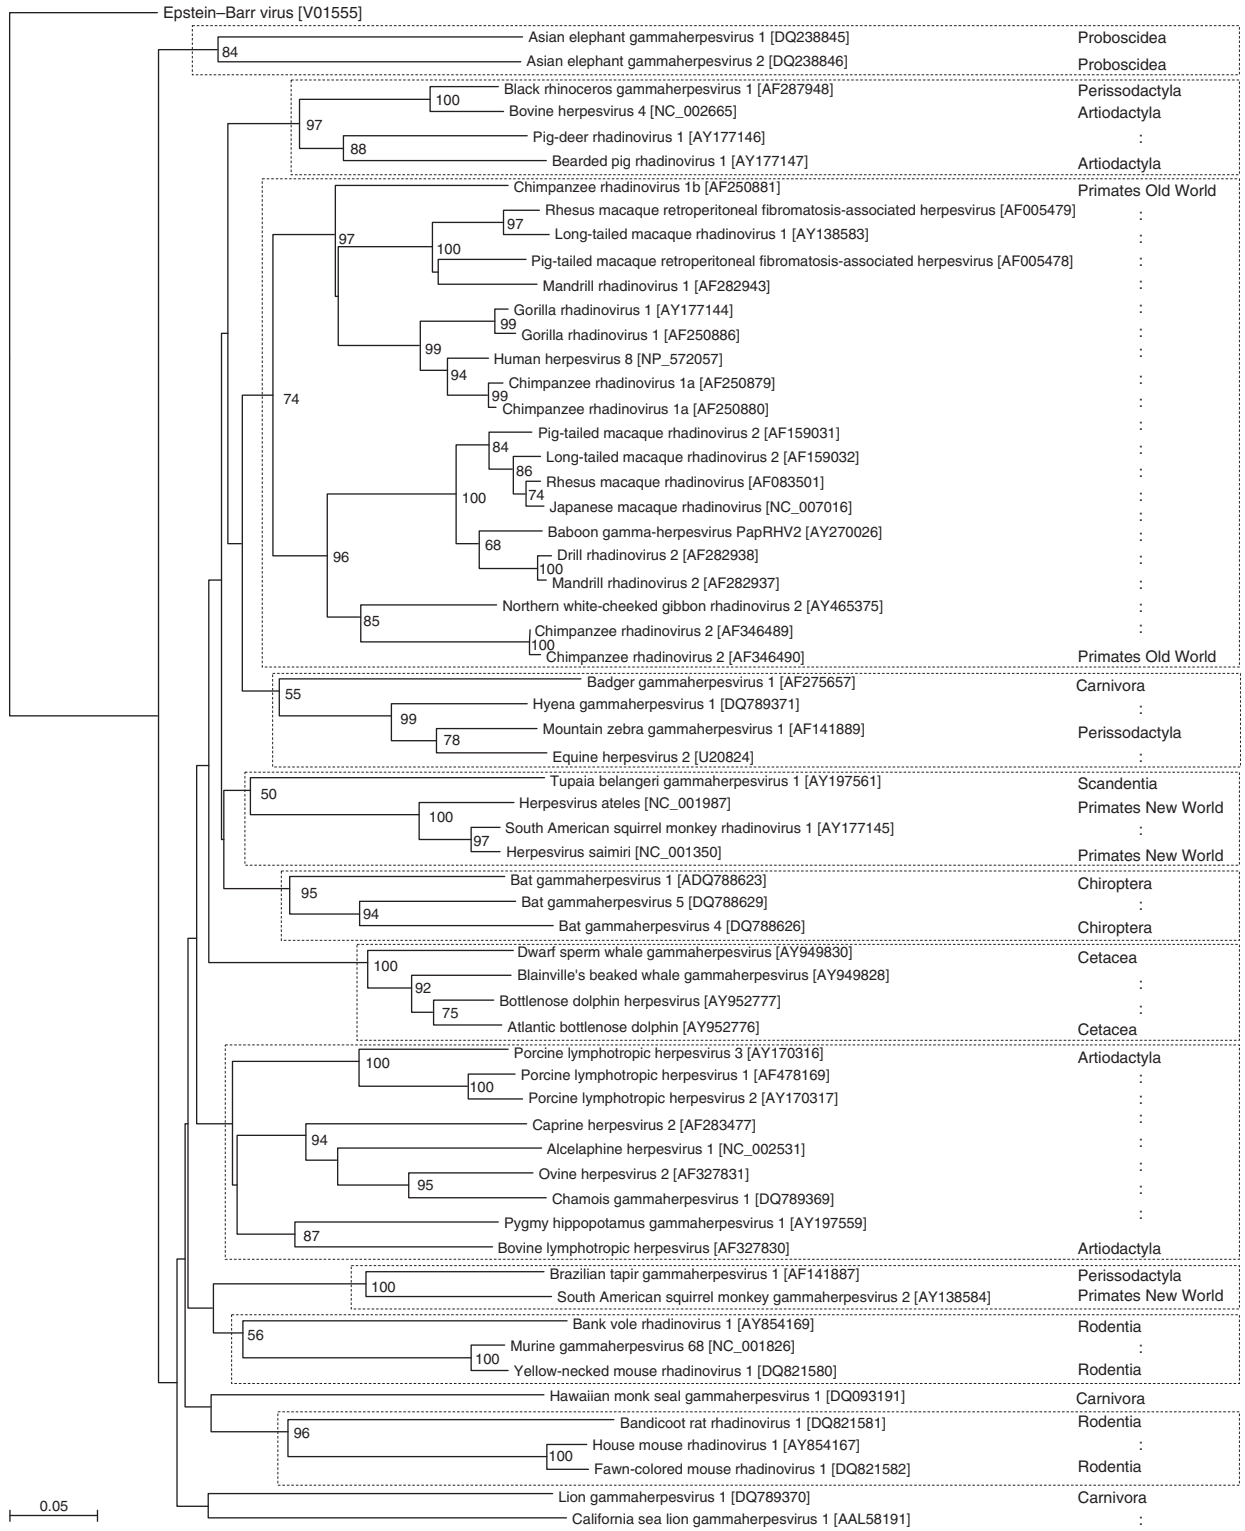

Figure 4 Phylogenetic analysis of well-known and recently discovered RHVs. A phylogenetic tree was constructed with DPOL sequences of 150–160 amino acid residues. They were aligned using the ClustalW module of MacVector™, and gaps were removed. The resulting alignment was analyzed using the neighbor-joining tree-construction module. A rooted phylogram is shown, with EBV as the outgroup. Bootstrap values of >50% are indicated at the nodes of the tree. All sequences are available in GenBank, and the accession numbers are given following the virus names. Host families are indicated.

two distinct RHV groups from artiodactyls (even-toed ungulates, such as cattle, sheep, goat, and pig) and rodents are present. Two mixed groups of carnivore/perissodactyl RHVs are seen, the latter also containing a New World primate RHV. Finally, distinct groups of cetacean (dolphin and whale) and chiropteran (bat) RHVs exist, and a small group of New World primate RHVs clusters loosely with a tree shrew RHV (host: *Tupaia belangeri*) (**Figure 4**).

In phylogenetic trees constructed using short conserved sequences, the deeper nodes close to the center of the tree are often not supported by statistical significance (e.g., see **Figure 4**). In addition, when a great number of herpesviruses from closely related hosts are very similar on the DPOL sequence level, tree resolution is insufficient. A good example is the huge number of EBV-like lymphocryptoviruses (LCVs) in Old World (African and Asian) primates. A satisfactory solution is the consensus amplification of a part of the gB gene, which is located immediately upstream of the DPOL gene in beta- and gammaherpesviruses. Subsequent long-distance PCR and sequencing of all amplification products results in a contiguous sequence of 3–4 kbp, covering large parts of the gB and DPOL genes – a 'bigenic approach' (**Figure 5**). This region codes for approximately 1100 amino acid residues and generally gives rise to considerably improved resolution in phylogenetic trees. This is exemplified by a tree in which 20 EBV-like LCVs of Old World and New World primates are included (**Figure 6**). In this tree, the New World LCVs are clearly separated from two groups of Old World LCVs. In the first group of Old World LCVs, EBV clusters with

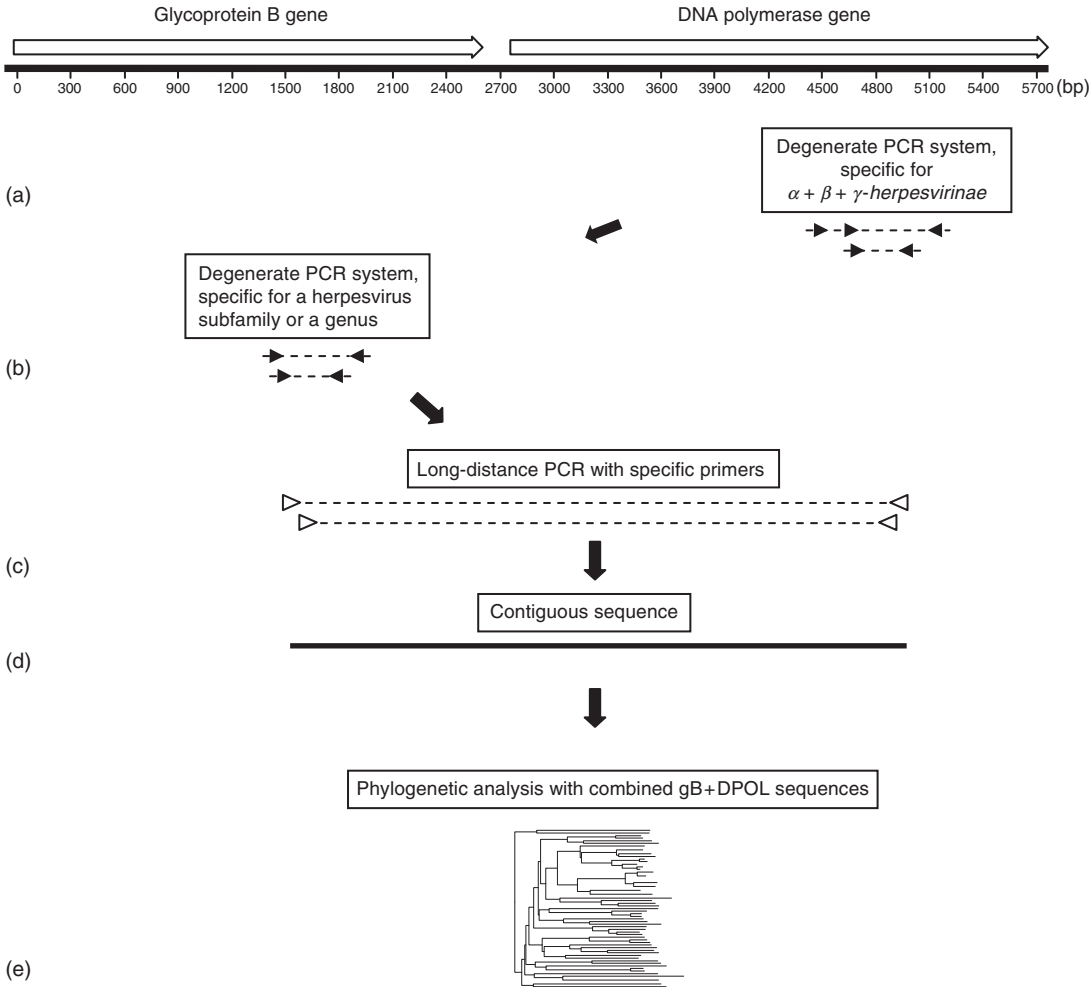

Figure 5 Bigenic amplification of beta- and gammaherpesviruses. Schematic diagram of the analytical strategy. (a) Initially, panherpes-nested PCR with degenerate and deoxyinosine-substituted primers (black triangles) is performed for amplification of the herpesvirus DPOL sequence. (b) According to the sequence of the amplification product and a tentative assignment of the novel DPOL sequence to a herpesvirus subfamily or genus, a degenerate PCR strategy for amplification of the gB gene is chosen, suited to the novel virus. (c) After both gB and DPOL sequences are determined, long-distance PCR is performed with specific primers binding to gB (sense) and DPOL (antisense). (d) A final contiguous sequence of >3 kbp is obtained (solid line) and (e) used for phylogenetic analysis.

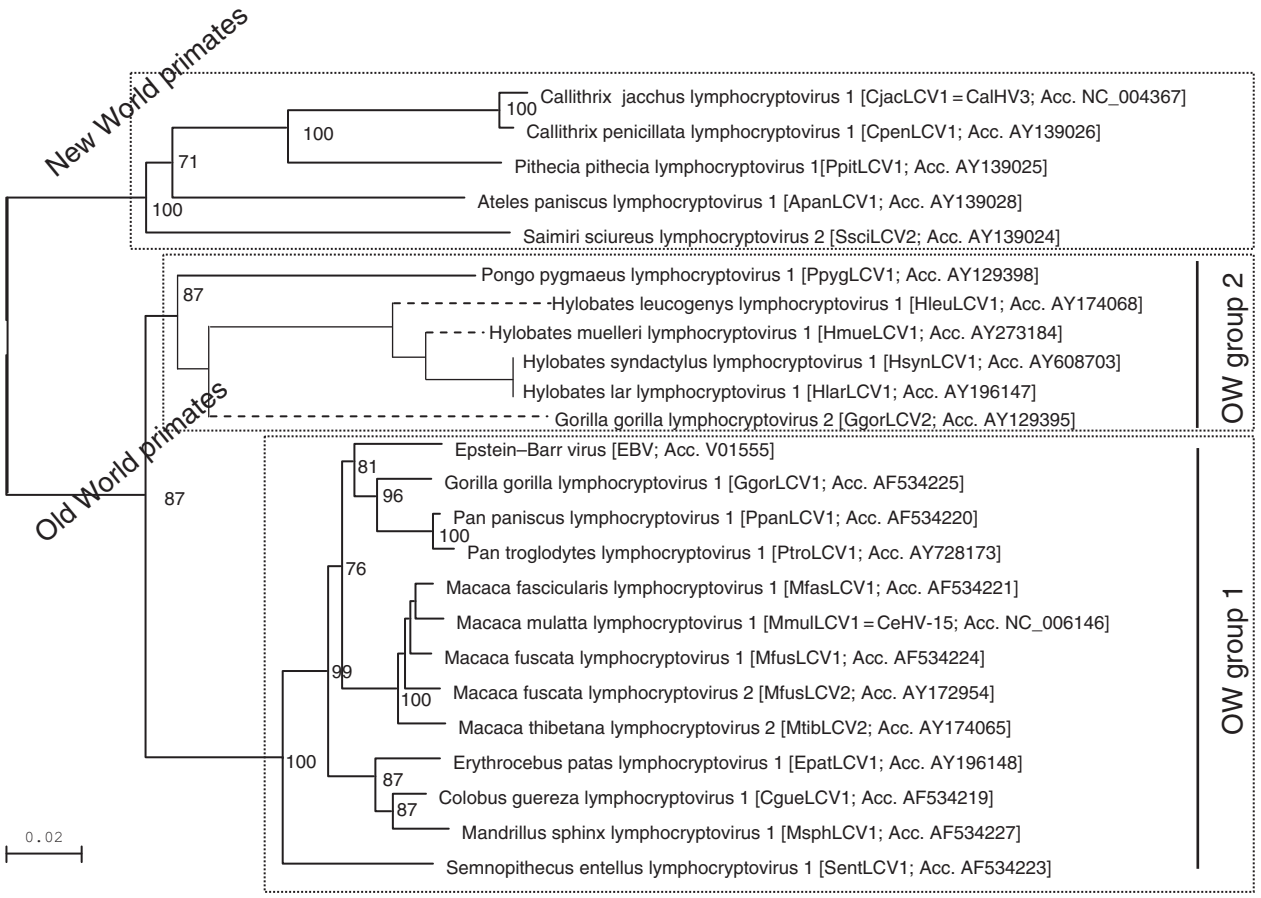

Figure 6 Phylogenetic analysis of well-known and recently discovered LCVs. 400 amino acid residues of gB and 700 residues of DPOL were concatenated for each LCV and analyzed as described in **Figure 2**. For most of the gibbon (genus *Hylobates*) LCVs and the second gorilla LCV (GgorLCV2), the analyzed gB to DPOL region was not available. Therefore, the branches of these viruses were taken from a tree that was constructed on the basis of short DPOL sequences (<160 residues), and are shown by broken lines. OW, Old World.

high probability with LCVs of great apes (chimpanzee, bonobo, and gorilla), as expected from co-evolution of the herpesviruses with their hosts. This subgroup is well separated from a subgroup of macaque LCVs and a subgroup consisting of other cercopithecine LCVs and a colobine LCV. The second group of great ape LCVs contains several distinct gibbon (genus *Hylobates*) LCVs, a second gorilla LCV, and an orangutan (*Pongo pygmaeus*) LCV (**Figure 6**). It can be speculated that this second group should also contain a second human LCV, but this virus, if it exists, remains to be discovered.

The 'bigenic approach' yields more sequence data and improves considerably the reliability of phylogenetic analyses. It has so far been applied to more than 30 novel herpesviruses from nine different orders of vertebrate hosts. It has the potential to become the gold standard for initial genetic characterization of novel beta- and gammaherpesviruses. However, it cannot be applied directly to alphaherpesviruses, in which the gB and DPOL genes are ordered differently, being separated by several kilobase pairs of sequence spanning two genes and, in some cases, the origin of DNA replication.

Pathogenic Impact of Novel Herpesviruses

The herpesviruses that were first discovered and studied in detail were those infecting either humans or animals of economical importance (pigs, PRV; cattle, bovine rhinopneumonitis virus (BoHV-1); horses, equine abortion virus (EHV-1); chickens, Marek's disease virus). Most of these viruses are alphaherpesviruses with overt primary pathogenicity. However, beta- and gammaherpesviruses such as HCMV or EBV often cause primary infections with mild or subclinical pathogenicity. Therefore, it is not surprising that for many of the more recently discovered herpesviruses a disease association is unknown. This is

especially the case for all sequences discovered through screening of healthy individuals, and even the detection of herpesviruses in autopsy specimens of animals suffering from lethal disease can be incidental. Therefore, further investigations are generally needed to confirm etiological involvement. Despite these difficulties, for some recently discovered animal herpesviruses, an association with a specific disease is probable.

One of the more exotic examples is the endotheliotropic elephant herpesvirus, which is a serious threat to the endangered Asian elephant. This virus was first described in 1999, and was found in benign skin lesions of African elephants. In several Asian elephants of American and European zoological gardens, this virus was found to cause a severe endotheliotropic infection with multiorgan failure and death within days or even hours after onset of symptoms. It is thought that the virus is well adapted to the African elephant but can cross the species barrier where both elephant species are housed together. Sequence analysis of the complete gB and DPOL genes (GenBank accession AF322977) placed the virus in the subfamily *Betaherpesvirinae*, and further classification into a new genus (*Proboscivirus*) has been proposed.

Crossing of a species barrier is also an attribute of several ruminant gammaherpesviruses. Ovine herpesvirus 2 (OvHV-2) and alcelaphine herpesvirus 1 (AlHV-1), two gammaherpesviruses infecting sheep and wildebeest, respectively, without clinical symptoms, are known also to infect cattle (OvHV-2 and AlHV-1) and pigs (OvHV-2). In these hosts, a lymphoproliferative disease with high mortality is caused, called malignant catarrhal fever (MCF). More recently, a number of novel gammaherpesviruses were discovered in several wildlife ruminants with an apparently similar pathogenic potential (e.g., GenBank accessions AY237360–AY237366 and AY212111–AY212114).

A lymphoproliferative disease of high mortality has been observed in pigs after pig-to-pig blood stem cell transplantation combined with immunosuppressive drug treatment. The disease was apparently associated with a novel porcine lymphotropic gammaherpesvirus (PLHV-1; GenBank accession AF478169), and resembled the post-transplantation lymphoproliferative disease (PTLD) which is associated with EBV after human-to-human allotransplantation. In pig-to-human xenotransplantation, PLHV-1 is discussed as a risk factor. Xenotransplantation is under investigation because it is seen as a solution for the shortage of human organs for allotransplantation.

Gammaherpesviruses are also closely associated with abnormal proliferation and cancer in primates. Several primate LCVs are known that are very similar to EBV in genome organization and gene content. Some have already been studied in detail and found to be associated with lymphoproliferative diseases that resemble those caused by EBV. Therefore, these LCV infections may be viewed as potential models for EBV infection. For the LCVs more recently detected by panherpes PCR methods (examples are in **Figure 6** and GenBank accessions AY608702–AY608714, AY28171–AY28177, and AF534219–AF534229), such associations remain to be elucidated.

A large number of primate RHVs have been discovered. The first to be described and one of the best studied is herpesvirus saimiri (HVS), which naturally infects a New World primate, the squirrel monkey (*Saimiri sciureus*), without producing symptoms. Upon experimental infection of other monkey species, it causes fatal acute T-cell lymphoma. In Old World primates, several RHVs have since been discovered that are genetically very similar to HHV-8. One, rhesus monkey rhadinovirus (RRV), has been completely sequenced by two research groups and found to induce hyperplastic lymphoproliferative disease in rhesus macaques upon experimental co-infection with simian immunodeficiency virus. This disease resembles a variant of multicentric Castleman's disease, which is a rare HHV-8-associated disease of the human lymphatic system that involves hyperproliferation of certain cytokine-producing B-cells. RRV infection of rhesus monkeys was therefore proposed as a model for certain aspects of HHV-8 pathogenicity in humans. Retroperitoneal fibromatosis in rhesus and pig-tailed macaques is associated with another group of macaque RHVs. Panherpes consensus PCR revealed that they are even more closely related to HHV-8 at the sequence level (**Figure 4**). In recent years, both groups of primate RHVs have been populated with many additional viruses, in particular those infecting great apes (chimpanzee, gorilla, and gibbon), and also other Old World monkeys (e.g., mandrill and baboon) and a New World monkey (squirrel monkey) (**Figure 4**). For the majority of these viruses, a disease association remains to be described.

The first alphaherpesvirus from great apes was isolated very recently from oral and pharyngeal ulcers of chimpanzees. It is a close relative of HSV-2. Serological evidence suggests that gorillas may host a similar alphaherpesvirus.

Fibropapillomatosis of marine turtles is an emerging neoplastic disease associated with infection by a novel virus, fibropapilloma-associated turtle herpesvirus (FPTHV). The DPOL gene of this virus has been amplified through panherpes consensus PCR and originates from an alphaherpesvirus. Later, several turtle species were reported to come down with the disease. These findings underline the fact that tumorigenicity is not an exclusive property of gammaherpesviruses.

In the world of reptiles, novel herpesviruses have also been reported to be associated with proliferative stomatitis in green tree monitors (*Varanus prasinus*) and plated lizards (*Gerrhosaurus major* and *Gerrhosaurus nigrolineatus*).

Several marine mammals of the family Cetaceae (dolphins and whales) have been described as suffering from lesions on oral and genital mucosa as well as from systemic, fatal disease. These were attributed to herpesviruses, and their assignment as alpha- and gammaherpesviruses, respectively, was reported recently on the basis of consensus PCR and sequence analysis.

Among fish, mass mortality in common carp (*Cyprinus carpio*) and colored carp or koi (*Cyprinus carpio koi*) has been observed during the last decade and was reported to be caused by a herpesvirus that differs substantially in sequence and gene content from mammalian herpesviruses but is related to a number of other fish herpesviruses from the families Cyprinidae (carps and minnows), Acipenseridae (ray-finned fish, including sturgeons), and Ictaluridae (catfish).

Finally, sporadic mortality of the Pacific oyster (*Crassostrea gigas*) is associated with a novel herpesvirus, ostreid herpesvirus 1. This is the only known herpesvirus that has an invertebrate host, and is the sole representative of a third major class of herpesvirus in addition to the two classes infecting vertebrates (mammals, birds, and reptiles, and bony fish and amphibians).

Outlook

For the vast majority of potential animal hosts, herpesviruses are completely unknown. This holds true in particular for mammalian families that are populated with a huge number of species, such as those encompassing rodents or bats. Also, many nonmammalian hosts remain to be investigated. The number of putative novel herpesvirus species is growing exponentially, most being characterized exclusively from limited sequence information. The novel sequences obtained can be used to refine the available panherpes consensus PCR methods in order to improve their general detection potential. Recent developments in diagnosing known and novel pathogens by microarray technology may evolve into an additional powerful tool for herpesvirus discovery. Thus, the goal of obtaining a much more extensive list of herpesviruses can be approached, and exciting questions tackled, such as the possible existence of as yet unidentified human herpesviruses.

Herpesviruses: General Features

A J Davison, MRC Virology Unit, Glasgow, UK

© 2008 Elsevier Ltd. All rights reserved.

Introduction

The family *Herpesviridae* consists of a substantial number of animal viruses that have large, double-stranded DNA genomes and share a defining virion structure. Herpesviruses have been discovered in vertebrates from fish to humans, and one has been found in invertebrates (bivalves). They exhibit a wide range of pathogenic properties, ranging from inapparent in many instances to life-threatening (including cancer) in some, and have the ability to establish lifelong latent infections that can reactivate periodically. This chapter introduces the fundamental molecular properties of the herpesviruses: structure, replication, classification, genome, genes, and evolution.

Virion Structure

Herpesvirus particles (virions) are spherical and have an approximate diameter of 200 nm. They have a unique morphology consisting of four basic components (**Figure 1**).

Core

The core is occupied by the virus genome, which is a large, linear, double-stranded DNA molecule packaged at high density.

Capsid

The capsid is an icosahedron of diameter 125–130 nm. It is fashioned from 161 protein capsomeres, which are contributed by 150 hexons and 11 pentons, plus the portal in the 12th pentonal position. The hexons and pentons contain six and five copies each, respectively, of the major capsid protein, each copy of which in the hexons is decorated by a small, external protein. The portal consists of 12 copies of the portal protein and forms the vertex through which DNA enters and leaves the capsid. The capsomeres in the capsid shell are joined together via complexes known as triplexes, which contain two copies of one protein and one copy of another.

The immature capsid shell is constructed in the cell nucleus around a scaffold that consists of approximately 1200 copies of the scaffold protein plus approximately 150 copies of an N-terminally extended form of this protein that contains a protease domain in the additional region. The scaffold is replaced by the virus genome during DNA packaging in a process that involves proteolytic cleavage and loss of all the scaffold protein fragments except for the protease domain.

Tegument

The capsid is embedded in the tegument, and is often not located centrally therein. The tegument contains many virus protein species and is poorly defined structurally except for the region close to the capsid, where a degree of icosahedral symmetry exists.

Envelope

The tegument is wrapped in the lipid envelope, which contains several virus membrane glycoproteins as well as some cellular proteins.

Replication Cycle

The lytic replication cycle has been studied in detail for relatively few herpesviruses, most information having come from herpes simplex virus type 1 (HSV-1). As a consequence, there is a substantial degree of generalization – and even controversy – about applying conclusions from one virus across the whole family. This is especially pertinent to aspects of virus growth involving functions that are not genetically conserved. The mechanisms involved in establishment of, and reactivation from, latency are in this class, with different groups of herpesviruses having evolved different ways of ensuring that the virus stays with the host for life. Herpesviruses possess elaborate means of modulating the host responses to infection, and the genetic functions involved are largely not conserved across the family.

In broad outline, the phases of the lytic replication cycle are as follows. Details on the lytic and latent replication cycles (and pathogenic properties) of specific viruses are available in the relevant articles.

Entry

The virion envelope fuses to the cell membrane via the interactions of cellular receptors with envelope glycoproteins, and the capsid and tegument enter the cytoplasm. Some – perhaps many – of the incoming tegument proteins have specific roles in modulating the replication cycle, for example, in inhibiting host macromolecular synthesis and initiating virus transcription. Some tegument proteins also reach the nucleus, perhaps independently of the capsid.

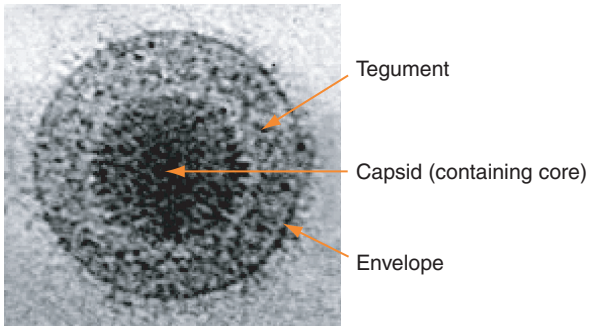

Figure 1 Structure of the herpesvirion exemplified by a cryoelectron microscope image of HSV-1. Adapted from Rixon FJ (1993) Structure and assembly of herpesviruses. *Seminars in Virology* 4: 135–144, with permission from Elsevier.

Expression

Capsids are transferred via microtubules to nuclear pores, through which the virus genome enters the nucleus. The genome is transcribed into mRNA by host RNA polymerase II in three major, regulated phases of transcription. Transcription of immediate early genes, unlike that of later phases, is not dependent on protein synthesis. Some of the immediate early proteins regulate the expression of early and late genes. Functions involved in DNA replication or nucleotide metabolism, and a subset of structural proteins, are in the former class, and many virion proteins are in the latter class.7

Some polyadenylated RNAs, or introns derived therefrom, appear to function via pathways not requiring translation into proteins. In some herpesviruses, small, noncoding RNAs are transcribed by RNA polymerase III. The functions of these RNAs are largely unknown.

Replication

In the nucleus, DNA replication initiates at one or more specific sequences (origins of replication) to generate head-to-tail concatemeric genomes, probably by a rolling circle mechanism. Unit-length genomes are cleaved from the concatemers and packaged into preformed capsids.

Maturation

Capsids acquire some tegument proteins in the nucleus and gain a temporary envelope by budding through the inner nuclear membrane. This envelope is lost upon transit across the outer nuclear membrane into the cytoplasm. Further tegument proteins are added in the cytoplasm, and the tegumented capsids gain their final envelope by budding into a post-Golgi compartment.

Exit

Mature virions are released from the cell by reverse endocytosis.

Classification

The task of classifying viruses, including herpesviruses, commenced in 1966 and is undertaken by the International Committee on Taxonomy of Viruses (ICTV). Various criteria have been utilized, as enabled by developments in knowledge and technology. The current taxonomy of herpesviruses, as laid out in the *Eighth Report of the ICTV* (2005), is summarized in **Table 1**. The family *Herpesviridae* is divided into three subfamilies populated by herpesviruses of higher vertebrates (mammals and birds): *Alphaherpesvirinae* (containing four genera: *Simplexvirus*, *Varicellovirus*, *Mardivirus*, and *Iltovirus*), *Betaherpesvirinae* (containing three genera: *Cytomegalovirus*, *Muromegalovirus*, and *Roseolovirus*), and *Gammaherpesvirinae* (containing two genera: *Lymphocryptovirus* and *Rhadinovirus*). The family also contains a genus (*Ictalurivirus*) that is not linked to any subfamily and has a single fish herpesvirus as a member.

In proposals under consideration by the ICTV (**Table 1**), an order (*Herpesvirales*) is introduced as the highest taxon. The family *Herpesviridae* is redefined as restricted to viruses of higher vertebrates (which in this context will eventually include reptiles as well as mammals and birds). Within this redefined family, an additional genus (*Proboscivirus*) is added to the *Betaherpesvirinae*, and two new genera (*Macavirus* and *Percavirus*) are split from the *Rhadinovirus* genus in the *Gammaherpesvirinae*. Two new families are also created: *Alloherpesviridae* to accommodate viruses of lower vertebrates (amphibians and fish), and *Malacoherpesviridae* for the single herpesvirus of invertebrates (bivalves).

The formal names of herpesvirus species follow a taxonomic designation derived from the natural host followed by the word 'herpesvirus' and a number (e.g., *Human herpesvirus 4* – the fourth of the eight species whose members infect humans). However, many herpesviruses are better known by common names (e.g., Epstein–Barr virus rather than human herpesvirus 4), and in this respect are characterized by a dual nomenclature. In addition, vernacular terms are often used to imply members of the family (e.g., herpesvirus), subfamily (e.g., gammaherpesvirus), or genus (e.g., rhadinovirus).

Herpesviruses are defined as separate species if their nucleotide sequences differ in a readily assayable and distinctive manner across the entire genome and if they occupy different ecological niches by virtue of their distinct epidemiology and pathogenesis or their distinct natural hosts. This definition implies that several criteria are employed in identifying a new species, and their application is to some extent arbitrary. The criteria are outlined below.

Morphological Criteria

Assignment of a virus to the family *Herpesviridae* depends primarily upon virion morphology, as described above.

Table 1 Present and proposed herpesvirus classification schemes. Species other than the type species of each genus are not included

Taxon level	*Current taxon*	*Proposed taxon*	*Common name of virus*
Order		*Herpesvirales*	
Family	*Herpesviridae*	*Herpesviridae*	
Subfamily	*Alphaherpesvirinae*	*Alphaherpesvirinae*	
Genus	*Simplexvirus*	*Simplexvirus*	
Type species	*Human herpesvirus 1*	*Human herpesvirus 1*	Herpes simplex virus type 1
Genus	*Varicellovirus*	*Varicellovirus*	
Type species	*Human herpesvirus 3*	*Human herpesvirus 3*	Varicella-zoster virus
Genus	*Mardivirus*	*Mardivirus*	
Type species	*Gallid herpesvirus 2*	*Gallid herpesvirus 2*	Marek's disease virus type 1
Genus	*Iltovirus*	*Iltovirus*	
Type species	*Gallid herpesvirus 1*	*Gallid herpesvirus 1*	Infectious laryngotracheitis virus
Subfamily	*Betaherpesvirinae*	*Betaherpesvirinae*	
Genus	*Cytomegalovirus*	*Cytomegalovirus*	
Type species	*Human herpesvirus 5*	*Human herpesvirus 5*	Human cytomegalovirus
Genus	*Muromegalovirus*	*Muromegalovirus*	
Type species	*Murid herpesvirus 1*	*Murid herpesvirus 1*	Murine cytomegalovirus
Genus	*Roseolovirus*	*Roseolovirus*	
Type species	*Human herpesvirus 6*	*Human herpesvirus 6*	Human herpesvirus 6
Genus		*Proboscivirus*	
Type species		*Elephantid herpesvirus 1*	Endotheliotropic elephant herpesvirus
Subfamily	*Gammaherpesvirinae*	*Gammaherpesvirinae*	
Genus	*Lymphocryptovirus*	*Lymphocryptovirus*	
Type species	*Human herpesvirus 4*	*Human herpesvirus 4*	Epstein–Barr virus
Genus	*Rhadinovirus*	*Rhadinovirus*	
Type species	*Saimiriine herpesvirus 2*	*Saimiriine herpesvirus 2*	Herpesvirus saimiri
Genus		*Macavirus*	
Type species		*Alcelaphine herpesvirus 1*	Wildebeest-associated malignant catarrhal fever virus
Genus		*Percavirus*	
Type species		*Equid herpesvirus 2*	Equine herpesvirus 2
Family		*Alloherpesviridae*	
Genus	*Ictalurivirus*	*Ictalurivirus*	
Type species	*Ictalurid herpesvirus 1*	*Ictalurid herpesvirus 1*	Channel catfish virus
Family		*Malacoherpesviridae*	
Genus		*Ostreavirus*	
Type species		*Ostreid herpesvirus 1*	Oyster herpesvirus

Biological Criteria

The three subfamilies *Alphaherpesvirinae*, *Betaherpesvirinae*, and *Gammaherpesvirinae* were defined initially on the basis of biological criteria, in the application of which a degree of generality is implicit: host range in cell culture, length of replication cycle, cytopathology, and characteristics of latency. Alphaherpesviruses exhibit a variable host range, have a short replication cycle, spread quickly with efficient destruction of infected cells, and establish latent infections primarily in sensory ganglia. Betaherpesviruses have a narrow host range and a long replication cycle with slow spread and cell enlargement. Viruses may become latent in secretory glands and lymphoreticular cells. Gammaherpesviruses are associated with lymphoproliferative diseases, and latent virus is present in lymphoid tissue. They infect B- or T-lymphocyte cells *in vitro*, in which infection is frequently arrested so that infectious progeny are not produced. However, some gammaherpesviruses are able to cause lytic infections in fibroblastoid or epithelial cell lines.

Serological Criteria

Closely related viruses may be detected using antisera or specific antibodies.

Genomic Criteria

The general layout of a genome in terms of unique and repeat regions (see below) is limited as a criterion since, although particular structures are found more commonly in certain subfamilies or genera, similar structures have evidently evolved more than once. The DNA sequences of herpesviruses are sufficiently diverged to limit extensive nucleic acid similarity (detectable by hybridization) to closely related viruses.

Sequence Criteria

Phylogenetic analysis based on sequence comparisons between conserved genes has become the predominant

criterion in classification of herpesviruses at all taxonomic levels. **Figure 2** shows one example of a phylogenetic tree supporting the current classification scheme. In recent years, many herpesviruses have been detected in animal tissues solely by polymerase chain reaction (PCR) of short sequences. Given the multifactorial nature of the herpesvirus species definition (see above), the absence of other information renders formal classification problematic in these cases.

Genome Organization

The herpesvirus genomes studied to date range in size from approximately 124 kbp (simian varicella virus) to 295 kbp (koi herpesvirus) and in nucleotide composition from 32% to 74% G+C. Alphaherpesviruses are not deficient in the 5′ CG dinucleotide, betaherpesviruses are deficient in very limited regions, and gammaherpesviruses are deficient throughout their genomes. 5′ CG deficiency is thought to be a consequence of spontaneous deamination of methylated cytosine residues in DNA over evolutionary time to produce 5′ TG. There is evidence that methylation of certain regions of the Epstein–Barr virus genome resident in peripheral blood lymphocyte cells may be involved in perpetuating infection. Extensive methylation of the 5′ CG dinucleotide has been found in the virion DNA of two frog herpesviruses, both of which encode the enzyme DNA (cytosine-5-)-methyltransferase.

Herpesvirus genomes differ in the arrangements of direct and inverted repeat regions with respect to unique

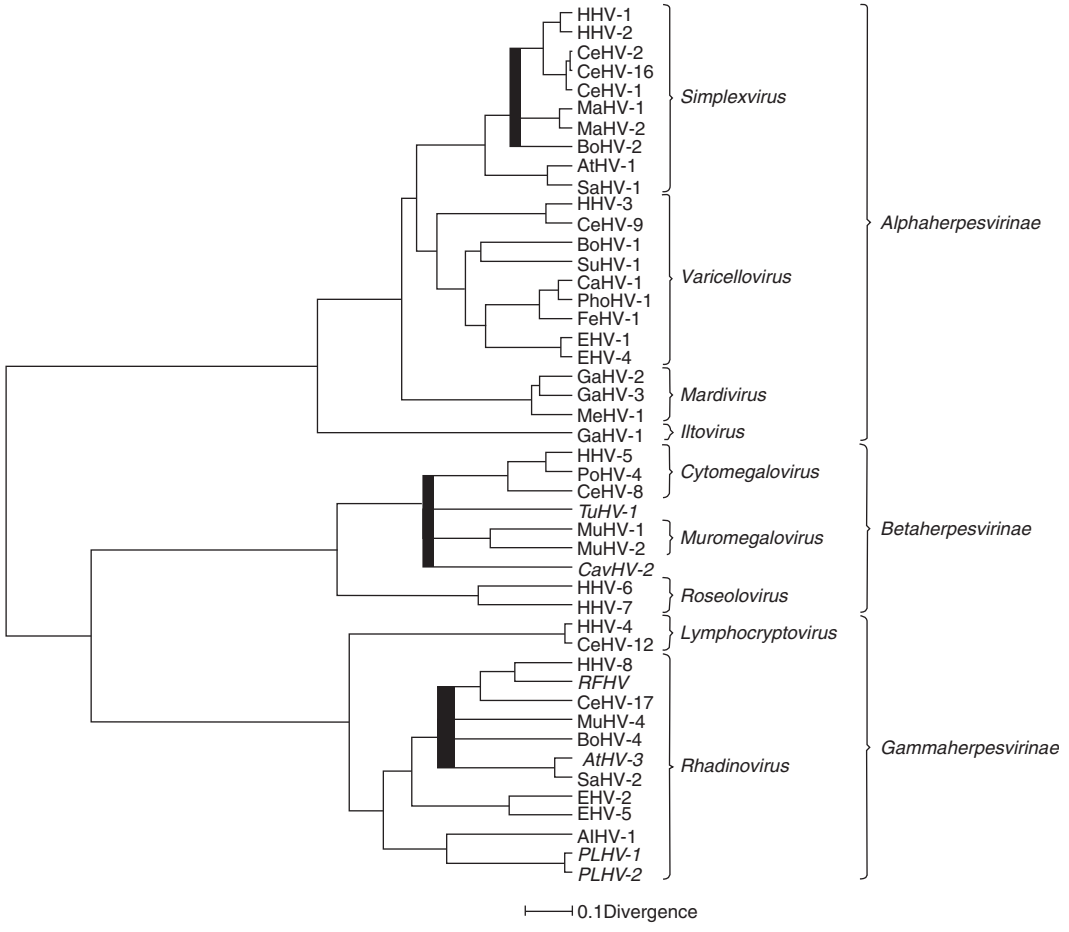

Figure 2 Phylogenetic tree for herpesviruses. The scope is limited to the three subfamilies that comprise the revised family *Herpesviridae*; see **Table 1**. The tree is a composite derived from sequence alignments of up to eight sets of core proteins, analyzed using the maximum-likelihood method with a molecular clock imposed. Thick lines denote regions of uncertain branching. Prefixes denote host species: H, human; Ce, cercopithecine; Ma, macropodid; Bo, bovine; At, ateline; Sa, saimiriine; Su, suid; Ca, canid; Pho, phocid; Fe, felid; E, equid; Ga, gallid; Me, meleagrid; Po, pongine; Tu, tupaiid; Mu, murid; Cav, caviid; and Al, alcelaphine. Other virus name abbreviations are: RFHV, retroperitoneal fibromatosis herpesvirus of macaques; and PLHV-1 and PLHV-2, porcine lymphotropic herpesviruses 1 and 2. Viruses that are not yet incorporated into genera are in italics. Genera and subfamilies are on the right. Adapted from McGeoch DJ, Dolan A, and Ralph AC (2000) Toward a comprehensive phylogeny for mammalian and avian herpesviruses. *Journal of Virology* 74: 10401–10406, with permission from American Society for Microbiology.

(nonrepetitive) regions. **Figure 3** illustrates the five types of structure that have been confirmed adequately. The type A structure (e.g., human herpesvirus 6) consists of a unique region (U) flanked by a direct terminal repeat (TR) at the genome ends. Type B genomes (e.g., human herpesvirus 8, also known as Kaposi's sarcoma-associated herpesvirus) contain variable numbers of a TR at each end of the genome. The type C structure (e.g., Epstein–Barr virus) has in addition a variable number of copies of an internal direct repeat (IR), which is unrelated to TR, and the presence of IR splits U into two unique regions (U_L and U_S). The type D structure (e.g., pseudorabies virus) also has two unique regions (U_L and U_S), with U_S flanked by an inverted repeat (TR_S/IR_S). In some type D genomes (e.g., varicella-zoster virus), U_L is flanked by a very small, unrelated inverted repeat (TR_L/IR_L). By virtue of recombination between inverted repeats, the two orientations of U_S are present in equimolar amounts in virion DNA populations, and U_L is present completely or predominantly in a single orientation. In the type E structure (e.g., HSV-1), TR_L/IR_L is larger and the two orientations of U_L and U_S are each present in equimolar amounts in virion DNA populations, giving rise to four genome isomers. A direct repeat (the *a* sequence) is also present at the termini, and an inverted copy (*a*′) is present internally.

In addition to large-scale repeats, regions consisting of tandem repeats of short sequences are found at various locations in many herpesvirus genomes. The elements that make these up may be identical to each other or merely similar, giving rise to simple or complex repeats, and their presence in variable numbers causes genome size heterogeneity.

Gene Content

To date, the genome sequences of herpesviruses belonging to 42 species have been published, with more than one strain determined for several of these species. Details are available via the genomic biology Web pages at the National Center for Biotechnology Information. In addition, a large amount of data is available for portions of other herpesvirus genomes. Analyses of these sequences provide detailed views of genetic content and phylogeny.

Herpesvirus genomes consist mostly of protein-coding sequences. Gene complements range from about 70 to 170 and are arranged about equally between the two DNA strands. They are not generally located in functionally related groups. Overlap between protein-coding regions in different reading frames on the same or opposing strands is infrequent and, where it does occur, is not extensive. In instances where extensive or complete overlap of two protein-coding regions has been mooted, evidence that both encode functional proteins is invariably unconvincing.

Most herpesvirus genes are transcribed from their own promoters and thus specify mRNAs with unique 5′ ends. Groups of genes are frequently arranged tandemly on the same DNA strand and share a common polyadenylation site, with mRNAs sharing the same 3′ end. Most genes are not spliced, particularly among the alphaherpesviruses. RNA polymerase II transcripts that do not encode proteins but may have other functions, and micro-RNAs, have been identified in representatives of all three subfamilies, and RNA polymerase III transcripts in certain gammaherpesviruses. The functions of such transcripts are largely unknown. Herpesvirus genomes also contain

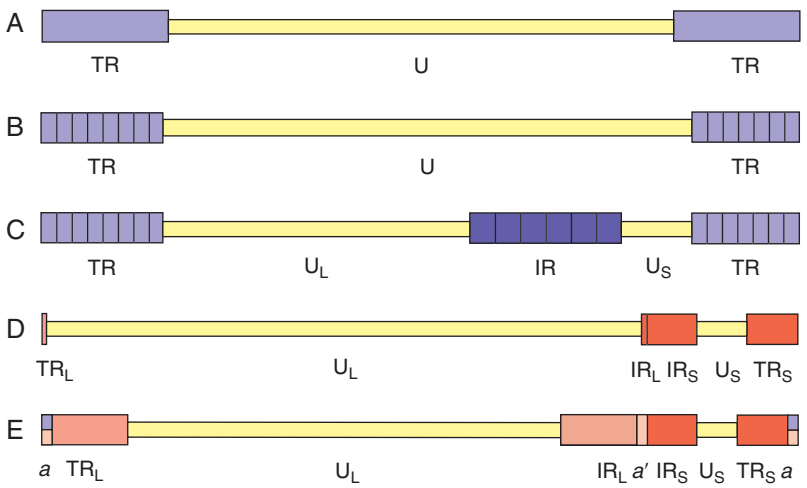

Figure 3 Types of herpesvirus genome structure. The disposition of unique regions (yellow), direct repeats (blue), and inverted repeats (red) are shown (not to scale). Within a structure, unique regions are unrelated to each other, and only the repeats depicted in the same color and shade are identical. Among the structures, repeats represented in the same color and shade are not necessarily related to each other. In the type E structure, an inverted copy of a direct repeat (*a*) at the genome termini is present internally (*a*′).

cis-acting signals in addition to those involved in transcriptional control, such as origins of DNA replication.

Sequence comparisons among members of the revised family *Herpesviridae* indicate that a set of 43 core genes has been inherited from the ancestor of the three subfamilies. This number of core genes is an approximation, since its derivation assumes that the *Alphaherpesvirinae* was the first subfamily to diverge (as indicated by molecular phylogeny; see **Figure 2**). Moreover, it is based not simply on primary sequence conservation but, in some cases, on positional and functional similarities. Three of the core genes derived from the ancestor have been lost subsequently from certain lineages. The core genes are generally arranged collinearly among members of the same subfamily, but in members of different subfamilies blocks of genes have been rearranged and sometimes inverted.

The most strongly represented functional categories among the core genes are involved in central aspects of lytic replication. Particularly prominent are genes encoding capsid proteins (six genes) or proteins involved in replication (seven genes) or processing and packaging of DNA (eight genes). Also featured are genes with roles in nucleotide metabolism or DNA repair (five genes), and, to a lesser extent, genes encoding tegument (seven genes) or envelope proteins (five genes). Genes with roles in niche-specific aspects of the life cycle, such as modulation of the host response and regulation of latency, do not generally belong to the core set. This feature illustrates the high degree of evolutionary flexibility that herpesviruses have exhibited in colonizing particular ecological niches. The fact that over half (in some cases well over half) of the genes in a herpesvirus genome may be removed individually without eliminating viral growth in cell culture, when all presumably have a role *in vivo*, testifies to the extensive interactions that the virus has with its host during natural growth and transmission.

The comments above refer to the revised family *Herpesviridae*, where most information is available. Similar points may be made about the proposed family *Alloherpesviridae*, though the number of core genes is considerably fewer (probably not more than 20), presumably due to the greater antiquity of the common ancestor.

Herpesvirus Evolution

The processes that have occurred during evolution of the three subfamilies of the *Herpesviridae* from their common ancestor are the same as in other organisms, and include the gradual effects of nucleotide substitution, deletion, and insertion to modify existing genes or produce genes *de novo*, and the recombinational effects of gene capture, duplication, and rearrangement. These processes are also evident in the proposed family *Alloherpesviridae*.

Herpesviruses are usually restricted to a single species in the natural setting, and severe symptoms of infection are often limited in the natural host to young or immunosuppressed individuals. This indicates that a substantial degree of co-adaptation and co-evolution have taken place over the long term between herpesviruses and their hosts. Although some exceptions suggesting ancient interspecies transfer have been registered, phylogenetic studies provide strong support for co-evolution as a general historic characteristic, in some instances supporting the idea that the viruses have speciated along with their hosts. This correspondence has allowed a timescale for herpesvirus evolution to be proposed on the basis of accepted dates for host evolution. For example, the most recent analyses suggest divergence dates of 400 million years (before present) for the three subfamilies, 120 million years for the genera *Simplexvirus* and *Varicellovirus* of the *Alphaherpesvirinae*, and 8 million years for HSV-1 and HSV-2. These dates are approximate, especially the further back they go, and vulnerable to the vicissitudes of estimated host dates and developments in analytical approaches.

The three lineages populated by the revised family *Herpesviridae* and the two proposed families *Alloherpesviridae* and *Malacoherpesviridae* share similarities in capsid structure and replication that indicate evolution from a common ancestor, the forerunner of all herpesviruses. However, in comparison with the situation within the families, detectable amino acid sequence similarity among proposed families is very limited, with evidence for a common ancestor focused on a single gene (encoding a subunit of the terminase complex responsible for DNA packaging). These features imply that the divergence events that gave rise to the three lineages are very ancient. Moreover, structural considerations focused on the capsid continue to stimulate the notion that herpesviruses might share an even earlier ancestor with T4-like bacteriophages.

Note: The proposals for new taxa mentioned in this article have been accepted by the ICTV.

Glossary

Ganglion A small organ containing the cell bodies, including nuclei, of neurons.
Iontophoresis Introduction through the skin or cornea by applying an electrical charge.

Introduction

Members of the family *Herpesviridae* exhibit the ability to remain latent in tissues of the host following primary infection. Latent virus is retained for the lifetime of the host, and can be reactivated to cause recurrent disease. Latency is a crucial property for the survival of herpesviruses, overcoming the requirement for rapid reinfection of new individuals in order to spread within a population. As described below, the characteristics of latency show variations when the different herpesvirus subfamilies are considered. Operationally, latency is defined as the presence of the viral genome without detectable virus production, coupled with the potential for resumption of virus replication in response to reactivation signals. For descriptive purposes, latency is characterized by three phases: establishment, maintenance, and reactivation.

Early thoughts on latency focused on two basic ideas, named the static and dynamic models. In the static model, the viral genome is considered to be nonreplicating due to a failure to undergo the normal program of gene expression, and reactivation is viewed as a change in intracellular conditions such that replication resumes. Dynamic models of latency envisage a slow persistent production of virus that is normally controlled by the host immune system and does not cause overt disease until a reactivation stimulus diminishes host defenses. There is currently no consensus that either of these models is correct; instead, research into latency continually reveals greater complexity in the interaction of virus with host. It is now thought that interference with virus replication occurs at many levels, ranging from repression of gene expression to control by immunological defenses. The requirement for long-term retention of the viral genome, coupled with an ability to spread within a population, demands that a complex and intimate relationship exists between virus and host. This relationship can be considered at two levels, namely the individual cell and the organism. At the cellular level, there must be mechanisms for sequestering the viral genome in a host cell that is potentially permissive for replication, and for retaining the ability to resume replication in response to appropriate stimuli. In terms of the organism, the virus must evade detection by the immune system during latency and must overcome host defenses when reactivating.

Latency will be considered in terms of the three subfamilies of the family *Herpesviridae*, focusing on human viruses since these are understood in the greatest detail.

Alphaherpesvirinae

The prototype of the subfamily *Alphaherpesvirinae*, herpes simplex virus (HSV) type 1 (HSV-1), is the most intensively studied in terms of latency. In humans, its natural host, primary exposure usually occurs during infancy and is characterized by a mild infection of the oropharynx that is frequently unnoticed. After the initial infection has resolved, a proportion of individuals experience periodic reactivation in response to stressful stimuli, such as excessive exposure to sunlight, resulting in the appearance of 'cold sore' lesions around the lip and less frequently on other areas of the face. HSV type 2 (HSV-2) is more

frequently associated with genital herpes, although nowadays genital HSV-1 is detected with increasing frequency. Genital herpes and facial cold sores are treated by application of acyclovir, but this agent is only effective in preventing lesions once reactivation has occurred. There is currently no antiviral that eradicates latent virus or prevents reactivation.

HSV establishes latency in sensory neurons that innervate the site of initial infection. The viral genome is retained in neurons of the relevant ganglia for the lifetime of the host, and upon reactivation virus is released into tissues served by neurons extending from the ganglion. During initial infection, replicating HSV enters nerve termini and virus particles are transported along axons in a retrograde manner to the ganglia. Upon reactivation, virus moves in an anterograde direction from the ganglion to the surface, where replication causes disease.

Animal models have been developed for the study of HSV latency, and although each has limitations, they have been important in linking molecular investigations with *in vivo* studies. Latency is established efficiently after infection of mice with HSV-1, but reactivation is difficult to achieve *in vivo*. The most common method of reactivating latent virus from mice is to explant ganglia, a process in which ganglia are removed by dissection and cultured in the laboratory. This invariably results in the appearance of infectious virus within a few days but its physiological relevance is debatable. Subjecting mice to transient hyperthermia reliably reactivates virus replication in ganglia *in vivo*, albeit at low efficiency. The best animal for the study of reactivation is the rabbit, since virus is spontaneously released in tear films after ocular infection and release can be stimulated by iontophoresis of epinephrine. Genital HSV-2 infection can be reproduced, to some extent, by intravaginal inoculation of guinea pigs.

In considering establishment of latency, a crucial question concerns the way in which the normally inexorable progression to lytic replication and cell death is interrupted. Transcripts and proteins characteristic of lytic infection cannot be detected easily during latency, indicating a global repression of gene expression. Furthermore, studies with HSV mutants have failed to identify a gene product that is dispensable for lytic replication but required for latency, thus the prevailing hypothesis is that establishment of latency results by default when viral gene expression is somehow arrested in neurons. It is currently thought that the block occurs early in the virus life cycle, and the most likely point for intervention by the cell is at the immediate early (IE) stage. A favored hypothesis contends that IE transcription is compromised in sensory neurons, possibly due to inefficient transport of the virion transactivator protein VP16 (virion protein number 16), which activates IE transcription, to the neuronal nucleus, or to lack of the cellular transcription factors Oct-1 (a cellular protein that binds sequences with the consensus ATGCAAAT) or host cell factor (HCF, a large cell protein), with which VP16 is able to form a complex. Alternatively, sensory neurons may contain proteins that act as competitive inhibitors of Oct-1 and/or HCF, blocking their interactions with VP16. The possibility of arrest at the IE stage is supported by experiments with tissue culture cells. HSV-1 mutants that are severely impaired for IE gene expression can be retained in cells for extended periods in a nontranscribed 'quiescent' state that apparently mimics the transcriptional silence characteristic of latency.

Despite the overall absence of viral lytic gene products, latently infected neurons can be readily identified by the presence of a 2 kbp viral RNA known as the latency-associated transcript (LAT). Thousands of molecules of this RNA are found in the nucleus, enabling its detection by *in situ* hybridization or RNA blots. The observed species is an unusually stable intron spliced from a larger precursor that is present in neurons at much lower levels. Structurally, LAT is a lariat, that is, a splicing intermediate of a type typically cleaved and rapidly degraded. The LAT lariat has an unusual branch point sequence that is not recognized by cellular debranching enzymes. A smaller 1.5 kbp RNA, derived by further splicing, is found only in neurons. Intriguingly, LAT is complementary to sequences encoding the C-terminal portion of the IE protein ICP0 (infected cell protein number 0), an important activator of gene expression, leading to the suggestion that LAT blocks ICP0 production by an antisense mechanism. At present, there is no evidence for protein products encoded by HSV-1 LAT or the longer precursor in latently infected neurons, although there is evidence that the bovine herpesvirus 1 latency-related transcript does encode one or more proteins.

The significance of LAT for latency is controversial. Viral mutants that are unable to produce LAT nonetheless establish latency and can be reactivated; thus, LAT does not have an essential role in any of the animal models currently available. In detail, however, LAT mutants are deficient in reactivation in a number of contexts, suggesting a modulatory role for the transcripts. In some animal models, the absence of LAT appears to reduce the efficiency of reactivation directly, whereas in others LAT mutants exhibit a defect in establishment, thereby indirectly reducing reactivation due to the smaller pool of latent genomes. It is relevant that LAT mutants cause greater destruction of neurons during the initial stages of infection. This may be because one of LAT's normal roles is to exert antisense inhibition of ICP0 expression, thereby restricting productive infection, but currently the favored interpretation is that LAT has anti-apoptotic properties that reduce neuronal death after infection. Therefore, LAT could be important for improving establishment of latency by preventing loss of infected neurons, but equally a direct effect on reactivation is possible by keeping reactivating neurons healthy for long periods.

During maintenance of latency, which can last for many decades in humans, it is thought that cellular factors contribute to the stable repression of transcription. The genome is believed to be organized into a chromatin-like structure, and indeed histones carrying post-translational modifications characteristic of inactive cellular chromatin are associated with latent HSV-1 genomes. Interestingly, the LAT region, which escapes repression, is associated with histones normally found on actively transcribed genes. Therefore, cellular mechanisms for global control of transcription may operate on latent HSV DNA.

The latent viral genome exists as a circular episome, structurally distinct from the linear molecule found in the virion. This suggests that the gene expression program is arrested at an early stage, since circularization occurs shortly after virus entry into the cell as a prelude to replication. Alternatively, circular molecules may be remnants from replication during productive infection. It is possible that circularization is important for the assembly of the latent genome into a chromatin structure. There is no evidence for integration of HSV DNA into the host genome during latency.

During latency in humans or experimental animals, only a fraction of neurons in the ganglion (typically 0.1–5% but in some cases up to 30%) harbor latent HSV-1, and neurons themselves constitute only about 5% of the cells in the ganglion. However, viral genomes can be detected by Southern hybridization of total ganglion DNA, demonstrating that neurons harbor many copies of HSV DNA. Analysis of single cells by polymerase chain reaction (PCR) confirms this conclusion and further reveals a wide disparity in the viral copy number per neuron. Most neurons harbor fewer than 100 viral genomes, but a minority can contain thousands.

Although it is clear that most latent genomes do not express lytic gene products at detectable levels, sensitive analysis of mouse ganglia by reverse transcriptase-PCR demonstrates the presence of viral transcripts from loci outside the LAT region. The transcripts are present in low amounts; they may signify infrequent viral lytic gene expression, but they may simply represent a small amount of background transcription of the latent genome. In an extensive analysis of mouse ganglia, a very small number of neurons (fewer than one per mouse) were undergoing an apparently productive infection, again showing that silencing of the genome is not absolute. Therefore, a low level of viral lytic gene expression may occur during latency.

Immunological studies support the view that virus lytic gene expression may occasionally occur during latency. Leukocytes, predominantly CD8+ T cells, can be found in ganglia from humans or latently infected experimental animals, often in intimate association with neurons. In mice, the infiltrating T cells are HSV-1 specific, with the majority recognizing a single immunodominant epitope on glycoprotein B. Furthermore, latently infected ganglia contain cytokines such as RANTES (an attractant for T cells), γ-interferon, and tumor necrosis factor (both produced by T cells). The continued presence of CD8+ T cells and derived cytokines is indicative of persistent stimulation of the immune system during latency. The favored interpretation of the data is that T cells respond to and eliminate a low level of virus that is produced from infected neurons.

The exact nature of the stimuli that provoke reactivation is unclear, and at present the general term 'stress' is used. The stress can be delivered at the periphery, directly to the neuron, or systemically. In experimental animals, explantation of ganglia efficiently reactivates latent HSV, but virus is only released from a small proportion of infected neurons. Procedures that provoke reactivation *in vivo*, such as hyperthermic treatment of mice, are even less efficient. The low efficiency imposes constraints on studying the molecular basis of reactivation, since it is not possible to identify the small number of reactivation-competent genomes among the total latent population. The normal program of HSV gene expression probably does not operate during reactivation because VP16 is absent during latency. It is suspected that stress causes alterations to the transcription factor profile of neurons, resulting in changes at the ICP0 promoter and synthesis of ICP0 protein which then derepresses the entire viral genome. An alternative view of reactivation is that stresses impair immunological mechanisms that normally prevent a low level of reactivating virus from causing disease. The impairment may occur in the ganglion, at the periphery, or both, with the outcome that virus is able to replicate. The application of PCR has revealed that low-level asymptomatic shedding of HSV in humans is more common than previously thought, supporting the view that local immunity prevents reactivated virus from causing disease.

A summary of HSV latency is shown in **Figure 1**.

Varicella-zoster virus (VZV) causes varicella (chickenpox) as primary infection and zoster (shingles) upon reactivation. VZV is latent in neurons within ganglia throughout the body because the primary infection is widespread rather than localized as in the case of HSV. Studies on VZV latency have proceeded slowly, relying on analysis of human tissue in the absence of a satisfactory animal model to reproduce latency. Although rats can be infected with VZV and harbor genomes in ganglia, virus cannot be reactivated. In humans, latent VZV genomes appear to be retained as circular episomes. The pattern of gene expression during latency, however, differs from that found with HSV. Transcripts representing four lytic genes (ORF21, ORF29, ORF62, and ORF63) have been detected in human ganglia, and there is evidence that protein products, particularly that of ORF63, are also present in infected human and rat neurons. Thus, despite many similarities, there may be significant differences in the details of VZV and HSV latency.

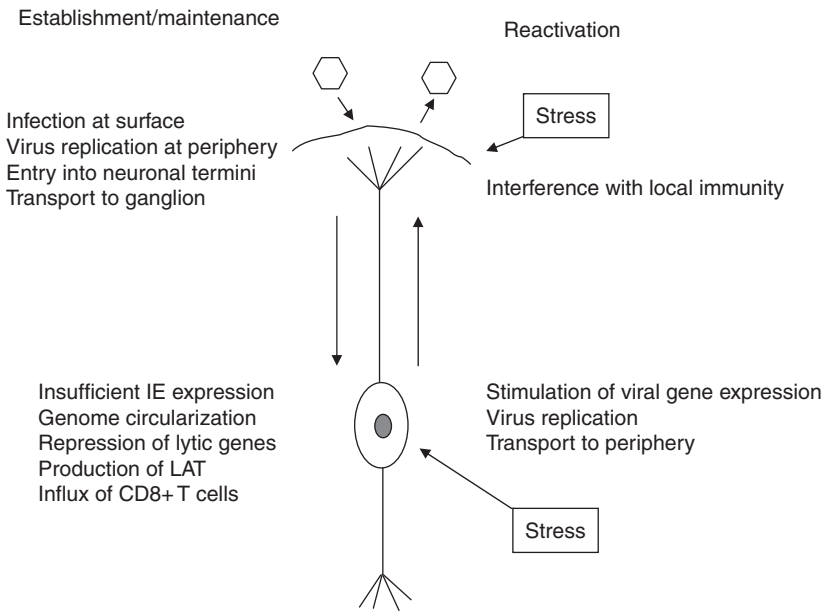

Figure 1 Schematic representation of HSV latency and reactivation.

Betaherpesvirinae

Most studies on latency of the subfamily *Betaherpesvirinae* are concerned with the cytomegaloviruses, particularly human cytomegalovirus (HCMV). In adults, initial infection with HCMV is normally asymptomatic unless it occurs *in utero*, but in immunocompromised individuals it may be serious. Reactivation of latent HCMV can cause rejection of organ transplants, due to replication of virus originating from either the recipient or the donated organ. In addition, AIDS patients can suffer a widespread HCMV infection that has serious consequences. HCMV can be transferred by blood transfusion, suggesting that circulating lymphocytes harbor latent virus, and sensitive PCR analysis, together with cell sorting, has detected the HCMV genome in a small proportion (1 in 10^4 cells) of peripheral blood monocytes. In addition, the HCMV genome can be detected in precursors of monocytes, the CD34+ myeloid progenitors in bone marrow, suggesting that these cells may be the primary reservoir of latent virus.

In view of the low proportion of myeloid cells containing latent HCMV, and the absence of animal models for this virus, molecular studies on HCMV latency have relied heavily on the use of cell culture models. The myelomonocytic line THP-1 is nonpermissive for HCMV replication, but becomes permissive upon differentiation by chemical treatment *in vitro*. Similarly, the teratocarcinoma line NT-2 is nonpermissive until induced to differentiate. The block in undifferentiated cells is due to failure of the major IE transcription unit to be expressed, resulting in arrest of the entire productive infection program. Plasmid-based transfection assays have indicated that specific sequence elements within the major IE promoter (MIEP) are targets for repression. Whereas the entire MIEP is inactive in undifferentiated cells but active in differentiated cells, a truncated MIEP, containing only the 300 base pairs proximal to the mRNA start site, is active in both situations. Mutational analysis has identified critical DNA elements in the MIEP at positions upstream of −300 that contain binding sites for two cellular proteins known to act as repressors. These proteins, known as Yin-Yang 1 (YY1) and Ets-2 repressor factor (ERF), mediate repression of the MIEP in transfection assays, and, furthermore, their levels decline after differentiation by chemical treatment. The implication is that differentiation changes the levels of repressors and hence permits IE gene expression in THP-1 and NT-2 cells.

Chromatin structure at the MIEP is a further important factor in determining permissiveness in cell culture models of HCMV latency. In undifferentiated cells, the MIEP is associated with methylated histones and heterochromatin protein 1 (HP1), both markers of inactive chromatin, whereas in differentiated cells the relative amount of HP1 is reduced and acetylation of histones, a correlate of active chromatin, is increased. It is suspected that YY1 and ERF exert their repressive effects by recruiting histone deacetylases (HDACs) to the MIEP, thereby promoting the formation of inactive chromatin, and this idea is supported by the fact that undifferentiated cells become permissive for IE transcription when treated with chemical inhibitors of HDACs.

The findings from the analysis of cell culture models have received support from studies on monocytes isolated from seropositive individuals and on CD34+ myeloid precursors from human bone marrow. Monocytes do not support HCMV replication, but virus is produced upon differentiation to macrophages in the laboratory. HCMV

can be reactivated *ex vivo* by inducing CD34+ cells from seropositive individuals to differentiate to a mature dendritic cell phenotype. Furthermore, differentiation of CD34+ precursors to dendritic cells reproduces the switch from inactive to active chromatin structure at the MIEP. Thus it is thought that HCMV remains latent in CD34+ myeloid precursors and that differentiation to macrophages or dendritic cells leads to intracellular changes that activate the MIEP and ultimately result in virus replication. Although the precise signals that provoke reactivation *in vivo* are not known, one reported means of inducing virus replication is by allogeneic stimulation of blood monocytes, achieved by mixing cells from histo-incompatible individuals. This may reproduce events that occur during transplantation.

The latent HCMV genome is thought to exist as an episome, but it is not known how it is retained in the host. It may be replicated during cell division, by cellular factors or with the participation of viral proteins, or alternatively a low level of persistent virus production may continually seed new latently infected cells. There have been reports of HCMV-specific transcripts produced during latency, but there is little consensus between different laboratories and thus the possibility that viral gene products control latency remains an open question.

At the level of the whole organism, reactivation of HCMV generally causes disease only when the immune system is compromised. A high proportion (>1%) of circulating CD8+ T cells is specific for HCMV, suggesting frequent stimulation of the immune system, presumably through virus reactivation. Indeed, differentiation of monocytes occurs constantly and if such an event frequently reactivates HCMV, immune clearance must be crucial to prevent disease. The potential significance of the immune response in limiting HCMV infection is best demonstrated in studies with murine cytomegalovirus (MCMV). In its natural host, the mouse, latent MCMV is found in numerous tissues, in contrast to the situation with HCMV. During MCMV latency, CB8+ T cells specific for a major IE protein are present, suggesting that immune control eliminates cells containing reactivating virus at an early stage of the gene expression program. Damage to the immune system can result in widespread infection, and although the simplest interpretation of this finding is that immune surveillance is critical for maintaining latency, it must be remembered that immunosuppression also represents a significant stress that may itself activate the latent genome.

HCMV latency is summarized in **Figure 2**.

Gammaherpesvirinae

Most latency studies with the subfamily *Gammaherpesvirinae* have focused on Epstein–Barr virus (EBV), a member of the genus *Lymphocryptovirus*. This virus is usually transmitted by exchange of saliva, with cells of lymphoepithelial structures such as the tonsils initially infected. Infection is generally asymptomatic but infectious mononucleosis, a self-limiting lymphoproliferative disease, can result if EBV is first acquired during adolescence or later. A defining feature of EBV is its ability to activate resting cultured B cells into unchecked proliferation with retention of the viral genome but without virus production, and indeed the distinction between latency and transformation is often blurred in discussion of this virus. It is clear, however, that EBV is latent in B cells, and that the virus utilizes many aspects of normal B cell development to establish and control latency. EBV, in contrast to HSV and HCMV, possesses a number of genes that are specific to the nonreplicating state and indeed are crucial for coordinating the establishment of latency. These encode the EBV nuclear antigens (EBNAs) 1, 2, 3A, 3B, 3C, and LP, and the latent membrane proteins (LMPs) 1, 2A, and 2B. Other loci specifying small RNAs, known as EBERs, and Bam A rightward transcripts are active during B cell transformation *in vitro*, although their significance for latency is unclear at present. During establishment of

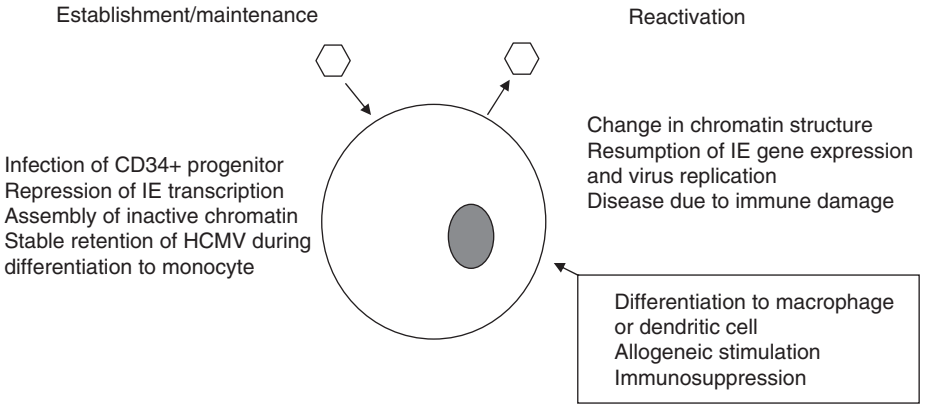

Figure 2 Stages in latency and reactivation of HCMV.

latency, the EBNAs and LMPs participate in a complex interaction with the host cell that results in utilization of the normal B cell development, to the advantage of the virus.

After penetration of the mucosal layers of the tonsils, virus replicates and naive B cells are infected and activated in a manner similar to that observed in culture. At this stage, no lytic gene transcription occurs but all of the EBNAs and LMPs are expressed in an interaction known as the growth program, or latency III. The combined action of the viral proteins gives the resting cell the characteristics of an activated B-lymphoblast, mimicking the first stage that occurs naturally after antigen recognition. Activated B cells are transported to the lymph node follicles, in which they replicate to form germinal centers. Again, following the normal pattern of B cell development after antigen stimulation, the infected cells undergo differentiation into memory B cells. At some stage during this process, the gene expression pattern changes to the default program, or latency II, in which only EBNA1, LMP1, and LMP2A are produced. Protein EBNA1 is crucial for maintaining the EBV genome in dividing cells, through stimulating its replication and by tethering it to cellular chromosomes. LMP1 and LMP2A provide survival signals that prevent the activated B cell from undergoing apoptosis. In the final step, the infected memory B cells are released from the germinal centers to become circulating memory B cells, and during this process gene expression changes to the latency program, or latency I, in which no viral gene products can be detected. During latency, the EBV genome is maintained as a circular episome. To retain the virus within the host, EBNA1 is produced during cell division, enabling the viral genome to replicate and persist in the memory compartment. Interestingly, each of the identified interactions with B cells is reflected in EBV-associated human tumors: viral gene expression in Burkitt's lymphoma (BL) cells resembles the latency program (but with EBNA1 continually expressed), Hodgkin's lymphoma has the default program, and nasopharyngeal carcinoma exhibits the growth program, albeit in epithelial-derived cells.

Reactivation of latent EBV occurs when a memory B cell differentiates into an antibody-secreting plasma cell, an event triggered by signaling from the B cell antigen receptor (BCR). The plasma cells migrate to the mucosal epithelium and virus is released into the saliva, possibly after replication in epithelial cells. The molecular mechanism of lytic cycle activation, and hence virus replication, has largely been studied by the use of BL cell lines, which express only EBNA1 and thus resemble the latent state in B cells. Cross-linking the BCR with immunoglobulin, possibly mimicking the natural differentiation signals provided by T cells, can activate EBV in certain BL lines. This process switches on expression of an IE protein, BZLF1, a transcription factor that triggers further viral gene expression and ultimately productive replication. The signal transduction pathways that respond to cross-linking the BCR result in activation of two transcription factors, MEF2D and ATF, which in turn induces histone acetylation and relief of repression by remodeling the chromatin structure. The BZLF1 protein activates its own promoter, providing a positive feedback loop that ensures rapid commitment to productive replication. In some BL cell lines, BZLF1 expression, and hence EBV replication, is activated in response to alternative agents, such as phorbol esters, but the relevance of these treatments to natural stimuli is unclear.

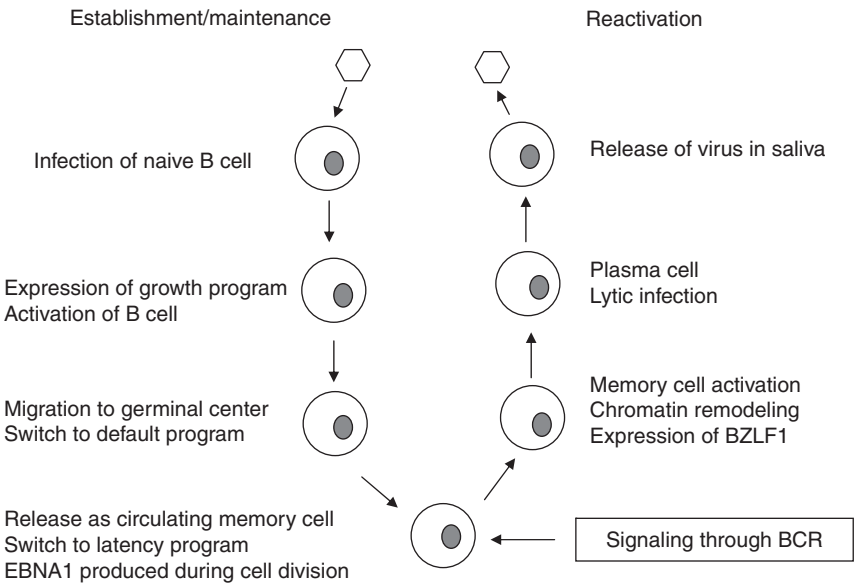

Figure 3 Establishment, maintenance, and reactivation of EBV latency in B cells.

The interaction between EBV and host B cells is summarized in **Figure 3**.

Members of the genus *Rhadinovirus* of the *Gammaherpesvirinae* have been studied in less detail than EBV. Murine herpesvirus 68 establishes latency in a number of cell types, including B cells, in mice. Kaposi's sarcoma-associated herpesvirus (KSHV) is also found in a variety of cell types, again including B cells. The natural pathways of latency and reactivation for these viruses are currently under investigation.

Common Themes

Although the examples described here deal with different viruses and host cells, some common themes emerge from the latent interactions. In establishment, specific features of the natural host cell are critical in preventing productive virus replication. Blocking IE protein production, an effective mechanism for inhibiting virus replication while minimizing cytopathology and immune recognition, appears to be common to establishment of latency. During maintenance, genomes are retained as circular episomes and viral gene expression is minimized to hide the virus from the immune system. Histones associated with the latent genome exhibit modifications characteristic of inactive chromatin. If repression of replication is not complete, low-level virus production may be neutralized by the immune system. Reactivation probably involves the virus utilizing normal cellular responses to a stimulus, but the stimulus may also damage the immune system and thereby cause disease.

Glossary

Bacteriophage 'Eater of bacteria' (Greek, phagein).
Eclipse Invisible phase during phage replication.
Lysogenic (1) Bacterium harboring a prophage. (2) Bacteriophage produced by such a bacterium.
Lysogeny Carriage of a prophage.
Metagenomics Sequencing of total genomic material from an environmental sample.
One-step growth Single cycle of phage multiplication.
Phage typing Testing bacteria with a set of phages of different host ranges.
Prophage Latent bacteriophage genome in a lysogenic bacterium.
T-even Phage of the T-series with an even number (T2, T4, T6).

Introduction

Phages or bacteriophages, also referred to as bacterial viruses, include eubacterial and archaeal viruses and are now more appropriately called 'viruses of prokaryotes'. Phages are ubiquitous in nature and may be the most

numerous viruses on this planet. They have a long evolutionary history, are considerably diverse, and include some highly evolved and complex viruses. Approximately 5500 phages have been examined in the electron microscope and they constitute the largest of all virus groups. The present system of phage taxonomy comprises 13 officially recognized families.

Following the discovery of phages, their study entered a symbiosis with the nascent science of molecular biology and then expanded to cover a multitude of subjects. The knowledge on phages grew by accretion and represents the efforts of thousands of scientists. For example, it took over 50 years and hundreds of publications to establish the genome map and sequence of coliphage T4. Phage literature is voluminous and comprises over 11 400 publications for the years 1915–65 and, to the author's reckoning, about 45 000 for 1965 to today. The volume of phage research is evident in the fact that there are two books each for single viruses, λ and T4, and that, by mid-2006, the journal *Virology* has published over 2000 phage articles since its start in 1955. The history of phages may be divided into three, partly overlapping periods. Because of the volume of phage research and the many scientists involved, the development of phage research is largely presented in tabular form. Any mention of individual scientists and facts is selective.

The Early Period: 1915–40

Discovery

Several early microbiologists had observed bacterial lysis. The British bacteriologist Ernest H. Hankin reported in 1896 that the waters of the Jumna and Ganges rivers in India killed *Vibrio cholerae* bacteria. The responsible agent passed bacteriological filters and was destroyed by boiling. In 1898, the Russian microbiologist Nikolai Gamaleya reported the lysis of *Bacillus anthracis* bacteria by a transmissible 'ferment'. It is probable that these scientists would have discovered bacterial viruses, if suitable techniques had been available.

Frederick William Twort (1877–1950), a British pathologist and superintendent of the Brown Institution in London, tried to propagate vaccinia virus on bacteriological media. He observed that 'micrococcus' colonies, in fact staphylococci, often became glassy and died. The agent of this transformation was infectious, passed porcelain filters, and was destroyed by heating. Twort proposed several explanations: an amoeba, an ultramicroscopic virus, a living protoplasm, or an enzyme with the power of growth. Subsequently, Twort joined the army and participated in the British Salonika campaign. Back at the Brown Institution, he published five more articles on phages and spent the rest of his career trying to propagate animal viruses on inert media.

Félix Hubert d'Herelle (1873–1949), born in Montreal, went to France as a boy and returned to Canada, styled himself a 'chemist', studied medicine without obtaining a degree, and finally went to Guatemala as a bacteriologist with minimal knowledge of this science. Later in Yucatan, he isolated the agent of a locust disease, the *Coccobacillus acridiorum* (now *Enterobacter aerogenes)*, was sent to the Pasteur Institute of Paris, returned to Mexico and France, and went to fight locusts in Argentine, Turkey, and Tunisia. He noticed the appearance of holes ('plaques') in coccobacillus cultures. In 1915, again in Paris, he investigated an epidemic of bacillary dysentery in military recruits. He noted that his *Shigella* cultures were destroyed by a filterable, plaque-forming agent, whose appearance coincided with convalescence of the recruits. His discovery was published in 1917. D'Herelle understood immediately that he had found a new category of viruses and he used phages for the treatment of bacterial infections. D'Herelle then went to Vietnam, Holland, Egypt, India (Assam), the USA, the Soviet Union (Tbilisi), and finally to Paris. He coined the term 'bacteriophage', devised the plaque test, and stated that there was only one kind of phage, with many races, the *Bacteriophagum intestinale*. He promoted and practiced phage therapy in many countries and founded several phage institutes. The Tbilisi Institute, which he co-founded with G. Eliava in 1934, still exists.

Twort and D'Herelle could not have been more different personalities. Twort was a medical doctor and a self-effacing person; he traveled little, and showed minimal interest in his discovery. He published only five more articles on phages. D'Herelle was self-educated, peripathetic, worldly, and combative. He devoted the rest of his career to phages and wrote five books and nearly 110 articles on them. The almost simultaneous discovery of bacteriophages by two different scientists is a remarkable coincidence.

Phage Research: General

The years 1920–40 were characterized by research on the nature of phages and lysogeny, phage therapy, and the detection of phages in a wide variety of bacteria and a wide range of habitats (**Table 1**). D'Herelle and his followers asserted that bacteriophages were viruses. A major argument was that they formed plaques. Others, observing that some bacteria produced lytic agents that could be transmitted from one culture to another, held that 'bacteriophages' were generated spontaneously and were endogenous in nature. The famous Belgian immunologist, J. Bordet, proposed that phages were enzymes produced by 'lysogenic' bacteria. He stated bluntly: "The invisible virus of d'Herelle does not exist." When Bordet discovered Twort's paper from 1915, a nasty controversy on the nature of phages and the priority of phage discovery ensued.

Table 1 Phage discovery: phages of selected host organisms

Year	*Investigators*	*Host species or group*
1915	Twort	*Staphylococcus* sp.
1917	D'Herelle	*Shigella dysenteriae*
1918	D'Herelle	*Salmonella typhi*

1963	Safferman and Morris	Cyanobacteria
1970	Gourlay	Mycoplasmas
1974	Torsvik and Dundas	Halophilic archaea
1983	Janekovic and coll.	Hyperthermophilic archaea

Phages Become Viruses

The viral nature of phages was demonstrated by physicochemical studies. W. J. Elford and C. H. Andrewes (1932) showed that phages could differ in size. M. F. Burnet and colleagues (1933) demonstrated that phages differed in antigenicity and resistance to inactivation by heat, urea, and citrate. M. Schlesinger (1934) found that phages were made of DNA and protein. The publication of phage electron micrographs (1940) settled the matter of phage nature and made the enzyme theory untenable. It was now clear that phages were particulate and morphologically diverse. In retrospect, however, both d'Herelle and his opponents were right: phages are viruses with a dual nature.

Phage Therapy

Phage therapy was practiced by D'Herelle himself (1919) soon after phage discovery. He treated human dysenteria, chicken cholera, bovine hemorrhagic fever, bubonic plague, cholera, and a variety of staphylococcal and streptococcal infections. His phage laboratory in Paris was devoted to phage therapy. Many people embarked on phage therapy. Spectacular successes and dismal failures ensued. The failures had many reasons: use of crude, uncontrolled, inactivated, or endotoxin-containing lysates, narrow host specificity of some phages; absence of bacteriological controls; and plain charlatanism. The literature on phage therapy peaked in 1930 and totaled 560 publications for 1920–40. At this time, antibiotics were introduced and interest in phage therapy quickly waned.

Phage Typing and Ecology

Host range tests had shown that bacteria, even of the same species, usually differed in phage sensitivity. Some strains were lysed and some were not. By testing bacteria with a battery of phages, they could be subdivided into 'phage types', which greatly facilitated the tracing of bacterial infections to their sources and gave epidemiology an enormous boost. The first phage typing scheme, introduced in 1938, was for *Salmonella typhi* bacteria, which were subdivided by means of a series of adapted derivatives of phage ViII. For the first time, viruses were found to have a practical use. Phage typing developed rapidly in the following decades.

New phages were sought and found everywhere. It appeared that most bacterial pathogens had phages (**Table 1**) and that these viruses were omnipresent in water and soil, on plants, in food, on the skin of humans and animals, and in their body cavities and excreta. It also was discovered that bacteriophages caused faulty fermentations in the dairy industry. A few bacteriophages isolated during this early period are still available today: a streptococcal and a T4-like phage, two microviruses, and, possibly, the original phage isolated by Twort himself (**Table 2**, **Figure 1**).

The early period ended with the rise of dictatorships and World War II, first in the Soviet Union and later in Europe. Scientists were silenced, persecuted, forced into exile, or outright killed (G. Eliava was shot in 1937 by Stalin's secret police and Eugène and Elisabeth Wollman disappeared in 1943 in a Nazi concentration camp). Phages now had their martyrs. D'Herelle himself, a Canadian citizen, was interned by the Vichy Government and prevented from pursuing phage therapy. Phage research was obliterated in much of Europe.

The Intermediate Period: 1939–62

Phages as Tools and Products of Molecular Biology

Phage research survived and attained new heights in the USA. It helped to start molecular biology and provided crucial insights into vertebrate and plant virology. In turn, phage research benefited enormously from both disciplines. The next two decades became a legendary period of phage research, as a small number of researchers produced results of fundamental scientific importance (**Tables 3** and **4**).

In 1939, E. L. Ellis devised the 'one-step growth' experiment to measure the kinetics of phage infection and to establish the viral nature of bacteriophages. He was joined by Max Delbrück (1906–81), a German immigrant and physicist. Delbrück proposed to concentrate phage research on the seven coliphages T1–T7, collected and studied by F. Demerec and U. Fano in 1945 and all easily propagated. Fortunately, these phages were both diverse and partially related, thus allowing useful comparisons. Electron microscopy showed that the T phages (T for type) belonged to four morphotypes: T1, T3–T7,

T2–T4–T6, and T5 (**Figure 2**). Morphotypes correlated with growth parameters and antigenic properties. The T phages became the raw material for fundamental studies which, although limited to tailed phages of the T series, provided a general understanding of the phage life cycle. It became clear that:

1. Phages have different morphologies.
2. Phages contain DNA and transmit it from parent to progeny. The DNA is the carrier of heredity and genetic information. Phage coats consist of proteins.
3. Phages adsorb to bacteria by their tails.
4. Phage DNA enters the bacteria while the protein coat remains outside.
5. Phage synthesis occurs in stages, one of which is the 'eclipse'. Neither phages nor particulate precursors can be detected during the eclipse period. Novel phages are liberated ready-made in a single event ('burst').

Lysogeny

The problem of lysogeny, a leftover from the previous period, was solved by the French bacteriologist André Lwoff (1902–94) from the Pasteur Institute of Paris. The Wollmans had already postulated the dual nature of some phages: they were infectious outside the bacterium and noninfectious inside. Starting in 1949, Lwoff isolated single cells of a phage-carrying strain of *Bacillus megaterium* with a micromanipulator and transferred them into microdrops of fresh medium. After 19 successive generations, there was still no lysis. When lysis occurred, it was sudden and phages were plentiful in the microdrops. Lysis and phage production were inducible, especially by ultraviolet (UV) light. It was concluded that lysogenic bacteria perpetuate latent phages as 'prophages' in a repressed state. They do not secrete phages. Spontaneously or after induction, the prophage enters a vegetative phase, new phages are produced, and the bacterium dies. A major review article published in 1953 clarified the nature of lysogeny. The prophage became the origin of the 'provirus' concept in vertebrate virology.

In 1951, Esther Lederberg isolated the lysogenic coliphage λ. Small and easily manipulated, it was to have an extraordinary future and became perhaps the best studied of all viruses. As the prototypic lysogenic phage, it was the subject of countless publications on the nature of

lysogeny, genetic regulation, and transduction. It was shown that defective prophages could carry specific bacterial genes and insert them into bacteria (specific transduction). Certain phages such as P22 could transfer any bacterial genes and thus mediate 'general transduction'. This led to an understanding of phage conversion. It appeared that the converting phages were lysogenic and that their prophages converted bacteria by coding for novel properties, such as the production of antigens. As early as 1951, V. J. Freeman reported that the production of diphtheria toxin depended on the presence of prophages. The study of lysogeny culminated in 1962 when A. Campbell proposed his model of prophage insertion by a crossover process.

Varied and Interesting

In 1959, Brenner and Horne revolutionized electron microscopy by introducing negative staining with phosphotungstic acid. This produced pictures of unprecedented quality. They showed that T4 tails were contractile and that tail contraction was part of the T4 infective process. The same year, single-stranded (ss) DNA was discovered in the minute phage ϕX174 *(Microviridae)*. Filamentous phages *(Inoviridae)* and phages with ssRNA *(Leviviridae)* were isolated in 1960 and 1961, respectively. True marine phages and phages of cyanobacteria, then called 'blue-green algae', were also found. This offered some hope to control 'algal' blooms.

While phage therapy disappeared, phage typing became a major epidemiological tool (**Table 5**). In addition to the *S. typhi* typing scheme, international typing sets for *S. paratyphi B* and *Staphylococcus aureus* were devised and are still in use. Typing schemes for many medically important bacteria (e.g., corynebacteria, various *E. coli* and *Salmonella* serotypes, shigellae, *Pseudomonas aeruginosa*, and *Vibrio cholerae*) appeared. A literature survey by H Raettig lists no less than 2000 articles on phage typing, mostly in the years 1940–65. Phage research was considerably promoted by M H Adams' book *Bacteriophages*, which summarized phage research until 1957 and introduced the agar-double-layer method of phage propagation

Diversification and the Ongoing History of Bacteriophages: 1965–Today

Phage research now expanded explosively and divided into many, partly overlapping fields. No particular time periods are discernible; all fields developed gradually and are still expanding. As judged from literature listings, the present number of phage publications is 800–900 articles or monographs per year. The following is a selection of research activities.

Basic Phage Research

1. The present period of phage research started in 1965 (**Table 3**) after D. E. Bradley published a seminal, still cited paper on phage morphology (republished in 1967). Bradley classified phages into six basic types defined by morphology and nature of nucleic acid. Phages were divided into tailed phages (with contractile, long and noncontractile, or short tails), isometric phages with ssDNA or ssRNA, and filamentous phages. This became the basis of present-day phage classification.
2. Novel phages were isolated at a rate of about 100 per year. A first phage survey, published in 1967, listed 111 phages examined by electron microscopy, 102 of which were tailed and 9 isometric or filamentous. Most infected enterobacteria. Presently, the number of phages with known morphology exceeds 5500 and the number of host genera has grown to 155. It includes mycoplasmas, cyanobacteria, and archaea.
3. Replication and assembly of most phage families were studied. A highlight was the description of the assembly pathway of phage T4 (1967), obtained by a combination of electron microscopy and genetics.
4. Many phage genomes were sequenced. The first was that of ssRNA phage MS2 (*Leviviridae*), the first viral genome ever to be sequenced. This was followed by the sequences of various small viruses of the families *Microviridae*, *Inoviridae*, and *Leviviridae*. A landmark was the sequencing of the complete λ genome (1982), followed by that of coliphage T7. The complete

sequence of the T4 genome was established in 1994. This was the beginning of large-scale phage genome sequencing (**Table 3**(**b**)) and of the novel science of 'genomics', devoted to computer-assisted comparisons of phage and other genomes. By 2006, the genomes of representatives of all phage families and of many individual tailed phages had been sequenced.

5. Bacteriophages appeared as major factors of bacterial virulence, coding for bacterial exotoxins (e.g., botulinus and Shiga toxins), antigens, and other virulence factors. A momentous discovery made in 1996 was that filamentous phages in their double-stranded replication form were able to convert nontoxigenic cholera strains to toxigenic forms. Virulence genes were found to be present in converting phages and integrated prophages. Sequencing of bacterial genomes showed that prophages with virulence factors were generally organized into 'pathogenicity islands'.

6. Cryoelectron microcopy and three-dimensional image reconstruction revealed the capsid structure of various isometric phages (*Microviridae*, *Leviviridae*, *Tectiviridae*) and of the tail and base plate structure of phage T4. It was also shown that the capsids of adenoviruses and tectiviruses and of representatives of all three tailed phage families (T4, HK97, ϕ29) were structurally related. This indicated phylogenetic relationships between adeno- and tectiviruses and provided the long-sought evidence that tailed phages are a monophyletic evolutionary group.

Applied Research

See **Table 5** for a listing of research activities, arranged chronologically.

1. In the dairy industry, phages of lactococci and *Streptococcus thermophilus* were shown to cause major economic losses by destroying starter cultures and causing faulty fermentations. The phages involved were studied in detail by electron microscopy and genome sequencing.
2. Phages were investigated for use as indicators of fecal pollution. Phages with ssRNA (*Leviviridae*), somatic coliphages, and tailed phages of *Bacteroides fragilis* were proposed as indicators, but their usefulness was not conclusively proven. On the other hand, phages of many types proved useful as tracers of groundwater movements.
3. Phages were harnessed for the detection of bacteria, particularly by the construction of 'reporter' phages carrying luminescent (luciferase) genes, which are expressed when these phages infect a bacterium.
4. In biotechnology, phages are used as cloning and sequencing vectors, notably the filamentous phage M13 *(Inoviridae)*, phages λ and P1, and hybrids of phages and plasmids (named 'cosmids' or 'phagemids'). Phage products such as T4 ligase and T7 promoters are used in cloning reactions and phage lysozymes are used to free useful intracellular bacterial enzymes.
5. The technique of 'phage display', introduced in 1985, mainly uses filamentous phages (M13, fd). Foreign peptide genes are fused to phage coat proteins. This

powerful technique led to the development of antibody technology and has many medical and pharmaceutical applications.

6. Phage therapy reappeared. In France, it had always been practiced on a small scale. In the mid-1980s, a team in Wroclaw, Poland, conducted phage treatments of various human diseases (mainly pyogenic infections). After the fall of communism, the West learned with surprise that phage therapy had been practiced in the Soviet Union since the 1940s and that the institute founded in Tbilisi par d'Herelle and Eliava produced phages for the Soviet Union with up to 1200 employees engaged in production. Phage therapy is still practiced in Georgia.

Phage Ecology

1. Marine phages were investigated worldwide, including Arctic and Antarctic waters, largely by electron microscopy and the novel epifluorescence technique. Marine phages were found in vast numbers and appeared as part of a food web of phages, bacteria, and flagellates. Many marine phages were cyanophages and, all those investigated so far have tailed particles. Sequencing of uncultured virus DNA ('metagenomics') detected known entities such as T7-like phages and showed that only 25% of sequences matched known genes. Seawater appears as an immense phage reservoir (**Table 5**).
2. Phages were sought and found in extreme habitats such as volcanic hot springs, alkaline lakes, or hypersaline lagoons. This led to the discovery of several families of archaeal viruses (**Table 2**).

History of Virology: Plant Viruses

R Hull, John Innes Centre, Norwich, UK

© 2008 Elsevier Ltd. All rights reserved.

Introduction

History shows that the study of virus infections of plants has led the overall subject of virology in the development of several major concepts including that of the entity of viruses themselves. To obtain a historical perspective of plant virology, five major (overlapping) ages can be recognized.

Prehistory

The earliest known written record describing what was almost certainly a plant virus disease is a poem in Japanese written by the Empress Koken in AD 752 and translated by T. Inouye as follows:

> In this village
> It looks as if frosting continuously
> For, the plant I saw
> In the field of summer
> The color of the leaves were yellowing

The plant, identified as *Eupatorium lindleyanum*, has been found to be susceptible to tomato yellow leafcurl virus, which causes a yellowing disease.

In Western Europe in the period from about 1600 to 1660, many paintings and drawings were made of tulips that demonstrate flower symptoms of virus disease. These are recorded in the Herbals of the time and in the still-life paintings of artists such as Johannes Bosschaert in 1610. During this period, blooms featuring such striped patterns were prized as special varieties leading to the phenomenon of 'tulipomania'. The trade in infected tulip bulbs resulted in hyperinflation with bulbs exchanging hands for large amounts of money or goods (**Table 1**).

In describing an experiment to demonstrate that sap flows in plants, Lawrence reported in 1714 the unintentional transmission of a virus disease of jasmine by grafting. The following quotation from Blair in 1719 describes the procedure and demonstrates that even in this proto-scientific stage, experimenters were already indulging in arguments about priorities of discovery.

> The inoculating of a strip'd Bud into a plain stock and the consequence that the Stripe or Variegation shall be seen in a few years after, all over the shrub above and below the graft, is a full demonstration of this Circulation of the Sap. This was first observed by Mr. Wats at Kensington, about 18 years ago: Mr. Fairchild performed it 9 years ago; Mr. Bradly says he observ'd it several years since; though Mr. Lawrence would insinuate as if he had first discovered it.

Recognition of Viral Entity

In the latter part of the nineteenth century, the idea that infectious disease was caused by microbes was well established, and filters were available that would not allow the passage of known bacterial pathogens. Mayer in 1886 showed that a disease of tobacco (*Mosaikkrankheit*; now

Table 1 Tulipomania: the goods exchanged for one bulb of Viceroy tulip

4 t of wheat	4 barrels of beer
8 t of rye	2 barrels of butter
4 fat oxen	1000 lb cheese
8 fat pigs	1 bed with accessories
12 fat sheep	1 full dress suit
2 hogsheads of wine	1 silver goblet

known to be caused by tobacco mosaic virus; TMV) could be transmitted to healthy plants by inoculation with extracts from diseased plants; Iwanowski demonstrated in 1892 that sap from such tobacco plants was still infective after it had been passed through a bacteria-proof filter candle. This work did not attract much attention until it was repeated by Beijerinck who in 1898 described the infectious agent as *contagium vivum fluidum* (Latin for contagious living fluid) to distinguish it from contagious corpuscular agents. Beijerinck's discovery is considered to be the birth of virology. In 1904 Baur showed that an infectious variegation of *Abutilon* could be transmitted by grafting, but not by mechanical inoculation. Beijerinck and Baur used the term 'virus' in describing the causative agents of these diseases, to contrast them with bacteria; this term had been used as more or less synonymous with bacteria by earlier workers. As more diseases of this sort were discovered, the unknown causative agents came to be called 'filterable viruses'.

Between 1900 and 1935, many plant diseases thought to be caused by filterable viruses were described, but considerable confusion arose because adequate methods for distinguishing one virus from another had not yet been developed.

The original criterion of a virus was an infectious entity that could pass through a filter with a pore size small enough to hold back all known cellular agents of disease. However, diseases were soon found that had virus-like symptoms not associated with any pathogen visible in the light microscope, but that could not be transmitted by mechanical inoculation. With such diseases, the criterion of filterability could not be applied. Their infectious nature was established by graft transmission and sometimes by insect vectors. Thus, certain diseases of the yellows and witches'-broom type, such as aster yellows, came to be attributed to viruses on quite inadequate grounds. Many such diseases are now known to be caused by phytoplasma or spiroplasma, and a few by bacteria or rickettsia.

The Biological Age

During most of the period between 1900 and 1935, attention was focused on the description of diseases using the macroscopic symptoms and cytological abnormalities as revealed by light microscopy, host ranges, and methods of transmission which were the only techniques available. The influence of various physical and chemical agents on virus infectivity was investigated, but methods for the assay of infective material were primitive. Holmes showed that the local lesions produced in some hosts following mechanical inoculation could be used for the rapid quantitative assay of infective virus. This technique enabled properties of viruses to be studied much more readily and paved the way for the isolation and purification of viruses a few years later. Until about 1930, there was serious confusion by most workers regarding the diseases produced by viruses and the viruses themselves. This was not surprising, since virtually nothing was known about the viruses except that they were very small. In 1931 Smith made an important contribution that helped to clarify this situation. Working with virus diseases in potato, he realized the necessity of using plant indicators, plant species other than potato, which would react differently to different viruses present in potatoes. Using several different and novel biological methods to separate the viruses, he was able to show that many potato virus diseases were caused by a combination of two viruses with different properties, which he named virus X (potato virus X, PVX) and virus Y (potato virus Y, PVY). As PVX was not transmitted by the aphid *Myzus persicae*, whereas PVY was, PVY could be separated from PVX. He obtained PVX free of PVY by needle inoculation of the mixture to *Datura stramonium* which does not support PVY. Furthermore, Smith observed that PVX from different sources fluctuated markedly in the severity of symptoms it produced in various hosts leading to the concept of strains.

An important practical step forward was the recognition that some viruses could be transmitted from plant to plant by insects. Fukushi recorded the fact that in 1883 a Japanese rice grower transmitted what is now known to be rice dwarf virus, RDV) by the leafhopper *Recelia dorsalis*. However, this work was not published in any available form and so had little influence. In 1922 Kunkel first reported the transmission of a virus by a planthopper; within a decade, many insects were reported to be virus vectors leading to the recognition of specific virus–vector interactions.

Since Fukushi first showed in 1940 that RDV could be passed through the egg of a leafhopper vector for many generations, there has been great interest in the possibility that some viruses may be able to replicate in both plants and insects. It is now well established that plant viruses in the families *Rhabdoviridae* and *Reoviridae* and the genera *Tenuivirus*, *Tospovirus*, and *Marafivirus* multiply in insects as well as in plants.

The Biochemical/Biophysical Age

Beale's recognition in 1928 that plants infected with TMV contained a specific antigen opened the age in which the

biochemical nature of viruses was elucidated. In the 1930s Gratia showed that plants infected with different viruses contained different specific antigens and Chester demonstrated that different strains of TMV and PVX could be distinguished serologically.

The high concentration at which certain viruses occur in infected plants and their relative stability turned out to be of crucial importance in the first isolation and chemical characterization of viruses, because methods for extracting and purifying proteins were not highly developed. In the early 1930s, various attempts were made to isolate and purify plant viruses using methods similar to those that had just been developed for purifying enzymes. Following detailed chemical studies suggesting that the infectious agent of TMV might be a protein, Stanley announced in 1935 the isolation of this virus in an apparently crystalline state. At first Stanley considered that the virus was a globulin containing no phosphorus but in 1936 Bawden *et al.* described the isolation from TMV-infected plants of a liquid crystalline nucleoprotein containing nucleic acid of the pentose type. They showed that the particles were rod-shaped, thus confirming the earlier suggestion of Takahashi and Rawlins based on the observation that solutions containing TMV showed anisotropy of flow. Electron microscopy and X-ray crystallography were the major techniques used in early work to explore virus structure, and the importance of these methods has continued to the present day. Bernal and Fankuchen applying X-ray analysis to purified preparations of TMV obtained accurate estimates of the width of the rods. The isolation of other rod-shaped viruses, and spherical viruses that formed crystals, soon followed. All were shown to consist of protein and pentose nucleic acid.

Early electron micrographs confirmed that TMV was rod-shaped and provided approximate dimensions, but they were not particularly revealing because of the lack of contrast between the virus particles and the supporting membrane. The application of shadow-casting with heavy metals greatly increased the usefulness of the method for determining the overall size and shape of virus particles but not structural detail. With the development of high-resolution microscopes and of negative staining in the 1950s electron microscopy became an important tool for studying virus substructure. From a comparative study of the physicochemical properties of the virus nucleoprotein and the empty viral protein shell found in TYMV preparations, Markham concluded in 1951 that the RNA of the virus must be held inside a shell of protein, a view that has since been amply confirmed for this and other viruses by X-ray crystallography. Crick and Watson suggested that the protein coats of small viruses are made up of numerous identical subunits arrayed either as helical rods or as a spherical shell with cubic symmetry. Subsequent X-ray crystallographic and chemical work has confirmed this view. Caspar and Klug formulated a general theory that delimited the possible numbers and arrangements of the protein subunits forming the shells of the smaller isodiametric viruses.

Until about 1948, most attention was focused on the protein part of the viruses. Quantitatively, the protein made up the larger part of virus preparations. Enzymes that carried out important functions in cells were known to be proteins, and knowledge of pentose nucleic acids was rudimentary. No function was known for them in cells, and they generally were thought to be small molecules primarily because it was not recognized that RNA is very susceptible to hydrolysis by acid, by alkali, and by enzymes that commonly contaminate virus preparations. In 1949 Markham and Smith isolated turnip yellow mosaic virus (TYMV) and showed that purified preparations contained two classes of particles, one an infectious nucleoprotein with about 35% of RNA, and the other an apparently identical protein particle that contained no RNA and that was not infectious. This result clearly indicated that the RNA of the virus was important for biological activity. Analytical studies showed that the RNAs of different viruses have characteristically different base compositions while those of related viruses are similar. About this time, it came to be realized that viral RNAs might be considerably larger than had been thought. A synthetic analog of the normal base guanine, 8-azaguanine, when supplied to infected plants was incorporated into the RNA of TMV and TYMV, replacing some of the guanine. The fact that virus preparations containing the analog were less infectious than normal virus gave further experimental support to the idea that viral RNAs were important for infectivity. However, it was the classic experiments in the mid-1950s of Gierer and Schramm, and Fraenkel-Conrat and Williams that demonstrated the infectivity of naked TMV RNA and the protective role of the protein coat. These discoveries ushered in the era of modern plant virology.

In the early 1950s Brakke developed density gradient centrifugation as a method for purifying viruses. Together with a better understanding of the chemical factors affecting the stability of viruses in extracts, this procedure has allowed the isolation and characterization of many viruses. The use of sucrose density gradient fractionation enabled Lister to discover the bipartite nature of the tobacco rattle virus genome. Since that time, density gradient and polyacrylamide gel fractionation techniques have allowed many viruses with multipartite genomes to be characterized. Their discovery, in turn, opened up the possibility of carrying out genetic reassortment experiments with plant viruses leading to the allocation of functions to many of the viral genes. Density gradient fractionation of purified preparations of some other viruses revealed noninfectious nucleoprotein particles containing subgenomic RNAs. Other viruses have been found to have associated with them satellite viruses or satellite RNAs that depend on the 'helper' virus for some function required during replication.

Further developments in the 1970s included improved techniques related to X-ray crystallographic analysis and a growing knowledge of the amino acid sequences of the coat proteins allowed the three-dimensional structure of the protein shells of several plant viruses to be determined in molecular detail.

For some decades, the study of plant virus replication had lagged far behind that of bacterial and vertebrate viruses mainly because there was no plant system in which all the cells could be infected simultaneously to provide the basis for synchronous 'one-step growth' experiments. However, following the initial experiments of Cocking in 1966, Takebe and colleagues developed protoplast systems for the study of plant virus replication. Although these systems had significant limitations, they greatly increased our understanding of the processes involved in plant virus replication.

Another important technical development has been the use of *in vitro* protein-synthesizing systems such as that from wheat germ, in which many plant viral RNAs act as efficient messengers. Their use allowed the mapping of plant viral genomes by biochemical means to begin.

The Molecular Biology Age

The molecular age opened in 1960 with the determination of the full sequence of 158 amino acids in the coat protein of TMV. The sequence of many naturally occurring strains and artificially induced mutants was also determined at about the same time. This work made an important contribution to establishing the universal nature of the genetic code and to our comprehension of the chemical basis of mutation.

Our understanding of the genome organization and functioning of viruses has come from the development of procedures whereby the complete nucleotide sequence of viruses with RNA genomes can be determined. In 1982 the genomes of both the first plant RNA virus (TMV) and DNA virus cauliflower mosaic virus (CaMV) were sequenced. Since then, the genomes of representatives of all the plant virus genera have been sequenced and there are many sequences of virus species.

The late 1980s and 1990s was a period when molecular biological techniques were applied to a wide range of aspects of plant virology. These included the ability to prepare *in vitro* infectious transcripts of RNA viruses derived from cloned viral cDNA allowing techniques such as site-directed mutagenesis to be applied to the study of genome function and reverse genetics being used to elucidate the functions of viral genes and control sequences. These approaches, together with others such as yeast systems for identifying interacting molecules, the expression of viral genes in transgenic plants, and labeling viral genomes in such a manner that their sites of function within the cell are known, were revealing the complexities of the interactions between viruses and their hosts. Nucleotide sequence information has had, and continues to have, a profound effect on our understanding of many aspects of plant virology, including (1) the location, number, and size of the genes in a viral genome; (2) the amino acid sequence of the known or putative gene products; (3) the molecular mechanisms whereby the gene products are transcribed; (4) the putative functions of a gene product, which can frequently be inferred from amino-acid-sequence similarities to products of known function encoded by other viruses; (5) the control and recognition sequences in the genome that modulate expression of viral genes and genome replication; (6) the understanding of the structure and replication of viroids and of the satellite RNAs found associated with some viruses; (7) the molecular basis for variability and evolution in viruses, including the recognition that recombination is a widespread phenomenon among RNA viruses and that viruses can acquire host nucleotide sequences as well as genes from other viruses; and (8) the beginning of a taxonomy for viruses that is based on evolutionary relationships. On the host side, advances in plant genome sequencing are identifying plant genes that confer resistance to viruses.

During the 1980s, major advances were made on improved methods of diagnosis for virus diseases, centering on serological procedures and on methods based on nucleic acid hybridization. Since the work of Clark and Adams reported in 1977, the enzyme-linked immunosorbent assay (ELISA) technique has been developed with many variants for the sensitive assay and detection of plant viruses. Monoclonal antibodies against TMV lead to a very rapid growth in their use for many kinds of plant virus research and for diagnostic purposes. The late 1970s and the 1980s also saw the start of application of the powerful portfolio of molecular biological techniques to developing other approaches to virus diagnosis, to a great increase in our understanding of the organization and strategy of viral genomes, and to the development of techniques that promise novel methods for the control of some viral diseases. The use of nucleic acid hybridization procedures for sensitive assays of large numbers of samples and the polymerase chain reaction, also dependent on detailed knowledge of genome sequences, are being increasingly used in virus diagnosis. Most recently DNA chips are being developed for both virus diagnostics and studying virus infection.

In the early 1980s, it seemed possible that some plant viruses, when suitably modified by the techniques of gene manipulation, might make useful vectors for the introduction of foreign genes into plants. Some plant viruses have been found to contain regulatory sequences that can be very useful in other gene vector systems, notably the widely used CaMV 35S promoter. Another practical application of molecular techniques to plant viruses has

been the modification of viral genomes so that products of interest to industry and medicine can be produced in plants. This is being done either by the introduction of genes into the viral genome or by modification of the coat protein sequence to enable epitopes to be presented on the virus.

Early attempts (early to mid-1900s) to control virus diseases in the field were often ineffective. They were mainly limited to attempts at general crop hygiene, roguing of obviously infected plants, and searching for genetically resistant lines. Developments since this period have improved the possibilities for control of some virus diseases. Heat treatments and meristem tip culture methods have been applied to an increasing range of vegetatively propagated plants to provide a nucleus of virus-free material that then can be multiplied under conditions that minimize reinfection. Such developments frequently have involved the introduction of certification schemes. Systemic insecticides, sometimes applied in pelleted form at the time of planting, provide significant protection against some viruses transmitted in a persistent manner by aphid vectors. It has become increasingly apparent that effective control of virus disease in a particular crop in a given area usually requires an integrated and continuing program involving more than one kind of control measure.

However, such integrated programs are not yet in widespread use. Cross-protection (or mild-strain protection) is a phenomenon in which infection of a plant with a mild strain of a virus prevents or delays infection with a severe strain. The phenomenon has been used with varying success for the control of certain virus diseases, but the method has various difficulties and dangers. In 1986 Powell-Abel and co-workers considered that some of these problems might be overcome by the application of the concept of pathogen-derived resistance of Sandford and Johnston. Using recombinant DNA technology, they showed that transgenic tobacco plants expressing the TMV coat-protein gene either escaped infection following inoculation or showed a substantial delay in the development of systemic disease. These transgenic plants expressed TMV coat-protein mRNA as a nuclear event. Seedlings from self-fertilized transformed plants that expressed the coat protein showed delayed symptom development when inoculated with TMV. Thus, a new approach to the control of virus diseases emerged. However, this approach revealed some unexpected results which led to the recognition that plants have a defense system against 'foreign' RNA. This defense system, initially termed post-translational gene silencing and now called RNA silencing or RNA interference (RNAi) was first recognized in plants and had, and is still having, a great impact on molecular approaches as diverse as disease control and understanding gene functions. Among the tools that have arisen from understanding this new phenomenon is virus-induced gene silencing which is being used to determine the functions of genes in plants and animals by turning them off.

However, the RNAi defense system in plants which targets double-stranded RNA, an intermediate RNA virus replication, raised the question of how RNA viruses replicated in plants. Studies on gene functions revealed that many plant viruses contain so-called 'virulence' genes. Many of these have been shown to suppress host RNA silencing, thus overcoming the defense system. Suppression of gene silencing is widespread among plant viruses and examples are being found in animal viruses. Thus, as noted at the beginning of this article, plant virology is still providing insights onto phenomena applicable to virology in general.

Introduction

As in other branches of experimental science, the development of our knowledge of viruses has depended on the techniques available. Initially, viruses were studied by pathologists interested in the causes of the infectious diseases of man and his domesticated animals and plants and these concerns remain the main force advancing the subject. The idea that viruses might be used to probe fundamental problems of biology arose in the early 1940s, with the development of the knowledge of bacterial viruses. These studies helped establish the new field of molecular virology in the period 1950–70, and this has revolutionized the study of viruses and led to an explosion of knowledge about them.

The Word Virus

Since antiquity the term virus had been synonymous with poison, but during the late nineteenth century it became a synonym for microbe (Pasteur's word for an infectious agent). It did not acquire its present connotation until the 1890s, after the bacterial or fungal causes of many infectious diseases had been discovered, using the agar plate, effective staining methods, and efficient microscopes. It then became apparent that there were a number of infectious diseases of animals and plants from which no bacterium or fungus could be isolated or visualized with the microscope. After the introduction in 1884 of the Chamberland filter, which held back bacteria, Loeffler and Frosch demonstrated that the cause of foot-and-mouth disease was a filterable (or ultramicroscopic) virus. The first compendium of all then known viruses was edited by T. M. Rivers of the Rockefeller Institute and published in 1928. Entitled *Filterable Viruses,* this emphasized that viruses required living cells for their multiplication. In the 1930s chemical studies of the particles of tobacco mosaic virus and of bacteriophages showed that they differed from all cells in that at their simplest they consisted of protein and nucleic acid, which was either DNA or RNA. Gradually, the adjectives filterable and ultramicroscopic were dropped and the word viruses developed its present connotation.

Early Investigations

Foot-and-Mouth Disease Virus

In 1898 F. J. Loeffler and P. Frosch described the filterability of an animal virus for the first time, noting that "the filtered material contained a dissolved poison of extraordinary power or that the as yet undiscovered agents of an infectious disease were so small that they were able to pass through the pores of a filter definitely capable of retaining the smallest known bacteria." Although the causative agent of foot-and-mouth disease passed through a Chamberland-type filter, it did not go through a Kitasato filter which had a finer grain. This led to the conclusion that the causative virus, which was multiplying in the host, was a corpuscular particle. Loeffler and Frosch gave filtration a new emphasis by focussing attention on what passed-through the filter rather than what was retained and established an experimental methodology which was widely adopted in the early twentieth century in research on viral diseases.

Yellow Fever Virus

Following the acceptance of the notion of filterable infectious agents, pathologists investigated diseases from which no bacteria could be isolated and several were soon shown to be caused by viruses. One of the most fruitful investigations, in terms of new concepts, was the work of the United States Army Yellow Fever Commission headed by Walter Reed in 1900–01. Using human volunteers, they demonstrated that yellow fever was caused by a filterable virus which was transmitted by mosquitoes and that the principal vector was *Aedes aegypti.* They also showed that infected persons were infectious for mosquitoes only during the first few days of the disease and that mosquitoes were not infectious until 7–10 days after imbibing infectious blood, thus defining the extrinsic incubation period and establishing essentially all of the basic principles of the epidemiology of what came to be called arboviruses (arthropod-borne viruses).

Physical Studies of Viruses

Further advances in understanding the nature of viruses depended on physical and chemical studies. As early as 1907 H. Bechhold in Germany developed filters of graded permeabilities and a method of determining their pore size. Subsequently, W. J. Elford, in London, used such membranes for determining the size of animal virus particles with remarkable accuracy.

In Germany, on the eve of World War II, H. Ruska and his colleagues had produced electron microscopic photographs of the particles of tobacco mosaic virus,

bacteriophages, and poxviruses. Technical improvements in instrumentation after the war, and the introduction of negative staining for studying the structure of viruses by Cambridge scientists H. E. Huxley in 1957 and S. Brenner and R. W. Horne in 1959 resulted in photographs of the particles of virtually every known kind of virus. These demonstrated the variety of their size, shape, and structure, and the presence of common features such as the icosahedral symmetry of many viruses of animals.

Following a perceptive paper on the structure of small virus particles by F. H. C. Crick and J. D. Watson in 1956, in 1962 D. L. D Caspar of Boston and A. Klug of Cambridge, England, produced a general theory of the structure of regular virus particles of helical and icosahedral symmetry. Structure of the virus particle became one of the three major criteria in the system of classification of viruses that was introduced in 1966.

The Chemical Composition of Viruses

If the ultramicroscopic particles found in virus-infected hosts were the pathogens, what did these particles consist of? Following observations on plant and bacterial viruses in 1935, in 1940 C. L. Hoagland and his colleagues at the Rockefeller Institute found that vaccinia virus particles contained DNA but no RNA. Thus evidence was accumulating that viruses differed from bacteria not only in size and their inability to grow in lifeless media, but in that they contained only one kind of nucleic acid, which could be either DNA or RNA.

The development of restriction-endonuclease digestion of DNA, based on studies of phage restriction by W. Arber (Nobel Prize, 1978) of Basel in the 1960s, and then elaborated by biochemist H. O. Smith of Baltimore in 1970, has simplified the mapping of the genomes of DNA viruses, a study initiated by D. Nathans (Nobel Prize, 1978), also of Baltimore, using Simian virus 40. The development of the polymerase chain reaction in 1985 by K. B. Mullis (Nobel Prize, 1993) revolutionized sequencing methods for both DNA and RNA, leading to the availability of the complete genomic sequences of most viruses and the ability to make diagnoses using minute amounts of material.

Investigations of bacterial viruses were motivated by scientific curiosity, but animal virology was developed by pathologists studying the large number of diseases of humans and livestock caused by viruses, and it has retained this practical bias. Over the first two decades of the twentieth century, testing of filtrates of material from a number of infected humans and animals confirmed that they were caused by viruses. Among the most important was the demonstration in 1911 by P. Rous (Nobel Prize, 1966), at the Rockefeller Institute, that a sarcoma of fowls could be transmitted by a bacteria-free filtrate.

The Cultivation of Animal Viruses

The first systematic use of small animals for virus research was Pasteur's use of rabbits, which he inoculated intracerebrally with rabies virus in 1881. It was not until 1930 that mice were used for virus research, with intracerebral inoculations of rabies and yellow fever viruses. By using graded dilutions and large numbers of mice, quantitative animal virology had begun. The next important step, initiated by E. W. Goodpasture in 1931–32, was the use of chick embryos for growing poxviruses. This was followed a few years later by the demonstration by F. M. Burnet that many viruses could be titrated by counting the pocks that they produced on the chorioallantoic membrane, whereas others grew well in the allantoic and/or amniotic cavities of developing chick embryos.

Tissue cultures had first been used for cultivating vaccinia virus in 1928, but it was the discovery by J. F. Enders, T. H. Weller, and F. C. Robbins of Harvard University (Nobel Prize, 1954) in 1949 that poliovirus would grow in non-neural cells that gave a tremendous stimulus to the use of cultured cells in virology. Over the next few years their use led to the cultivation of medically important viruses such as those causing measles (by J. F. Enders and T. C. Peebles in 1954) and rubella (by T. H. Weller and F. C. Neva in 1962). Even more dramatic was the isolation of a wide variety of new viruses, belonging to many different families. Also the different cytopathic effects produced by different viruses in monolayer cell cultures were found to be diagnostic.

The next great advance, which greatly increased the accuracy of quantitative animal virology, occurred in 1952, when the plaque assay method for counting phages was adapted to animal virology by R. Dulbecco (Nobel Prize, 1975), using a monolayer of chick embryo cells in a petridish. In 1958 H. Temin and H. Rubin applied Dulbecco's method to Rous sarcoma virus, initiating quantitative studies of tumor viruses. Biochemical studies of animal virus replication were simplified by using continuous cell lines and by growing the cells in suspension.

Biochemistry

During the 1950s virus particles were thought to be 'inert' packages of nucleic acid and proteins, although in 1942 G. K. Hirst of the Rockefeller Institute had shown that particles of influenza virus contained an enzyme, later identified by A. Gottschalk of Melbourne as a neuraminidase.

Further advances in viral biochemistry depended on methods of purification of virus particles, especially the technique of density gradient centrifugation. In 1967 J. Kates and B. R. McAuslan demonstrated the presence of a DNA-dependent RNA polymerase in purified vaccinia

virus virions, a discovery that was followed the next year by the demonstration of a double-stranded (ds) RNA-dependent RNA polymerase in reovirus virions and then of single-stranded (ss) RNA-dependent RNA polymerases in virions of paramyxoviruses and rhabdoviruses. In 1970 came the revolutionary discovery by D. Baltimore of Boston (Nobel Prize, 1975) and H. Temin of Wisconsin (Nobel Prize, 1975), independently, of the RNA-dependent DNA polymerase, or reverse transcriptase, of Rous sarcoma virus. Many other kinds of enzymes were later identified in the larger viruses; for example, no less than 16 enzymes have now been identified in vaccinia virus virions.

Just as investigations with bacterial viruses were of critical importance in the development of molecular biology, studies with animal viruses have led to the discovery of several processes that have proved to be important in the molecular biology of eukaryotic cells, although many of these discoveries are too recent for serious historical appraisal. Thus, in 1968 M. Jacobson and D. Baltimore of Boston showed that the genomic RNA of poliovirus was translated as a very large protein, which was then cleaved by a protease that was subsequently found in the viral replicase gene. RNA splicing was discovered in 1977, independently by P. A. Sharp (Nobel Prize, 1993) and L. T. Chow and their respective colleagues during studies of adenovirus replication. Work with the same virus by Rekosh and colleagues in London in 1977 resulted in the definition of viral and cell factors for initiation of new DNA strands using a novel protein priming mechanism. Capping of mRNA by m^7G and its role in translation was discovered in 1974, during work with reoviruses by A. J. Shatkin. Other processes first observed with animal viruses and now known to be important in eukaryotic cells were the existence of 3′ poly A tracts on mRNAs, the pathway for synthesis of cell surface proteins, and the role of enhancer elements in transcription.

Analysis of viral nucleic acids progressed in parallel with that of the viral proteins. Animal viruses were found with genomes of ssRNA, either as a single molecule, two identical molecules (diploid retroviruses), or segmented; dsRNA; ssDNA, dsDNA, and partially dsDNA. The so-called unconventional viruses or prions of scrapie, kuru, and Creutzfeld–Jacob disease, which have been extensively investigated since 1957 by D. C. Gajdusek of the US National Institutes of Health (Nobel Prize, 1976) and S. B. Prusiner of the University of California at San Francisco (Nobel Prize, 1997), appear to be infectious proteins. Soon after the discovery that the isolated nucleic acid of tobacco mosaic virus was infectious (see below), it was shown that the genomic RNAs of viruses belonging to several families of animal viruses were infectious; namely those with single, positive-sense RNA molecules. Then in 1973 came the discovery of recombinant DNA by P. Berg of Stanford University and his colleagues, using the animal virus SV40 and bacteriophage l.

Structure of the Virion

Using more sophisticated methods of electron microscopy, many animal virus virions have been shown to be isometric icosahedral structures, or roughly spherical protein complexes surrounded by a lipid-containing shell, the envelope, which contains a number of virus-coded glycoprotein spikes. X-ray crystallography of crystals of purified isometric viruses has revealed the molecular structure of their icosahedra; similar revealing detail has been obtained for the neuraminidase and hemagglutinin spikes of influenza virus.

Tumor Virology

After the discovery of Rous sarcoma virus in 1911, there was a long interval before the second virus to cause tumors, rabbit papilloma virus, was discovered by R. E. Shope in 1933. However, after that viruses were found to cause various neoplasms in mice, and in 1962 J. J. Trentin of Yale University showed that a human adenovirus would produce malignant tumors in hamsters. Since then, direct proof has been obtained that several DNA viruses (but not adenoviruses) and certain retroviruses can cause tumors in humans. Molecular biological studies have shown that oncogenicity is largely caused by proteins they produce that are encoded by viral oncogenes, a concept introduced by R. J. Huebner and G. Todaro of the US National Institutes of Health in 1969 and corrected, refined, and greatly expanded since the mid-1970s by J. M. Bishop, H. Varmus (Nobel Prize, 1989), and R. A. Weinberg of Boston.

Only one group of RNA viruses, the retroviruses, which replicate through an integrated DNA provirus, cause neoplasms, whereas viruses of five groups of DNA viruses are tumorigenic. Study of these oncogenic viruses has shed a great deal of light on the mechanisms of carcinogenesis. Oncogenic DNA viruses contain oncogenes as an essential part of their genome, which when integrated into the host cell DNA may promote cell transformation, whereas the oncogenes of retroviruses are derived from proto-oncogenes of the cell.

Impact on Immunology

Immunology arose as a branch of microbiology and several discoveries with animal viruses were important in the development of important concepts in immunology. It was the discovery in the 1930s by E. Traub in Tübingen of persistent infection of mice with lymphocytic choriomeningitis virus that led to the development by F. M. Burnet (Nobel Prize, 1960) of the concept of immunological tolerance in 1949. It was work with the same

virus that led to the discovery of MHC restriction by P. C. Doherty and R. Zinkernagel in Canberra (Nobel Prize, 1996) in 1974.

Vaccines and Disease Control

From the time of Pasteur's use of rabies vaccine in 1885, a major concern of medical and veterinary virologists has been the development of vaccines. Highlights in this process have been the development of the 17D strain of yellow fever virus by M. Theiler (Nobel Prize, 1951) of the Rockefeller Foundation laboratories in 1937, the introduction of influenza vaccine in 1942, based on Burnet's 1941 discovery that the virus would grow in the allantois, the licensing in 1954 of inactivated poliovaccine developed by J. Salk and in 1961 of the live poliovaccine introduced by A. B. Sabin, both based on the cultivation of the virus in 1949 by Enders, and development of the first genetically engineered human vaccine with the licensing of yeast-grown hepatitis B vaccine in 1986. Finally, 1977 saw the last case of natural smallpox in the world and thus the first example of the global eradication of a major human infectious disease, the result of a 10-year campaign conducted by the World Health Organization with a vaccine directly derived from Jenner's vaccine, first used in 1796.

Recognition of HIV-AIDS

In 1981 a new disease was described in the male homosexual populations of New York, San Francisco, and Los Angeles. It destroyed the immune system, and the disease was called the acquired immune deficiency syndrome (AIDS) and the causal virus, human immunodeficiency virus (HIV), a retrovirus, was first isolated by L. Montagnier, of the Pasteur Institute in Paris, in 1983. A sexually transmitted disease, it has now spread all over the world, with about 40 million cases worldwide, and without very expensive chemotherapy is almost always fatal. It is now clear that it arose from an inapparent but persistent infection of chimpanzees in Africa. In spite of enormous efforts over the past 20 years, it has so far been impossible to devise an effective vaccine.

Arthropod-Borne Viruses of Vertebrates

Arthropods, mainly insects and ticks, were early shown to be important as vectors of virus diseases of vertebrates (the arboviruses) and of plants. Sometimes, as in myxomatosis, carriage was found to be mechanical, but in most cases the virus was found to multiply in the vector as well as the vertebrate concerned. The development of methods of growing insect cells in culture by T. D. C. Grace in Canberra in 1962 opened the way for the molecular biological investigation of the replication of insect viruses and arboviruses in invertebrate cells.

Taxonomy and Nomenclature

After earlier tentative efforts with particular groups of viruses, viral nomenclature took off in 1948, with the production of a system of latinized nomenclature for all viruses by the plant virologist F. O. Holmes. This stimulated others, in particular C. H. Andrewes of London and A. Lwoff of Paris, to actions which resulted in the setting up of an International Committee on Nomenclature (later Taxonomy) of Viruses in 1966. Adopting the kind of viral nucleic acid, the strategy of replication, and the morphology of the virion as its primary criteria, this committee has now achieved acceptance of its decisions by the great majority of virologists. One interesting feature of its activities is that its rules avoid the controversies about priorities that plague taxonomists working with fungi, plants, and animals.

The Future

The future will see an explosive expansion of understanding and knowedge of viruses of vertebrates, with the application of techniques of genetic engineering, nucleic acid sequencing, the polymerase chain reaction, and the use of monoclonal antibodies. All these discoveries are addressed in the appropriate sections of this encyclopedia. Molecular biology, which was initially conceived during studies of bacterial viruses, is now being used to study all the viruses of vertebrates and the pathogenesis and epidemiology of animal viral diseases. The expansion in knowledge of these subjects in the next decade can be expected to exceed that of the previous century.

Hordeivirus

J N Bragg, H-S Lim, and A O Jackson, University of California, Berkeley, Berkeley, CA, USA

© 2008 Elsevier Ltd. All rights reserved.

Introduction

Hordeiviruses represent a unique genus of serologically related viruses with rigid rods that are composed of 96% protein and 4% RNA. Although members of the hordeiviruses have similar particle structure, they collectively infect both monocots and dicots and exhibit considerable biological diversity. The type member of the group, barley stripe mosaic virus (BSMV), has been known to cause serious worldwide disease problems in cultivated barley for more than 75 years, but during this time has been isolated only infrequently from wheat and wild oats. Because of the yield losses caused in barley, a number of strains of the virus have been isolated and their biological properties evaluated. The survival of BSMV in nature depends solely on direct plant-to-plant contact and seed transmission; consequently, virus spread can be prevented by planting virus-free seed. The advent of sensitive virus detection methods has permitted seed to be screened prior to planting, thus virus-free seed production has resulted in eradication of the virus in most areas of North America and Europe.

In addition to *Barley stripe mosaic virus*, three additional species, *Poa semilatent virus* (PSLV), *Lychnis ringspot virus* (LRSV), and *Anthoxanthum latent blanching virus* (ALBV) have been included in the genus *Hordeivirus* in the *Eighth Report of the International Committee on Taxonomy of Viruses.* This assignment is based on serological relatedness of the coat proteins, genome organization, and sequence relatedness of BSMV, LRSV, and PSLV. The coat proteins of BSMV, PSLV, and LRSV are the same size, but have different mobilities on polyacrylamide gels and are distantly related serologically. Serology and analyses of the coat protein sequences indicate that BSMV and PSLV are more closely related to each other than to LRSV. Serological studies also show that ALBV is closely related to BSMV, and may be a strain of BSMV. However, ALBV has not been investigated by hybridization or sequence analysis to determine whether it is a strain of BSMV or is a distinct virus.

PSLV has been recovered on two occasions from native grasses in Canada from widely separated locations, so the virus may be relatively abundant among members of the Poaceae in Western Canada. LRSV was first isolated from *Lychnis divaricata* seeds imported into the USA, and an additional LRSV strain, Mentha, has been isolated in Hungary. ABLV has been described only in Britain and little is known about its biological or biochemical properties. As is the case with BSMV, LRSV is highly seed transmitted, but seed transmission has not been reported for PSLV or ABLV. There are no known biological vectors for the four viruses, but all reach high concentrations in infected plants and are easily transmitted from plant to plant by mechanical contact.

In addition to their limited range of natural hosts, the experimental hosts of hordeiviruses have been expanded substantially by mechanical inoculation. BSMV has been shown to infect several monocots and a few dicots. Local lesions on *Chenopodium* species have been used for several genetic studies of BSMV disease phenotype, and systemic infections in *Nicotiana benthamiana* have provided a basis for analyses of movement functions and RNA silencing. PSLV also infects numerous species of the Poaceae and several dicots, while LRSV has been shown to infect several experimental dicot hosts, including members of the families. Caryophyllaceae and Labiatae. Reverse genetic systems for BSMV, PSLV, and LRSV have resulted in considerable information about biological properties of the viruses and the molecular biology of infection processes.

Genome Structure and Expression

Hordeivirus genomes are composed of three RNAs that have been designated α, β, and γ based on hybridization patterns of the RNAs. The sizes of the BSMV α, β, and γ genomic (g) RNAs vary between strains, with the ND18 strain sizes being 3.8, 3.2, and 2.8 kb, respectively. RNAs α and β are similar in size among strains of BSMV, but the sizes and complexity of the γ RNAs vary considerably.

The type strain gRNAγ has a 366 nucleotide (nt) sequence duplication at the 5′ end of the genome and comigrates with RNAβ in agarose gels. The Argentina mild strain contains mixtures of three gRNAγ species of 3.2, 2.8, and 2.6 kb. The 3.2 kb RNA has a duplicated sequence similar to that of the type strain, and the 2.6 kb RNA is defective as the result of a deletion in the 3′ terminus of the γa gene. The PSLV and LRSV α, β, and γ gRNAs are similar in size (3.9, 3.6, and 3.2 kb, and 3.7, 3.1, and 2.6 kb, respectively) and sequence to those of BSMV. Strain-specific comparisons are not available for PSLV and LRSV.

Each of the hordeivirus RNAs has a 7-methylguanosine cap at the 5′ terminus, and among the gRNAs within a species, the 5′ untranslated regions (UTRs) that are necessary for replication have very little sequence similarity. Obvious sequence similarity is not evident among the 5′ UTRs of the α and γ RNAs of BSMV, PSLV, and LRSV, but the RNAβ components of the three viruses have considerable sequence similarity. However, the 5′ UTR of LRSV RNAβ is 65 nt longer than that of BSMV or PSLV due to a 5′ terminal extension that is identical to 53 nt at the 5′ end of LRSV RNAα. Interestingly, a 70 nt 5′ UTR recombination between the α and γ RNAs of the BSMV CV17 strain has also been described. These results and the sequence variability exhibited by the Argentina mild strain of BSMV indicate that recombination has played an important role in evolution of the hordeiviruses.

The hordeiviruses gRNAs also contain a conserved 3′ terminal nontranslated sequence that is required for replication. The 3′ termini are variable in length between the different viruses, ranging from 148 nt in LRSV to 330 nt in PSLV. The sequences form tRNA-like structures that in BSMV and PSLV are capable of binding tyrosine *in vitro*. Sequence comparisons indicate that the structures are very similar except that the 3′ UTRs upstream of the conserved tRNA regions of the PSLV and BSMV RNAs have a large stem loop element and an array of possible pseudoknot stem loop regions that make the 3′ UTR longer than that of LRSV. An internal poly(A) sequence of varying length is located directly after the stop codon of the 3′ proximal gene of each RNA, and resides immediately upstream of the conserved 3′ tRNA termini in the BSMV and LRSV genomes. The poly(A) sequence is absent in the PSLV genome.

Hordeivirus gRNAs (**Figure 1**, BSMV) encode seven proteins. The replicase protein subunits are encoded by

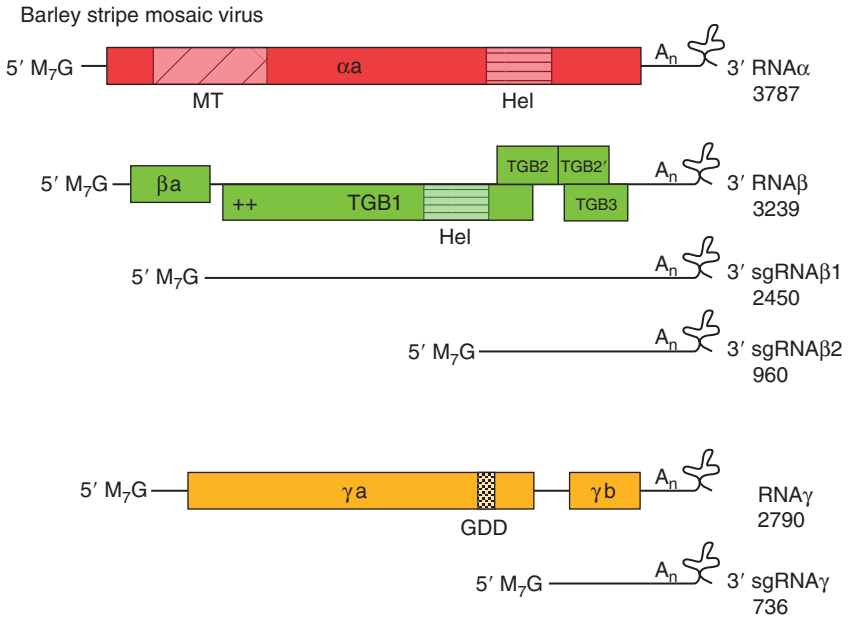

Figure 1 The tripartite genome of BSMV and sgRNAs used for expression of the genes encoded by the β and γ RNAs. Each RNA contains a 5′ cap structure (M_7G), and each 3′ proximal open reading frame (ORF) terminates with a UAA codon initiating an internal polyadenylate sequence (A_n) that precedes the 238 nt tRNA-like terminus. The three genomic RNAs (gRNAs), with ORFs represented by rectangular blocks, are designated α, β, and γ. The αa protein, which is the methyltransferase subunit of the RNA-dependent RNA polymerase (RdRp), is translated directly from RNAα. The αa protein is required for replication and contains methyltransferase (MT) and helicase (Hel) motifs that identify it as the 'helicase subunit' of the viral replicase complex. RNAβ encodes four major proteins. The coat protein, βa, is translated directly from the gRNAβ. The overlapping triple gene block (TGB) proteins, TGB1, TGB2, and TGB3, are each required for virus movement and are expressed from two subgenomic RNAs, sgRNAβ1 and sgRNAβ2, that are illustrated below gRNAβ. TGB1 contains two positively charged regions toward the N-terminus of the protein and an Hel domain, while TGB2 and TGB3 are small hydrophobic transmembrane proteins. RNAγ is bicistronic, and the 5′ ORF encodes the γa protein, which is the GDD-containing polymerase subunit of the RdRp. The cysteine-rich γb protein is involved in pathogenesis.

the α and γ gRNAs. The α RNAs encode a single protein (αa) that contains methyltransferase and helicase domains that are highly conserved between Sindbis-like viruses. The bicistronic γRNAs encode the polymerase (γa) sub unit, which contains the conserved GDD motif found in RNA-dependent RNA polymerase (RdRp) proteins of RNA viruses, plus a 3′ encoded cysteine-rich protein (γb).

RNAβ encodes the coat protein in the first open reading frame (ORF), and is followed by a series of overlapping ORFs termed the 'triple gene block' (TGB) that are also present in allexi-, beny-, carla-, fovea-, peclu-, pomo-, and potexviruses. The first ORF of the TGB encodes the TGB1 protein (formerly designated βb). This protein contains a conserved helicase domain similar to the helicase domain present in the αa protein. The remaining two TGB ORFs encode the small hydrophobic proteins, TGB2 and TGB3 (formerly βd and βc, respectively).

The αa, βa (coat protein), and γa proteins encoded by RNAα, RNAβ, and RNAγ, respectively, are translated directly from the gRNAs (**Figure 1**). Expression of the TGB proteins is mediated by two subgenomic (sg) RNAs, designated sgRNAβ1 and sgRNAβ2. TGB1 is translated from sgRNAβ1, and the other overlapping proteins, TGB2 and 3, are expressed from sgRNAβ2. The γb protein is translated from sgRNAγ. Each of the encoded proteins is expressed at different levels and times during the replication cycle, and the three sgRNAs have similar variances in their abundance during replication. High-level constitutive expression of sgRNAγ occurs throughout the replication cycle, but expression of sgRNAβ1 and sgRNAβ2 is temporal. In addition, sgRNAβ1 is considerably more abundant than sgRNAβ2. The three sgRNA promoters have little obvious sequence relatedness; however, the individual BSMV, LRSV, and PSLV sgRNA promoters share a number of blocks of conserved sequence. Pairwise combinations indicate that the BSMV and PSLV promoters have the highest conservation, whereas the LRSV promoters have undergone more divergence. These results and the protein comparisons described below support the existing evidence for a common origin of the hordeiviruses and buttress biological evidence suggesting that BSMV and PSLV are more closely related to each other than to LRSV. Additional comparisons of the TGB promoter sequences of several other viruses possessing TGB movement proteins have revealed no strong correlations in sequence or secondary structure between these putative promoter sequences and those of BSMV.

Replication of BSMV gRNAs requires the 5′ and 3′ terminal regions, but additional internal *cis*-elements are required for replication of each of the RNAs. RNAα replication is *cis*-preferential, with replication appearing to be coupled to translation of a functional αa protein. Each of the proteins encoded by RNAβ is dispensable for replication; however, the 117 nt intergenic region separating the βa (coat protein) ORF and the TGB1 ORF has a *cis*-acting function required for replication. In contrast, RNAγ replication is not dependent upon the 42 nt intergenic region separating γa and γb, but essential *cis*-acting elements are present in the first 500 nt of the γa gene.

Function and Relatedness of the Hordeivirus Proteins

Replicase Proteins (αa and γa)

BSMV gRNAs expressing αa and γa are able to replicate in protoplasts. The αa and γa proteins are essential subunits of the RdRp and are members of the tobamo-lineage of supergroup III RdRps. A histidine-tagged γa protein recovered from infected barley fractionates with the αa protein. The recovered complex exhibits BSMV RNA-specific polymerase activity and does not contain detectable levels of other BSMV-encoded proteins. Therefore, the αa and γa proteins constitute the helicase and polymerase subunits of the RdRp complex.

The αa protein contains amino-terminal methyltransferase and carboxy-terminal NTPase/helicase domains. The methyltransferase domain likely functions in capping of the viral RNAs and the DEAD box helicase domain consists of at least six amino acid motifs that are conserved among the RdRps of different groups of RNA viruses.

The γa RdRp subunit contains a GDD polymerase motif toward its C-terminus that is characteristic of the supergroup III polymerases, and this domain falls into the 'tobamo-lineage' among the plant viruses. Phylogenetic comparisons of hordeivirus polymerase subunits reveal more than 75% conservation within the genus and lower levels of conservation extend into members of the genera *Pecluvirus*, *Furovirus*, and *Tobravirus* (>65%), and *Tobamovirus* (>30%). Sequence comparisons of the NTPase, helicase, and GDD motifs have revealed significant conservation among the polymerase subunits of Sindbis-like viruses (supergroup III). Among the plant viruses within this group, the conserved domains of BSMV and PSLV are more closely related than those of LRSV, and these sequences also share close relatedness with viruses in the genera *Furovirus* and *Pomovirus*. Lower levels of sequence relatedness are observed when comparisons are extended to the genera *Tobravirus* and *Tobamovirus* and members of the family *Bromoviridae*.

Coat Protein (βa)

The coat protein (CP) is translated directly from gRNAβ and is the most abundant of the viral proteins in infected plants. The CPs of all hordeiviruses are approximately 22 kDa (~200 amino acids) in size, but exhibit different electrophoretic mobilities. The CP interacts with the genomic RNAs to form rod-shaped particles that appear to contain 3 nt per protein subunit, with approximately

24 protein subunits per turn of the helix. In agreement with their serological relatedness, the BSMV and PSLV coat protein sequences are more similar to each other than to the CP of LRSV. Although the CP shares several conserved motifs with other rod-shaped viruses, the hordeivirus CPs are closely related to that of members of the fungal-transmitted virus species *Peanut clump virus* and *Indian peanut clump virus* but show more limited similarity to SBWMV.

Studies of BSMV and PSLV show that the CP is not essential for infectivity of two systemic hosts (barley and *N. benthamiania*), or hosts that form local lesions (*Chenopodium* species). Moreover, infections elicited by CP-deficient BSMV mutants appear to be more aggressive, and the phenotype is more severe and protracted in barley than derivatives expressing the CP. Plants infected with CP deletion mutants remain stunted and appear to lack the recovery phase of infection that is usually observed in barley inoculated with BSMV. These results suggest that the CP is a multifunctional protein that may affect replication and gene expression through a feedback mechanism rather than acting to suppress host RNA silencing.

TGB Movement Proteins

The hordeiviruses encode Class I TGB proteins that differ in several features from the Class II TGB proteins of PVX and other viruses of the family *Flexiviridae*. The coordinated actions of each of the three TGB proteins are required for cell-to-cell and systemic movement. The proteins are expressed transiently and simultaneously during the early stages of infection and decline in abundance at later stages of infection.

TGB1

The TGB1 protein, encoded by the 5′ proximal gene of the TGB, is expressed from sgRNAβ1 and accumulates to high levels early in infection. Among the hordeivirus species, the TGB1 proteins range from 50 to 63 kDa in size. These proteins can be distinguished from the ~25 kDa Class II TGB proteins of the flexiviruses by having substantially larger N-terminal domains preceding the helicase domain. The N-terminal half of the hordeivirus TGB1 proteins contains two positively charged regions rich in lysine and arginine residues, while the C-terminal half of the protein contains an NTPase/helicase domain with seven conserved motifs (I, IA, II, III, IV, V, and VI) that are characteristic of superfamily I helicases of alpha-like viruses. The TGB1 protein has RNA helicase activity *in vitro* that is dependent on Mg^{2+} and ATP and can unwind RNA duplexes in both 5′- to -3′ and 3′- to -5′ directions. The TGB1 protein also binds ATP and dATP, and exhibits ATPase activity that maps to the helicase-containing, C-terminal half of the protein.

The TGB1 protein has RNA-binding activity at high ionic strength and exhibits a higher binding affinity for double-stranded (ds) RNAs than single-stranded (ss) RNAs. RNA sequence specificity has not been detected in binding studies, and TGB1 has little detectable affinity for DNA. The TGB1 proteins of both BSMV and PSLV contain multiple RNA-binding regions, and in PSLV, the N-terminal half of TGB1 containing the positively charged regions is able to bind RNA under high-salt conditions, whereas the C-terminal half containing the helicase motif binds RNA only under low-salt conditions.

A BSMV TGB1/RNA ribonucleoprotein (RNP) complex has been purified from infected barley, demonstrating that TGB1 also binds to RNA *in vivo*. The complex contains positive-sense α, β, and γ RNAs, but additional BSMV-encoded proteins are not present in detectable amounts. However, the TGB1 protein participates in both homologous interactions and in associations with TGB3. The TGB1 protein is membrane associated in infected cells, and visualization of a GFP:TGB1 fusion protein reveals paired foci on opposite sides of the cell wall, suggesting localization at plasmodesmata (PD). When TGB1 is transiently expressed in the absence of TGB2 or TGB3, the TGB1 protein is localized in cytoplasmic membranes. Due to its RNA-binding activities and presence in the RNP complex recovered from infected plants, the TGB1 protein appears to function in formation of viral RNA complexes that are transported to adjacent cells during interactions with TGB2 and 3.

TGB2 protein

Among the hordeivirus TGB proteins, the TGB2 protein contains the highest amount of sequence similarity, and the degree of sequence similarity extends to the class I TGB2 proteins encoded by PVX and other members of the family *Flexiviridae*. The TGB2 sequence contains two hydrophobic stretches and a conserved hydrophilic region that separates the hydrophobic residues. The hydrophobic regions are predicted to integrate into membranes with a U-shaped topology that directs the termini of the proteins to the cytoplasmic side of the membrane, and the strong conserved central portion of the protein is exposed to the ER lumen.

The TGB2 protein is associated with cellular membranes, and associates with the cortical ER and motile vesicles resembling Golgi stacks. In the presence of RNAα and RNAγ, a small portion of BSMV TGB2 fluorescent fusion proteins also associates with chlorophyll-containing vesicles that appear to be chloroplasts or derived from chloroplasts. From a functional perspective, a GFP:TGB2 fusion protein moves through several cells during transient expressions lacking TGB3, suggesting that TGB2 can modify the size exclusion limits of PD.

TGB3 protein

The TGB3 protein is encoded by the 3′ proximal ORF of sgRNAβ2 and is translated by leaky scanning of ribosomes past the TGB2 AUG, which is in a poor context for translation initiation. This mechanism normally produces about a 10:1 ratio of TGB2 to TGB3 during *in vitro* translation. The TGB3 proteins are the most poorly conserved of the TGB proteins, and the class 1 and 2 proteins are thought to have a polyphyletic origin, in contrast to the TGB2 proteins that are thought to have originated from a common ancestor.

The N-terminus of the approximately 17 kDa TGB3 protein from each of the hordeivirus species contains a stretch of conserved amino acids that includes one histidine and three cysteine residues. The TGB3 protein has two hydrophobic domains separated by a hydrophilic region that contains a conserved tetrapeptide (QDLN) sequence. The transmembrane regions are predicted to direct the termini of TGB3 toward the ER lumen. This topology is quite distinct from that of the class II TGB3 proteins, which have only a single membrane-spanning domain that results in location of the C-terminus on the cytoplasmic side of the ER.

When expressed alone, TGB3 localizes to paired peripheral bodies at the cell wall (CW) that appear to lie on opposite sides of the PD channels connecting adjacent cells. The targeting of PSLV TGB3 to the CW requires the central hydrophilic and the C-terminal transmembrane regions, whereas the BSMV TGB3 protein requires the five C-terminal residues, LSSKR, for PD targeting. Furthermore, TGB3 redirects the targeting of TGB1 and 2 to paired peripheral bodies at the CW, and protein interaction studies demonstrate that TGB3 binds with both TGB1 and TGB2.

Pathogenesis Protein (γb)

The 3′ proximal ORF of the hordeivirus γRNAs encodes a cysteine-rich γb protein that ranges in size from 16 to 20 kDa. The hordeivirus γb proteins share some structural similarities, but have little direct amino acid sequence similarity with the cysteine-rich proteins of tobra- and carlaviruses. Studies of the BSMV ND18 strain demonstrate that γb is not strictly required for infectivity in plants, but that it affects pathogenicity, viral RNA accumulation, and expression of genes encoded by RNAβ. Extensive mutational analyses of γb have revealed a number of distinct phenotypes in barley and *Chenopodium* that can ameliorate or exacerbate disease symptoms.

The majority of the cysteine residues in γb are concentrated in the N-terminal half of the protein. These residues are clustered in two zinc-finger-like motifs, designated C1 and C2. A basic motif (BM) rich in lysine and arginine residues is located between the cysteine-rich regions. The BSMV γb protein has been expressed and purified from *Escherichia coli* and shown to bind ssRNAs and zinc *in vitro*. The basic motif mediates RNA-binding activity, and the C1, BM, and C2 regions each show independent zinc-binding activity. A coiled-coil structure near the C-terminus of the γb protein mediates self-interactions that affect pathogenicity.

The PSLV γb protein is targeted to peroxisomes via a C-terminal SKL signal sequence, but deletion of the tripeptide does not affect infection phenotype. This sequence is also found in LRSV and in the BSMV type and China strain γb proteins, but is absent in the ND18 and CV17 strains. The BSMV ND18 γb:GFP fusion protein fluorescence is dispersed throughout the cytoplasm, and subcellular fractionation of infected barley tissue confirms that the majority of the protein is located in the soluble fraction. However, in the presence of the α and γ RNAs, a small portion of the γb protein is associated with vesicles surrounding the nucleus that contain chlorophyll. These associations with chloroplast membranes suggest that the γb protein may have a previously unrecognized role in virus replication or that it may protect viral replication factories against host RNA defense mechanisms.

Several lines of evidence indicate that a major function of γb is to serve as an inhibitor of host defense mechanisms that target RNA replication. A recombinant BSMV derivative that lacks γb expression compromises systemic virus infection and the γb function can be complemented by expression of other known silencing suppressor proteins. Similarly, expression of the γb protein is able to suppress silencing in heterologous virus-induced silencing systems. An agrobacterium-mediated transient silencing assay also provides strong support for a role of γb in suppression of RNA silencing. In this assay, γb interferes with silencing of GFP fluorescence that was induced by expression of a dsRNA. The BSMV γb coiled-coil region is required for silencing suppression in this system, suggesting that homologous interactions of γb are required for suppression activity. These results thus provide a persuasive argument that a major function of γb is to counter host innate RNA interference defenses.

Cytopathology and Replication

Microscopy studies of BSMV-infected barley indicate that most of the visible changes in leaf appearance can be attributed to the disruption of organelles, most notably chloroplasts, in the rapidly expanding cells of the growing leaf. The morphology and shape of chloroplasts are altered drastically during infection as grana become disorganized, and numerous small vesicles appear between the inner and outer membranes of the chloroplast envelope. Reduced amounts of chloroplast ribosomal RNA and decreased rates of synthesis of chloroplast proteins are also noted as BSMV RdRp activity increases. Some

evidence also indicates that chloroplasts or chloroplast membrane vesicles may become reoriented around the nuclei of infected leaf cells. Additional membranes often proliferate and form large globular inclusions of unknown function. Late in infection, virions accumulate to high levels in the cytoplasm in disordered arrays, but a small proportion of rod-shaped particles presumed to be of viral origin accumulate in the nuclei. Biochemical studies undertaken to extend the ultrastructural studies show that BSMV infection inhibits chlorophyll accumulation, and suggest that alterations in photosystem II may result in decreased light absorbance. Reductions in lipids and galactolipids are also correlated with infection and proplastid degradation.

Natural plant-to-plant transmission of hordeiviruses involves mechanical entry of virions into cells. A model for replication posits that virions are disassembled by ribosomes and that RdRp subunits are translated from the α and γ gRNAs (**Figure 2**). Indirect evidence indicates that the polymerase subunits assemble with host components and establish sites of replication on invaginated membrane vesicles originating from chloroplasts or proplastids. Based on dsRNA serological assays, replicating RNAs also appear to be associated with the vesicles. The requirement for translation of a functional αa protein for replication of RNAα raises the hypothesis that the protein may function to recruit RNAγ to sites of replication and initiate vesicle formation. During the replication cycle, the replicase initiates at the 3′ termini of each of the gRNAs during synthesis of dsRNAs, and also initiates sgRNA transcription at internal promoters on the minus strands of RNAβ and RNAγb. Recent results indicate that in the presence of RNAs α and γ, small amounts of TGB2 and the γb protein are targeted to abnormal chloroplast-like vesicles in barley and *N. benthamiana*. These results suggest that the γb protein and the TGB proteins may be recruited to the chloroplast vesicles to interfere with host defenses and to interact with viral RNAs destined for cell-to-cell movement. Serological studies also suggest that small amounts of CP are present in chloroplast-associated vesicles, so it is possible that the CP has regulatory functions related to replication. These findings thus fit a model whereby replication is initiated in vesicles associated with proplastids that mature into chloroplasts.

During the initial stages of replication, the TGB1 movement protein probably functions to unwind and encapsidate positive-sense gRNAs to form nucleoprotein complexes in the vesicles. Biochemical experiments have shown that the resulting TGB1 nucleoprotein complexes can be recovered from infected plants and that TGB1 associates with TGB2 and TGB3. These interactions are thought to mediate transit of the nucleoproteins through the cortical ER to the lumen of the PD. An attractive model postulates that during transit to the PD, the nucleocapsid is associated with vesicles containing RdRp and that these vesicles are targeted by actin to the periphery of the cell. Although cytochalasin D fails to noticeably affect the membrane localization of TGB1, recent work shows that the diameter of actin cables increases significantly in infected cells and in cells expressing TGB2 and TGB3. Transient expression studies with PSLV and BSMV also show that TGB3 forms opposing pairs of punctate foci across PD, so it is plausible that TGB3 interacts with TGB2 to target TGB1 nucleoprotein movement complexes, and possibly replication complexes, through the PD.

In contrast to viruses such as PVX, which contain class II TGB proteins, the coat protein of hordeiviruses is dispensable for cell-to-cell and vascular movement and, therefore, nucleocapsid complexes must have a primary role in movement. During the early phases of cell-to-cell spread, GFP:TGB1 forms brightly fluorescent concentric rings at the advancing infection front and greatly reduced fluorescence behind the front. These results suggest that the TGB proteins are rapidly downregulated after movement, as is the case with TMV where the 30 kDa protein appears to be targeted to the host 26S proteosome for degradation.

Pathogenesis

Natural mutants in both the noncoding and coding regions of BSMV RNAs have been shown to have strain-specific effects on pathogenesis. For example, the ND18 strain is unable to infect oats, whereas the CV42 strain is pathogenic in this host. ND18 virulence in oats can be engineered by altering a single amino acid in the αa protein, so this phenotype may result from relatively simple associations of αa with a host protein. Natural variation among BSMV strains has also facilitated identification of factors affecting seed transmission. Primary determinants influencing the efficiency of seed transmission reside in RNAγ sequences in the 5′ UTR and in the γb gene. Therefore, it appears that RNAγ sequences that are crucial to seed transmission influence replication and have effects that counter host RNA interference mechanisms. In a fourth case of strain-specific virulence, ND18 is able to systemically infect *N. benthamiana*, while the type strain is able to replicate and move in the inoculated leaf but is unable to invade systemically. This aberrant phenotype appears to be caused by the presence of a short ORF in the 5′ UTR that reduces γa translation. Infections with the ND18 or type strains also result in different local lesion phenotypes on *C. amaranticolor*. These differences are complex, but are primarily due to the presence of an amino-terminal 372-nucleotide duplication in RNAγ of the type strain that downregulates expression of γa, and to differences in amino acids of the γb proteins.

Advances in understanding pathogenesis have also been obtained by induction of mutations by reverse

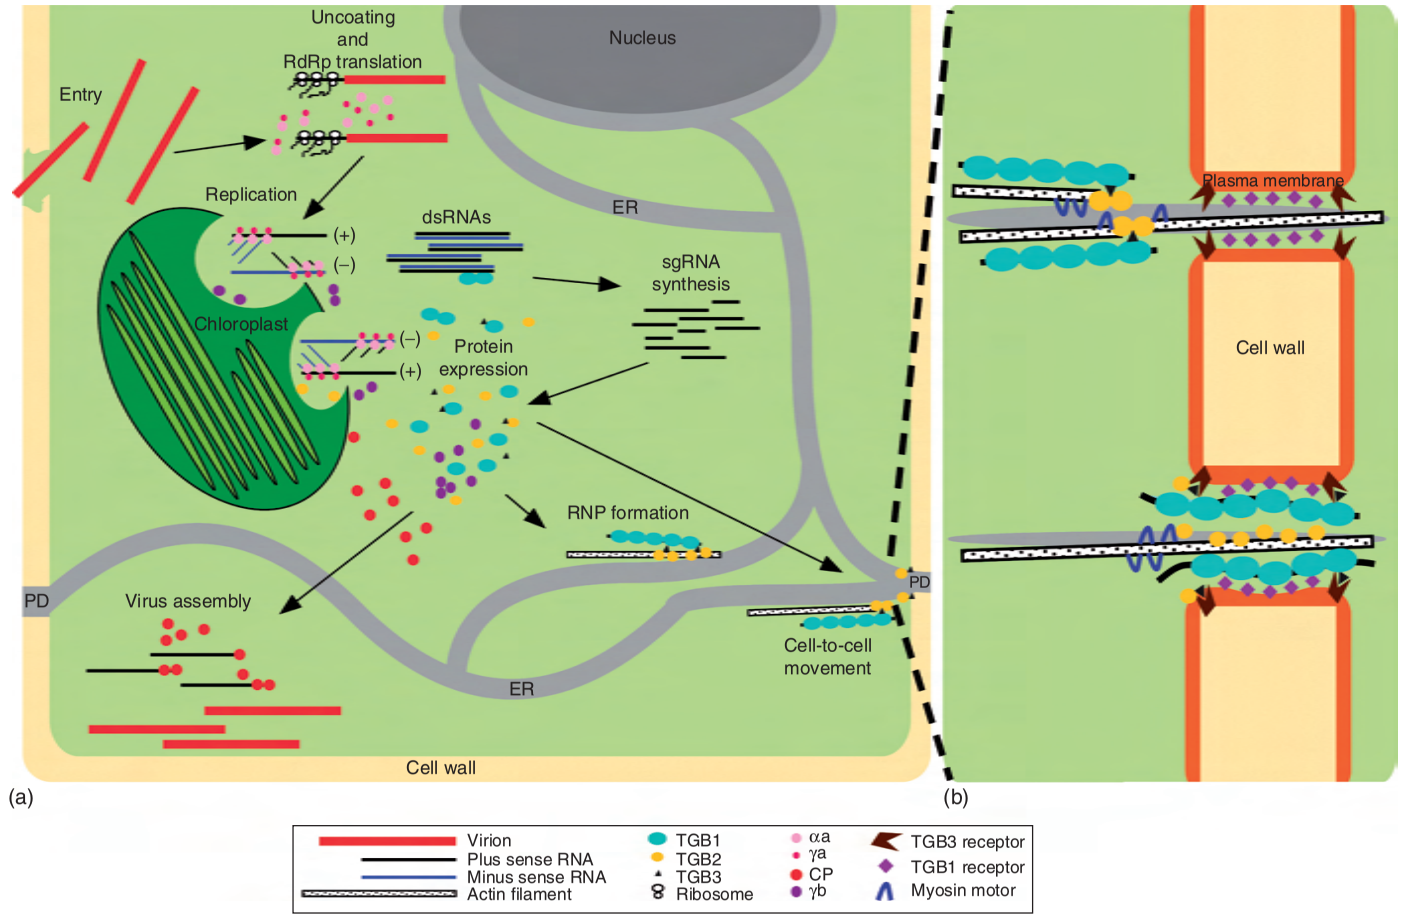

Figure 2 Model of the hordeivirus infection cycle and movement mechanisms. (a) Cycle of replication and formation of movement complexes. Virus particles mechanically enter the cell through breaks in the plant cell wall. Entry is followed quickly by uncoating of the gRNAs in the cytoplasm and translation of the αa and γa proteins to form the RdRp. The RdRp associates with host factors and recruits positive-sense gRNAs to chloroplast membranes where genome replication occurs on invaginated membrane vesicles. Production of positive- and negative-sense gRNAs results in the formation of dsRNA replicative intermedite species. The RdRp also initates transcription at internal promoters located on the negative-strand RNAs to generate sgRNAs that function as messengers for the translation of proteins encoded by the 3′ ORFs of the gRNAs. Small amounts of the TGB2 and γb proteins are also targeted to abnormal chloroplast-like vesicles where they may function in movement and protection against host defenses. The TGB1 protein binds to positive-sense gRNA to create hordeivirus ribonucleoprotein (RNP) movement complexes that associate with the TGB2 and 3 proteins for transport to the plasmodesmata (PD) to facilitate virus cell-to-cell spread. The CP, which is translated directly from gRNAβ, binds positive-sense gRNAs to form progeny virions. (b) Expanded view of events occurring during entry into PD. RNP movement complexes containing TGB1 and positive-sense gRNA associate with the TGB2 and TGB3 integral membrane proteins for transport along actin filaments that are associated with the ER. The TGB3 protein targets the complex to PD and is presumed to interact with host receptor proteins in the PD desmotuble. TGB2 mediates RNP entry into PD, possibly through remodeling of actin filaments within the desmotubule. Host proteins within the PD are predicted to interact with TGB1 to convey RNP complexes to the adjacent cell. The TGB2 and 3 proteins may move through PD along with the RNP, or be recycled by the endocytic pathway to facilitate the movement of additional RNP complexes.

genetics. The early results showed that γb is not strictly required for infectivity in plants, but that it has important pathogenicity effects. For example, null mutations in γb inhibit infections of the BSMV type strain in barley, but the ND18 strain is able to establish systemic infections albeit with an altered symptom phenotype. However, the failure of the type strain to establish systemic infections in the absence of γb can be reversed by mutations that increase the translation of the γa replicase or that remove an amino-terminal extension of the γa protein that may reduce the function of the protein. Individual site-specific mutations within the cysteine-rich region of γb can also result in a variety of phenotypes ranging from striking white regions to necrotic streaks on systemically infected leaves of barley. In addition, plants infected with site-specific γb mutants have secondary effects that culminate in greatly reduced abundance of RNAβ, the CP, and the TGB1 protein. Although the CP is not required for infectivity in barley, *N. benthamiania*, or *Chenopodium* species, infections elicited by CP-deficient BSMV mutants appear to be more aggressive, because recovery is protracted and the symptoms are more severe than in the presence of the CP. These results suggest that in addition to being essential for formation of virions, the coat protein may have a critical role in downregulating kinetics of replication late in infection. Overall, these genetic analyses suggest that complex interactions may affect virulence and disease phenotype, and that the levels of replication may have important effects on movement, host range, and seed transmission.

Natural genes that condition resistance to the ND18, type, and other BSMV strains have been identified in several barley cultivars. The recessive nature of these genes indicates that resistance is due to the absence of a function required for virus replication rather than an active response to infection. The fact that related strains of BSMV can overcome resistance suggests that resistance may result from mutation of a factor required for replication rather than the complete absence of a host factor. This hypothesis is supported by evidence that virus strains targeted by resistance genes are unable to replicate in protoplasts from resistant varieties, whereas the protoplasts fully support the replication of strains able to overcome the resistance genes. Accordingly, single amino acids or short stretches of amino acids in the αa and γa proteins appear to have been targeted by host resistance responses. As more resistance genes are identified, it will be interesting to see whether dominant genes target other functions such as the CP and movement proteins to elicit dominant protective mechanisms.

Hordeivirus Applications to Cereal Genomic Analyses

Virus-induced gene silencing (VIGS) has provided useful approaches to improve our understanding of the functional genomics of dicots, and several virus vectors have been developed for this purpose. Recently, BSMV has been developed into an effective VIGS vector by modifying sequences downstream of the γb gene to enable expression of untranslatable foreign inserts. This strategy was first applied to barley by targeting phytoene desaturase (PDS) for VIGS. Subsequently, applications of VIGS to downregulate genes known to be involved in disease resistance have also enabled identification of genes required for powdery mildew resistance in barley. Extension of the VIGS system to hexaploid wheat has also been used to effectively downregulate PDS, subunit H of the magnesium–protoporphyrin chelatase complex, and the β7 subunit of the 20S proteosome complex. An additional study has identified genes required for rust resistance in wheat. These studies indicate that BSMV provides a powerful and robust system for gene silencing that may have numerous applications for genetic analyses of a large number of cereal crops.

Future Perspectives

The broad host range of hordeiviruses and the information accumulated about virus genes involved in replication, movement, and responses to host resistance afford a rich resource for obtaining insight into the mechanics of infection. Although considerable effort has recently focused on the requirements and interactions of hordeivirus-encoded proteins, very little is known about how virus and host proteins interact to facilitate replication and movement. New genomics findings arising from host sequencing projects, development of advanced tools for analysis of host genes and cell biology, and the ability to modulate expression of individual genes are accelerating the pace of research findings and enabling dissection of individual steps in many of these processes. Of particular importance is characterization of host genes regulated during infection and the effects of these genes on pathogenesis. An understanding of events leading to the establishment of replication factories will provide important information on hordeivirus replication and the interplay between chloroplasts and cytoplasmic elements during the early stages of infection. Additional cell biological analyses of the TGB-encoded proteins and their interactions with host proteins are required to hone our understanding of the cell-to-cell and vascular movement mechanisms that permit systemic virus infections. In addition to enhancing the understanding of how viruses invade vegetative tissue, seed, and pollen, these studies may also provide insights into global aspects of subcellular transport, chloroplast, and PD functions in plants.

Glossary

APOBECs A family of cytidine deaminases, the prototypic member is a component of apolipoprotein B editing complex.
Restriction factor A cellular protein whose major role is to inhibit retrovirus replication.
Vif Virion infectivity factor encoded by many lentiviruses which induces degradation of some APOBEC proteins.
Vpu Viral protein U, a small transmembrane protein encoded by HIV-1 and its close relatives.
Xenotropic Able to infect cells only from other species.

Introduction

The evolution of organisms and the viruses that colonize them is, obviously, closely linked. Often, pathogenic viruses impose a negative selection pressure on a host that results in the survival of a subpopulation in which infection is resisted, attenuated, or tolerated. In the case of retroviruses, the evolutionary association of virus and host can be exceptionally close, because of the unusual degree to which retroviral infection persists. Retroviral infection is normally lifelong, in part due to the propensity of retroviral genomes to irreversibly integrate into host DNA. Sometimes the targets of retroviral infection include germline cells, and infection of these cells, which generate so-called endogenous proviruses, enables persistence, not only for the host's own lifetime, but also that of its progeny. This persistence and inextricable association of host and virus may allow retroviruses to impose a uniquely sustained selection pressure and may explain why hosts have evolved unique and specific ways for their cells to resist colonization by retroviruses.

In principle, hosts could evolve resistance to the negative consequences of retroviral infection through changes in components of their innate and adaptive immune systems, but it has also become clear that host factors which directly inhibit the ability of retroviruses to replicate in host cells evolve under pressure of retroviral infection. Host resistance to retroviral infection can be acquired in many forms and be manifested at various stages of the retroviral life cycle (**Figure 1**). Of particular note are a collection of autonomously and constitutively active intracellular proteins, termed restriction factors, whose major function appears to be to provide intrinsic immunity to retroviral infection. As such, they are uniquely capable of actively preventing retrovirus replication at the very earliest stages of host colonization. Naturally, some retroviruses have adapted to cellular host resistance in its various forms. Since exogenous retroviruses evolve much more rapidly than their hosts, it seems obvious that they would do so. Nevertheless, some of the obstacles that cells have placed in the path of retroviral replication are not easily escaped by simple mutation, and in some cases retroviruses have learned

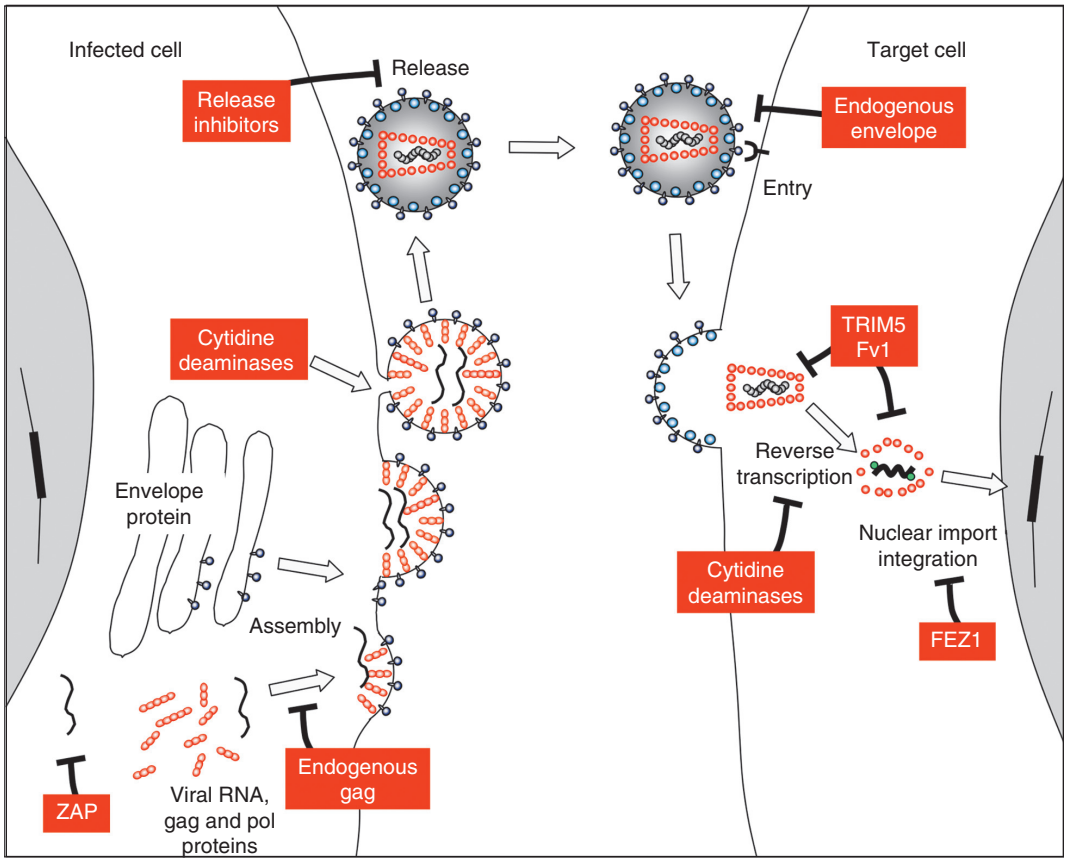

Figure 1 Overview of the retrovirus life cycle and activities encoded by cells that are known to inhibit retrovirus replication.

how to avoid or ablate host restriction factors in interesting and unique ways.

Host Cell Resistance Defined Early in the Retrovirus Life Cycle

Resistance to Retrovirus Entry

Imagine a cell attempting to thwart an infection event by a retrovirus. Optimal strategies would involve aborting the viral life cycle before integration into the genomic DNA and avoiding permanent residence of the retrovirus in the cell and all of its progeny. This could be achieved in numerous ways, an obvious approach being removal or alteration of the receptors that are exploited by retroviruses to enable entry. Several occurrences of this phenomenon are known. A striking example is the occurrence of endogenous murine leukemia viruses (MLVs) that are termed xenotropic because they are unable to replicate in their own hosts. Xenotropism generally occurs as a consequence of mutations that are acquired in the gene encoding the relevant receptor, presumably after colonization of the germline by the xenotropic MLV. Another important example of a receptor mutation that confers resistance to infection is present in humans. In this case a defective allele of the CCR5 co-receptor (*CCR5Δ32*) for HIV-1 exists at high frequency in certain human populations, and individuals that are homozygous for this mutation are resistant to infection by many strains of HIV-1. Although it is quite unlikely that HIV-1 itself is the source of the original evolutionary pressure that led to the dissemination of the *CCR5Δ32* allele, widespread HIV-1 infection in humans would clearly sustain or even increase the prevalence of the *CCR5Δ32* allele in populations where it is present. Other polymorphisms in the human *CCR5* gene also appear to have more modest effects on the acquisition and consequences of HIV-1 infection.

While receptor inactivation could clearly confer resistance to infection by certain retroviruses, some species have acquired or amplified specific genes that actively inhibit retroviral infection at the level of receptor–envelope interaction. Endogenous retroviruses themselves have proved to be a good source of such inhibitors and a few endogenous retroviral genes can efficiently control infection and inhibit the progression of disease caused by exogenous retroviruses. Certain of these preserved endogenous retroviral gene products, for example, Fv4 and Rmcf in mice, are viral envelope glycoproteins that bind and block the receptors shared by exogenous viruses, and constitute especially effective and specific entry

inhibitors. The natural cellular ligands of viral receptors can also provide resistance to infection. For example, the chemokine ligands of CCR5 act as competitive inhibitors of HIV-1 envelope binding and one of the genes encoding a CCR5 ligand (*CCL3-L1*) exists in variable copy numbers in humans. Individuals with higher copy numbers tend to be less likely to acquire HIV-1 infection, and once infected seem less susceptible to its effects. While it is not yet certain that these effects are not immunologically mediated, it seems most likely that the *CCL3-L1* gene product acts as a direct inhibitor of HIV-1 infection and replication in humans.

Post-Entry Resistance Factors Targeting Incoming Retroviruses

In addition to providing a source of receptor-blocking viral envelope proteins, endogenous retroviruses have provided additional factors that restrict retroviral replication. A particularly intriguing restriction factor of endogenous retroviral origin is Friend virus susceptibility factor 1 (Fv1), a protein with about 60% homology to human and mouse endogenous retroviral Gag proteins. *Fv1* was first characterized as a dominant, heritable trait in laboratory mice that conferred resistance to infection by particular MLV strains. The two principal alleles of Fv1 are functionally distinguished by the spectrum of MLV strains to which they confer resistance: The $Fv1^n$ allele renders cells permissive to infection by N-tropic MLV but restricts B-tropic MLV infection, whereas $Fv1^b$ renders cells permissive to B-tropic MLV but resistant to N-tropic MLV. Heterozygous animals that carry both *Fv1* alleles are resistant to both N- and B-tropic MLV strains, while certain MLV strains are not susceptible to restriction by either *Fv1* allele and are known as NB-tropic. Additional *Fv1* alleles that induce partly overlapping patterns of sensitivity/resistance exist, as do inactive variants. While Fv1 restriction is not absolute, it can be very substantial at low multiplicities of infection and Fv1 restriction can have extremely dramatic effects on MLV pathogenesis.

An important feature of Fv1-mediated resistance is that it is saturable and infection by any given virus particle is greatly facilitated by the presence of large numbers of additional restricted virus particles, even if they are inactivated. Most interestingly, the Fv1-imposed block in MLV infection occurs after reverse transcription has been completed but before integration of the provirus in the host genome. The viral determinant governing Fv1 sensitivity is the capsid protein and a single-amino-acid change from arginine to glutamate at position 110 is sufficient to convert an N-tropic MLV strain to B-tropism. Other residues in proximal positions can also affect Fv1 sensitivity and together these data suggest that Fv1 is an inhibitor that inactivates incoming MLV capsids in the cytoplasm of target cells.

Several non-murine mammalian cells, including those from humans, African green monkeys (AGMs), and cows, restrict infection by N-tropic, but permit infection by B-tropic, MLV. Remarkably, this occurs despite the absence of an Fv1-like gene in species other than mice. The characteristics of restriction of N-MLV in these cells are similar to those mediated by Fv1 in mouse cells, that is, restriction can be saturated and amino acid 110 of capsid determines restriction sensitivity. However, in most cases of nonmurine mammalian cells, capsid-specific blocks to infection appear to occur before reverse transcription is completed.

In addition, lentiviruses are also subject to a similar type of post-entry restriction in primate cells. Again, dominant saturable factors are responsible and the viral determinant governing restriction is the capsid protein. Cells from different primate species often exhibit distinct retrovirus restriction specificities. For example, human cells restrict infection by equine infectious anaemia virus (EIAV) but not primate lentiviruses. Conversely, AGM cells restrict multiple primate lentiviruses and EIAV but not simian immunodeficiency viruses (SIVs) naturally found in AGMs. Remarkably, in many cases, restriction of one retrovirus can be abolished by saturation with another even if the two viruses are not closely related, provided that both viruses are restricted in the target cell. For example, in AGM cells, which restrict N-tropic MLV as well as HIV-1, HIV-2, SIVmac, and EIAV, saturation with lentivirus particles can completely abrogate restriction of N-tropic MLV infection. These findings demonstrate the divergence in specificity of mammalian restriction factors but also predict the presence of a single restriction factor capable of recognizing retroviruses whose capsids share little sequence homology.

Indeed, recent work shows that the gene that is largely responsible for the retrovirus restriction properties of primate cells is *TRIM5* and that variation in its sequence can account for most of the variation in species-specific retrovirus restriction properties. Unlike Fv1, TRIM5 has no homology with any known retroviral sequences. Rather, *TRIM5* is one member of a family of dozens of cellular genes that share a similar architecture. Indeed, *TRIM5* itself exists as one of a small cluster of closely related *TRIM* genes on human chromosome 11. Each *TRIM* gene encodes a protein with an amino-terminal tripartite motif, comprised of a RING domain, one or two additional zinc-binding or 'B-box' domains, and a coiled-coil domain (**Figure 2**). The TRIM domain can be linked to one of a number of C-terminal domains, and a single *TRIM* gene can encode several variant proteins with different C-terminal domains as a result of alternative splicing. The α-spliced variant of *TRIM5* gene is responsible for retrovirus restriction and encodes a C-terminal SPRY domain, which is related to domains found in other proteins of diverse organization and function, as well as in

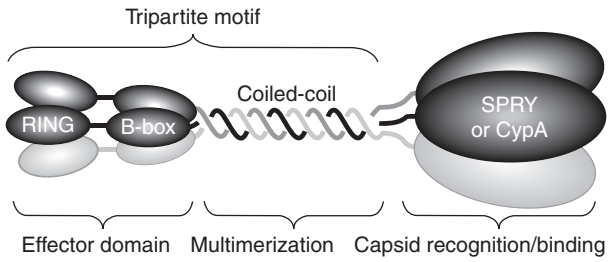

Figure 2 Domain and functional organization of the TRIM5 class of retrovirus restriction factors that block viral infection by targeting incoming capsids. Three major domains that are required for restriction are the N-terminal effector domain, of unknown function, a cenrtal coiled-coil that mediates trimerization, and a C-terminal domain that is responsible for capsid recognition.

several other members of the TRIM protein family. Functional dissection of the TRIM5α protein has revealed that the amino-terminal RING and the B-box sequences comprise a so-called effector domain that is required for restriction but not for recognition of incoming capsids. Conversely, the central coiled-coil is necessary for TRIM5 trimerization while the C-terminal SPRY domain is the principal specificity determinant that governs which retroviruses are inhibited by a given TRIM5α variant. The fact that TRIM5α exists as a trimer suggests a mode of capsid recognition that involves threefold symmetry, since the viral target of TRIM5 consists primarily of a hexameric array of capsid molecules. Moreover, residues on the outer surface of the hexameric capsid lattice of both HIV-1 and MLV have been shown to be important determinants of cell tropism and, in some cases, sensitivity to TRIM5α and Fv1.

The sequences of *TRIM5* genes in various primate species reveal rapid evolution and an excess of nonsynonymous mutations, specifically in the SPRY domain that determines restriction specifically. This finding is consistent with the notion that TRIM5 has been placed under evolutionary pressure by a variable selective force, most likely viral infections. Remarkably, in one particular New World monkey species, namely owl monkeys, a retrotransposition event has resulted in the almost precise replacement of the C-terminal SPRY domain with a cyclophilinA (CypA) domain. The resulting protein, termed TRIMCyp, inhibits HIV-1 and certain other retroviruses whose capsids bind to CypA.

The ability of certain retroviral capsid proteins, particularly that of HIV-1, to bind CypA can influence their sensitivity to TRIM5α as well as TRIMCyp, and there is a complex relationship between CypA:capsid interactions and sensitivity to restriction in various cell types. CypA binds to a flexible loop that is exposed on the surface of the viral capsid and overlaps with viral determinants that govern sensitivity to TRIM5α. The CypA:capsid interaction can be inhibited by drugs such as cyclosporine A (CsA), and treatment of certain human cells with CsA inhibits replication of HIV-1 while lentiviruses whose capsids do not bind CypA are unaffected. While CsA does not appear to render HIV-1 highly sensitive to human TRIM5α, mutations in the CypA-binding site do confer partial sensitivity to it and allow HIV-1 capsids to saturate human TRIM5α. These findings suggest that HIV-1 capsid may have specifically adapted to bind CypA in order to avoid inhibition by restriction factors, like TRIM5α, in humans.

However, the situation is more complex than these findings would suggest. The requirement for CypA for replication in human cells is HIV-1 strain and host cell-type dependent. Indeed, there are several examples of viral strains whose capsid binds CypA but in which disruption of the interaction has no detectable effect on virus replication. This phenotype is conferred by both naturally occurring and *in vitro* selected mutations that occur within the CypA binding loop but do not affect CypA binding. Remarkably, some of these mutations can confer CsA dependence in other human cell types. These differences among human cell types are not due to variation in TRIM5α sequence and suggest the existence of additional capsid-based restriction factors in human cells, whose activity is actually facilitated by the capsid:CypA interaction. Moreover, it appears that HIV-1 restriction by TRIM5α in Old World monkeys is facilitated by CypA:CA interactions.

Generally, the events immediately following entry of a retrovirus into the target cell are not well understood, complicating efforts to determine molecular details of the mechanism by which Fv1 and TRIM5α prevent retroviral infection. Although the hexameric capsid lattice forms the outer shell of the subviral complex that is delivered into the cell, biochemical studies suggest that the capsid shell may be discarded, in a process known as uncoating, shortly after entry. Therefore, there may be a relatively short time frame in which restriction factors such as TRIM5α and Fv1 can initiate events that inhibit infection. Experimental evidence is partly consistent with this notion, and irreversible TRIM5-mediated restriction events can indeed be initiated very rapidly, within minutes of virus entry into the target cell cytoplasm. TRIM5 can interact specifically with capsid proteins of restricted viruses *in vitro*, and direct binding of TRIM5 to capsids is almost certainly the initiating event in restriction. Ensuing events may involve accelerated capsid uncoating and/or degradation. While restriction by TRIM5 is often manifested as apparent inhibition of reverse transcription, this is not a necessary part of restriction since some TRIM5 variants do not affect viral DNA accumulation, nor does Fv1. The known involvement of RING domains in ubiquitin/sumoylation reactions is suggestive of potential effector mechanisms but neither of these pathways

appears to be required for restriction activity, although proteasome inhibition can restore DNA synthesis.

Other Cellular Inhibitors of Incoming Retroviruses

In addition to the intensively studied TRIM5 and Fv1 proteins, cell-type-dependent effects on the early post-entry event in retroviral replication suggest the existence of additional factors that may inhibit incoming retroviruses. For example, certain HIV-1 and HIV-2 strains appear restricted in particular human cells in a manner that depends on both the envelope and capsid. This finding suggests that the route of retroviral entry may affect the sensitivity to unknown capsid-specific restriction factors, although TRIM5 and Fv1 restriction is clearly independent of entry route. Moreover, studies of chemically mutagenized cell lines have revealed that overexpression of fasciculation and elongation protein zeta-1 can be detrimental to retroviral infection. Whether these additional apparent inhibitors of retroviral infection are physiologically relevant and the mechanisms by which they work has not yet been established. However, it is entirely possible that there remain more, and perhaps many, undiscovered inhibitors of incoming retroviruses.

Host Resistance to Infectious Virus Generation

Cells have also evolved alternative antiretroviral activities that act after retroviral DNA has integrated into the host genome. Several inhibitors that act at the level of viral genome accumulation, or affect particle assembly, release, or infectivity are known. While such activities cannot preserve the uninfected state of the cell that expresses them, these intrinsic immune functions can attenuate or prevent the spread of infection to subsequent generations of target cells.

Cellular Cytidine Deaminases as Retrovirus Resistance Factors

One such defense strategy relies on a group of genes, exemplified by *APOBEC3G*, that act primarily by deaminating cytidines in nascent retroviral DNA. *APOBEC3G* is one of a group of genes that exhibit cytidine deamination activity, and other members of this family (e.g., *APOBEC1* and *AID*) are involved in editing of specific cellular mRNAs and genomic loci in order to change their coding potential. APOBEC3G is incorporated into retroviral particles and deaminates nascent viral DNA during reverse transcription in subsequently infected target cells by virtue of its single-stranded DNA-specific deaminase activity (**Figure 3**). Cytidine deamination results in the generation of uracil-containing viral DNA, which likely becomes targeted by DNA repair/degradation enzymes. However, if the viral DNA escapes degradation then uracil is replicated to adenosine during second strand synthesis, resulting in viral DNA with characteristic G-to-A hypermutation. Generally, the burden of G-to-A mutations is high, rendering the proviral DNA incapable of encoding replication-competent progeny.

APOBEC3G is promiscuous with respect to its antiretroviral effect, because it is packaged into diverse retrovirus particles. The mechanism by which this is achieved involves a substantial nonspecific component, whereby APOBEC3G binds in an apparently sequence-independent manner to the RNA that is packaged into virions. Thus, APOBEC3G exploits an essential property of retroviruses to infiltrate particles and therefore makes it difficult for retroviruses to evolve mutations that avoid packaging APOBEC3G into virions. Perhaps because of this difficulty, primate lentiviruses have arrived at an unusual and highly effective solution to the problem imposed on them by APOBEC3G. Indeed, all primate lentiviruses encode an accessory gene, *vif,* whose only function appears to be to counteract APOBEC3G. Vif proteins bind simultaneously to APOBEC3G and to a ubiquitin ligase complex containing Cul5, elongin B, and elongin C to induce ubiquitination of APOBEC3G. Predictably, this leads to proteasome-dependent APOBEC3G degradation, effectively depletes APOBEC3G from the cell, and abolishes incorporation into virion particles. Interactions between APOBEC3G and Vif proteins form the basis of additional species tropism restrictions in primate lentiviruses. Although HIV-1 Vif can efficiently bind to and induce the degradation of human APOBEC3G, it is inactive against its rhesus macaque or AGM counterparts. In contrast, rhesus macaque and AGM APOBEC3G can be recognized by Vif proteins from SIVs found in macaques and AGMs. A single-amino-acid difference between human and monkey APOBEC3G proteins (K128D) is responsible for differential sensitivity to Vif proteins and imparts a second barrier to cross-species transmission for at least some primate lentiviruses. Foamy viruses that are also common in primates have also acquired a gene, Bet, whose function is to exclude APOBEC3 proteins from virion particles. Moreover, other retroviruses appear to avoid the APOBEC3 proteins without encoding accessory genes to exclude it from particles. However, in these cases the molecular mechanism of particle exclusion is not clearly defined.

Like *TRIM5*, the locus containing *APOBEC3G* has been under evolutionary pressure during mammalian speciation, most likely as a consequence of viral infections. Indeed, while mice have only one *APOBEC3* gene, humans have no less than seven that have arisen as a result of *APOBEC3* gene duplication and recombination events.

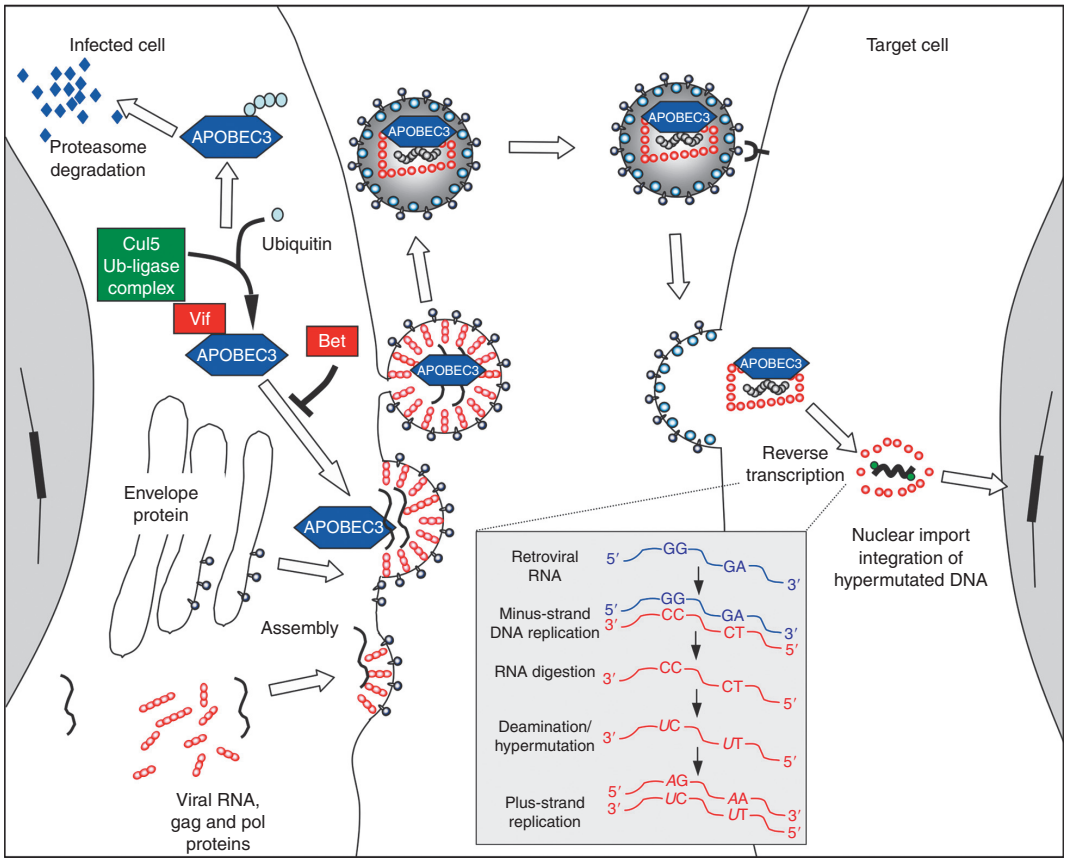

Figure 3 Major mode of action and alternative fates of APOBEC3 proteins that become incorporated into retrovirus particles and catalyzed cytidine deamination during infection of target cells. Some APOBEC3 proteins can be recruited by lentiviral Vif proteins to a ubiquitin ligase complex and degraded in a proteasome-dependent manner. Alternatively, foamy virus Bet proteins prevent incorporation of APOBEC3 into virus particles by unknown mechanisms.

Most of the *APOBEC3* genes, like TRIM5, exhibit excess nonsynonymous polymorphisms in primates, again suggesting evolutionary pressure. Several members of the *APOBEC3* gene cluster exhibit varying levels of activity against numerous retroviruses and retroelements, and some are targeted for degradation by primate lentiviral Vif proteins. In some cases, the APOBEC3 proteins are distinguishable by their substrate preference. For example, APOBEC3G-mutated retroviral DNA carries G-to-A changes primarily in the context of GG dinucleotides, while its close relative, APOBEC3F, preferentially targets GA dinucleotides. In the context of HIV-1-infected humans, APOBEC3G and its close relative APOBEC3F appear to be the major contributors to cytidine deamination-based host defense. Indeed, viral DNA carrying G-to-A hypermutation can be found quite easily in some patients, and the context in which the G-to-A changes occur suggests that both APOBEC3G and APOBEC3F are responsible.

While APOBEC3G and its relatives can clearly inhibit retrovirus replication by inducing catastrophic hypermutation, it may be that lentiviruses have turned its cytidine deamination activity to their advantage and are evolved to only partially resist APOBEC3 proteins. Less dramatic changes in viral DNA sequence may result from partial destruction of APOBEC3G by Vif, and infiltration of viral particles by a small number of APOBEC3 molecules. Indeed, Vif proteins with a range of potencies can be found in HIV-1-infected patients. Primate lentiviruses are capable of extremely rapid sequence divergence, and this is probably required to maintain their characteristic high levels of chronic replication in the presence of strong adaptive immune responses. Certainly, the A-rich nature of their genomes suggests that cytidine deaminases have played a role in influencing the rate and direction of sequence divergence in primate lentiviruses.

While cytidine deamination is thought to be the major mechanism by which APOBEC3 proteins inhibit retrovirus replication, some studies suggest that this class of proteins may also inhibit retrovirus and retroelement replication through mechanisms that do not involve hypermutation. In addition, it may be that inhibition does not require APOBEC packing into retroviral particles and that its presence in the cytoplasm of particular

target cells is sufficient to inhibit the early post-entry steps of the retrovirus life cycle. However, these additional apparent activities of APOBEC proteins are poorly understood at present.

Other Host Resistance Factors That Act during Virus Generation

The genomes of retroviruses appear to be the target of a further host defense activity that likely recognizes newly synthesized RNA. Zinc-finger antiviral protein (ZAP) inhibits the cytoplasmic accumulation of the genomes of some retroviruses and, more impressively, alphaviruses. Its mechanism of action may be related to that of the tristetraprolin-like proteins that it resembles, which induce the degradation of cytokine mRNAs by binding to AU-rich sequences in their 3′ untranslated regions. By doing so, ZAP may recruit viral RNAs to a collection of ribonucleolytic activities referred to as the exosome. ZAP obviously must distinguish between viral and cellular mRNAs but the molecular basis for this distinction is currently unknown.

It is also possible for cells to interfere with the assembly of retrovirus particles. There exists at least one example where defective Gag proteins encoded by an endogenous retrovirus, namely Jaagsiekte sheep retrovirus, can form heteromultimers with and interfere with the assembly of the Gag protein of its exogenous cousin. Yet another intrinsic immune mechanism targets retrovirus particle release. In some human cells, retrovirus particles are released very inefficiently, unless a protein that is expressed by a subset of primate lentiviruses, termed Vpu, is also present. Vpu is not required for the efficient release of retroviruses from some cell lines, but fusion of cells that do or do not require the presence of Vpu for efficient release results in heterokaryons that exhibit the Vpu-dependent virus release phenotype. While many retroviruses do not encode a Vpu protein, some envelope proteins appear to exhibit a similar activity. These findings suggest the existence of a cellular inhibitor of retrovirus release that is counteracted by Vpu or envelope proteins. Because Vpu can facilitate the release of a number of divergent retroviruses, the presumed release inhibitor must target particle release in a rather nonspecific way. A current model that explains many of the effects of Vpu invokes the existence of a release inhibitor that endows cells and/or nascent virions with an adhesive property. Virion–cell adhesion would result in the retention of viral particles on the cell surface, from where they would be subsequently endocytosed. Consistent with this model, retroviral particles generated by cells in which release is inefficient in the absence of Vpu accumulate at the cell surface and later within intracellular endosomes.

Perspectives

Historically, the ability or inability of retroviruses to colonize a particular species or cell type was thought to be defined almost entirely by its ability to parasitize host functions present therein that are necessary to complete its life cycle. However, recent findings have shown that evolution has equipped cells with an often robust and multicomponent defense against retroviruses that seek to colonize them. These activities constitute an equally important determinant of retroviral cell tropism. Studies of restriction factors are in their infancy, but these new insights have given a deeper understanding of the evolutionary relationships between retroviruses and their hosts and what governs the ability of retroviruses to engage in zoonosis. Moreover, the discovery of antiretroviral activities within cells that target pathogenic retroviruses may provide new opportunities for therapeutic intervention.

Introduction

Cytomegaloviruses, also known as salivary gland viruses, are widely distributed, species-specific herpesviruses, with an evolutionarily related representative identified in most mammalian hosts when cells of the same species have been used for isolation. Human cytomegalovirus (HCMV), formally called human herpesvirus 5 (HHV-5), infects a majority of the world population by adulthood, but causes acute disease in only a small proportion of immunocompetent individuals. Developing areas of the world typically exhibit widespread transmission early in life, whereas more developed areas show a broader range of patterns. Individuals may escape infection early in life and remain susceptible during the childbearing years. Once rubella was controlled by vaccination, transplacental transmission of HCMV emerged as the major infectious cause of congenital hearing loss preventable by vaccination. HCMV is an opportunistic pathogen associated with disease in immunocompromised hosts, predominating in the settings of genetic or acquired immunodeficiency, allograft tissue and organ transplantation, and pregnancy. Disease pathogenesis requires active viral replication and focuses on different target tissues and organs in different clinical settings, particularly in circumstances where the ability to mount a cellular immune response has been compromised. Transmission of this virus in the general population depends on direct contact with infected bodily secretions.

History and Classification

HCMV is designated formally in the species *Human herpesvirus 5* and belongs to genus *Cytomegalovirus* in subfamily *Betaherpesvirinae* of the family *Herpesviridae*. Human herpesvirus 6 (HHV-6; often considered as two variants, HHV-6A and HHV-6B) and human herpesvirus 7 (HHV-7) belong to the species *Human herpesvirus 6* and *Human herpesvirus 7*, respectively, and represent genus *Roseolovirus* in the same subfamily. All betaherpesviruses replicate slowly in cell culture, remain cell-associated, and exhibit species specificity.

Starting in the early 1930s, the most severe form of HCMV-associated congenital disease, cytomegalic inclusion disease (CID), was recognized by an 'owl's eye' cytopathology in salivary gland, liver, lung, kidney, pancreas, and thyroid autopsy materials from infants. By the early 1950s, CID diagnosis was based on the presence of inclusion-bearing cells in urine, and viral etiology was established by isolation on cultured human fibroblasts. By the early 1970s, the host species specificity of viral replication, widespread distribution of HCMV-like agents in mammals, and tissue and cell type distribution in the diseased host were well recognized. Most importantly, the relationship between transplacental transmission and neurological damage in newborns was established and the social cost of the major sequela, progressive sensorineural hearing loss, placed a high priority on control of this infection through vaccination, which has not been realized to this day. Although primary infection results in the most severe disease with congenital infection, less frequent transmission following recurrent maternal infection nevertheless remains important in the overall epidemiology of disease. Placental infection appears to be considerably more frequent than transplacental transmission, which overall is on the order of 0.5–1% of live births in the USA or Europe. Transplacental transmission is less frequent during recurrent infection (<1% of newborns) than during primary infection (~30–40% of newborns). Young children are a major reservoir of this virus, often responsible for transmitting primary infection in pregnant women.

The second prominent setting of HCMV disease is in the immunocompromised host, and this has driven initiatives for therapeutic intervention. HCMV is associated with various diseases in which T-lymphocyte immune surveillance is compromised. Infection of immunocompetent individuals, ranging from immediately postpartum through adulthood, does not generally lead to significant illness other than occasional (heterophile negative) mononucleosis. A remarkably strong and broad T-cell response, particularly the cytotoxic T-cell response, contributes to lifelong suppression of active virus replication. Immunosuppressive therapy necessary to prevent T-cell-mediated allograft rejection reduces HCMV immunosurveillance, allowing the virus to replicate to levels that lead to various diseases. The incidence of HCMV pneumonia in allogeneic hematopoietic cell transplantation (HCT) and the widespread incidence of HCMV retinitis in acquired immune deficiency syndrome (AIDS) contributed to the development of the antiviral drugs ganciclovir, foscarnet, and cidofovir, and to the later development of the orally administered drug, valganciclovir, as well as ongoing investigation of maribavir. HCMV plays a suspected role in chronic vascular diseases, and this is best illustrated by cardiac allograft vascular disease incidence in heart transplantation and the contribution of this virus to incidence of bacterial and fungal infections in allogeneic HCT settings.

Geographic and Seasonal Distribution

As a ubiquitous virus, HCMV does not show a particular seasonal distribution, although initial acquisition varies with living circumstances. In general, prevalence is more widespread in younger individuals in developing countries than in developed countries, and, within developed countries, it is more widespread in urban than in suburban groups, and low-socioeconomic groups than in high-socioeconomic groups. In a US-based survey, overall HCMV prevalence was approximately 60%, with a higher prevalence in females (64%) than males (54%) and in non-Hispanic blacks (76%) and Mexican Americans (82%) than in non-Hispanic whites (51%). There is a doubling in the prevalence of HCMV infection between childhood and old age, which rises to include 75–85% of the population regardless of demographic considerations. In addition to age and socioeconomic level, early acquisition of HCMV is observed in immigrants and is associated with fewer years of education, large family size, and residence in the southern states.

Host Range and Virus Propagation

Cytomegaloviruses are most readily propagated in fibroblasts cultured from the origin host species, although efficient replication of HCMV in human fibroblasts is facilitated by mutations in the viral genome that reduce the ability to replicate in other host-cell types. Studies on autopsy materials from immunocompromised individuals with acute HCMV disease have shown evidence of virus replication in epithelial, endothelial, macrophage, and dendritic cells. HCMV antigens are also readily detected in nonpermissive peripheral blood (PB) neutrophils of diseased individuals, probably as a result of phagocytosis, and this has become the basis of an important diagnostic assay (antigenemia) specific for a major viral structural antigen (pp65). Fresh clinical isolates replicate efficiently on primary or secondary cultures of epithelial, endothelial, macrophage, and dendritic cells, but this tropism is lost when virus is propagated in fibroblasts due to mutations that accumulate in the viral genome. Extensively passaged laboratory strains acquire a variety of large and small deletions that remove or disrupt tropism genes as well as other genes that are dispensable for replication in cultured fibroblasts. Variants of common laboratory strains, all used under a single name (e.g., AD169, Towne), have arisen via independent propagation since their isolation in different laboratories around the world. Although cellular receptors for HCMV are important determinants of entry into host cells, species specificity and human cell tropism is not determined solely by the distribution of receptors for this virus; nonpermissive fibroblasts from other species generally allow viral attachment and penetration, but are blocked at an early postentry step. An exception appears to be HCMV isolated and adapted to fibroblasts, during which variants arise that lack the ability to enter primary human endothelial cells, epithelial cells, and myeloid cells due to acquisition of mutations.

Genetics and Replication

Betaherpesviruses have linear DNA genomes with direct terminal repeats that contain the *cis*-acting signals for cleavage and packaging of progeny viral DNA during replication. Based on a subset of protein-coding genes conserved across mammalian members of the *Herpesviridae* (the core genes), all herpesviruses likely follow common pathways of DNA replication, DNA encapsidation, and virion maturation. Otherwise, betaherpesvirus genomes exhibit some divergent characteristics. Primate cytomegaloviruses undergo genome rearrangement similar to some alphaherpesviruses. HCMV packages any one of four isomers and has a genome organization that includes a unique long (U_L) component surrounded by a set of inverted repeats (*ab–b′a′*, or TRL–IRL) and a unique short component (U_S) also surrounded by a second set of inverted repeats (*a′c′–ca*, or TRS–IRS) (**Figure 1**). HHV-6 and HHV-7 do not rearrange, and have genomes with a large terminal repeat. Murine or rat CMV genomes also do not rearrange and have terminal repeats that are the smallest (<50 bp) of any characterized herpesvirus.

Genome sequence analysis has revealed evolutionary relationships and codified the classification of herpesviruses. Betaherpesvirus genomes are collinear and exhibit more extensive genetic similarity with each other than with other herpesviruses, where the 40 core genes are arranged in different clusters. Betaherpesviruses encode approximately 170 protein-coding gene homologs, 40 of which are common to alphaherpesviruses and 46 of which are common to gammaherpesviruses. **Figure 1** depicts these gene sets along with an estimate of the overall genomic coding capacity.

The HCMV virion has typical herpesvirus structure, although somewhat larger than alphaherpesviruses or gammaherpesviruses, at 200–300 nm diameter. The 125 nm icosahedral nucleocapsid is composed of five herpesvirus core proteins: the major capsid protein (MCP) comprising the hexons and pentons, the minor capsid protein (mCP or TRI2) together with the minor capsid protein-binding protein (mCP-BP or TRI1) comprising the intercapsomeric triplexes, the small capsid protein (SCP) that decorates the hexon tips, and the portal protein (PORT) that comprises one penton position and is used for encapsidation of viral DNA. The nucleocapsid encloses a single linear molecule of DNA as well as origin of lytic DNA replication (*ori*Lyt)-associated RNA. The nucleocapsid is embedded in a tegument (or matrix) containing at least 27

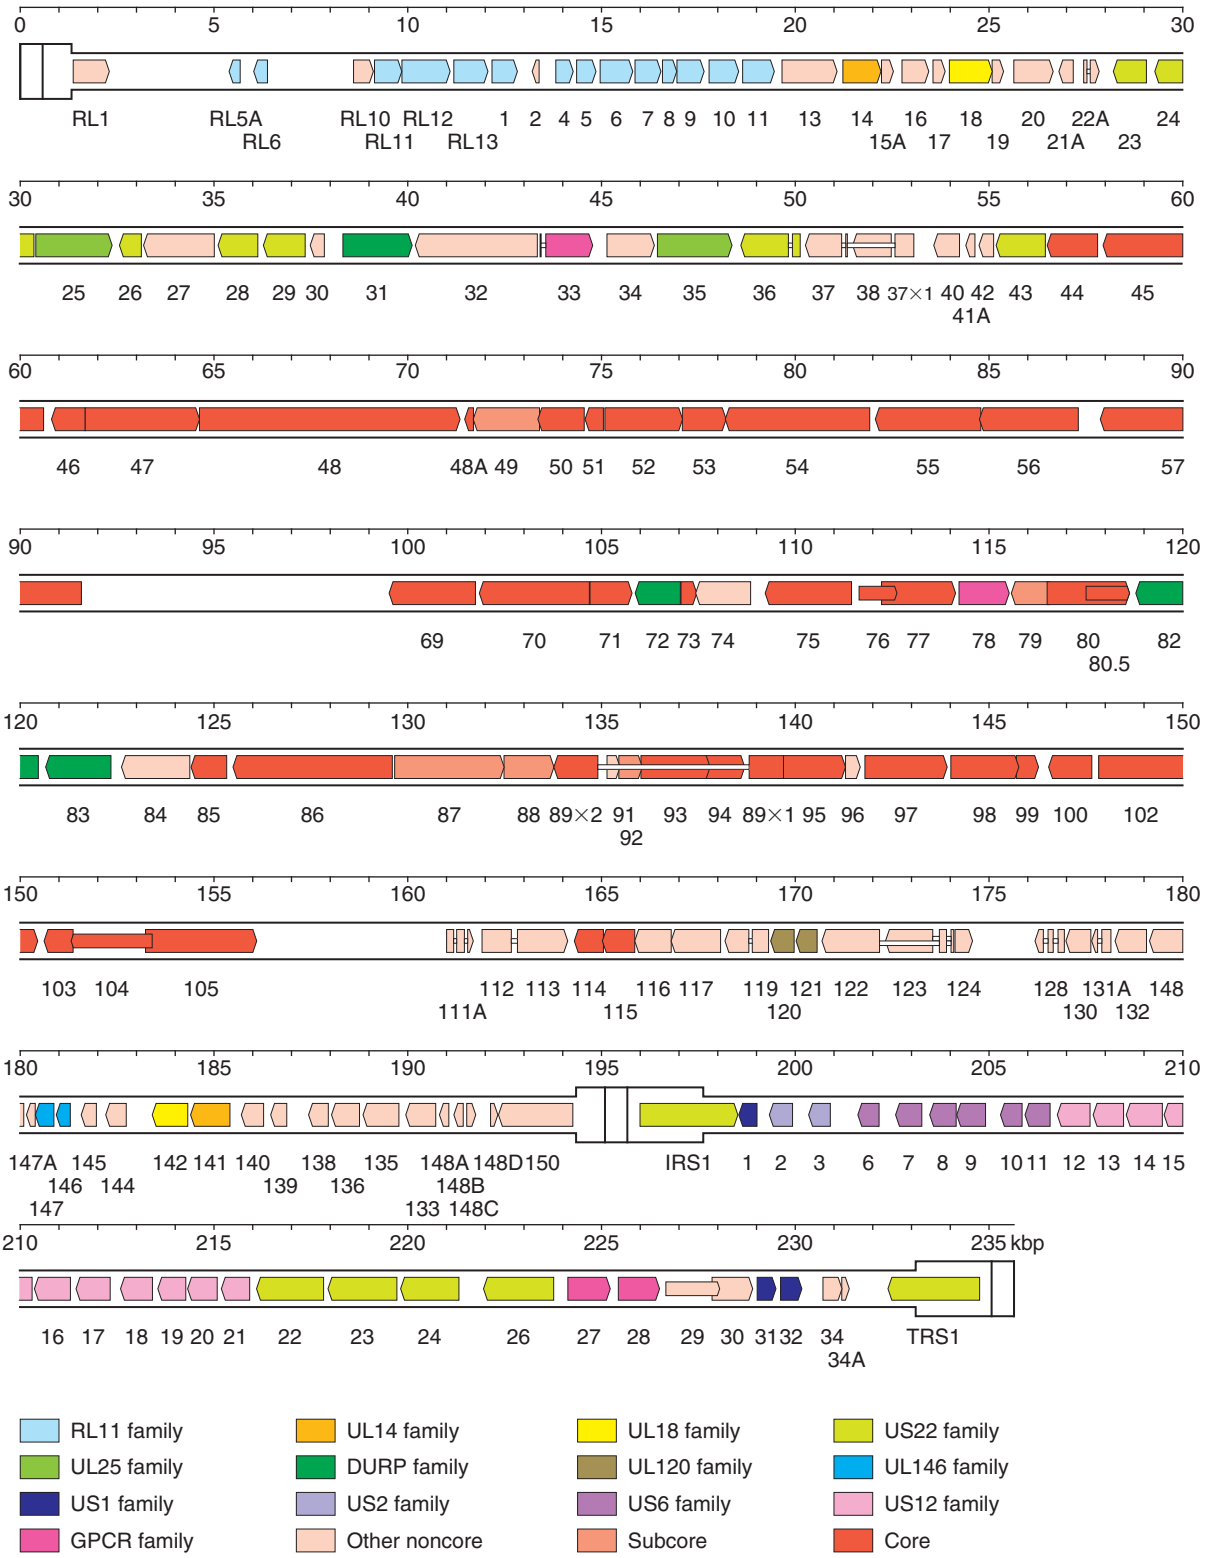

Figure 1 Genetic organization and content of wild-type human HCMV, based on low passage strain Merlin. The inverted repeats TRL/IRL (*ab–b′a′*) and TRS/IRS (*a′c′–ca*) are shown in a thicker format than U_L and U_S. Protein-coding regions are indicated by arrows and gene names are listed below. Introns are shown as narrow bars. Genes corresponding to those in TR_L/IR_L and TR_S/IR_S of strain AD169 are given their full nomenclature, but the UL and US prefixes have been omitted from UL1–UL150 and US1–US34A. Herpesvirus core genes (inherited from the ancestor of the alpha-, beta-, and gammaherpesviruses), subcore genes (inherited from the ancestor of beta- and gammaherpesviruses), other unique genes (homologs present only in betaherpesviruses), and members of families of related genes are color-coded as depicted in the key. Adapted from Dolan A, Cunningham C, Hector RD, *et al*. (2004) Genetic content of wild type human cytomegalovirus. *Journal of General Virology* 85: 1301–1312, with permission from Society for General Microbiology.

relatively abundant virus-encoded phosphoproteins as well as many more proteins and RNAs that are present in small amounts. About a dozen herpesvirus core as well as a dozen betaherpesvirus-specific structural proteins are considered tegument components. These appear to be involved in the earliest steps of infection and uncoating and release of the viral genome into the nucleus, as well as at late stages of replication for encapsidation of progeny viral DNA, capsid egress from nuclei, and, importantly, final envelopment and egress from the cytoplasm. Tegument proteins also modulate events in the host cell to block intrinsic resistance mechanisms that impede viral replication. The tegument is surrounded by a lipid bilayer envelope derived from cellular endoplasmic reticulum (ER)–Golgi intermediate compartment (ERGIC) membranes and into which some 20 or more virus-encoded glycoproteins are inserted. Unlike other herpesviruses that encode subgroup-specific envelope glycoproteins central to entry, the most prominent HCMV envelope glycoproteins are herpesvirus core gene products. These are known by common nomenclature as glycoprotein (g)B, gH:gL, and gM:gN, and all play essential replication functions. None of the numerous additional glycoproteins encoded by HCMV are essential for replication in cultured fibroblasts. Overall, HCMV is the most structurally complex herpesvirus, reflecting the large number of gene products encoded by this virus. During infection in cell culture, HCMV produces an abundance of noninfectious particles, including dense bodies that lack a nucleocapsid as well as other defective, capsid-containing particles. These particles constitute at least 99% of virion preparations, producing particle-to-PFU ratios of 100 or greater.

Complete or largely complete genome sequences have been determined for a number of laboratory and low-passage HCMV strains. All HCMV strains exhibit an average of >95% DNA sequence identity, although large deletion mutations are present in many highly propagated strains. Wild-type HCMV is estimated to carry a minimum of 166 protein-coding genes, the great majority of which are conserved in the closest relative of HCMV, chimpanzee CMV. A liberal upper estimate of 252 ORFs has been suggested. In addition to protein-coding genes and potential miRNA-like elements, the HCMV genome has three types of resident signals that act to control gene expression, DNA replication, and DNA packaging during replication. The genes on the viral genome are controlled by promoter-regulatory signals that are recognized by host-cell RNA polymerase II and influenced by viral regulatory proteins, and are expressed in a temporal cascade that initiates following penetration of the host cell.

Entry into cells depends upon envelope glycoproteins and release of virion DNA into the nucleus depends upon tegument proteins. Entry initiates with a series of distinct steps involving (1) binding to specific cell surface receptors, (2) fusion of the virion envelope with the cellular membrane to release nucleocapsids into the cytoplasm, (3) nucleocapsid association with cytoskeletal elements and translocation toward the nucleus, (4) nucleocapsid interaction with nuclear pores, and (5) release of the viral genome into the nucleus (**Figure 2**). Expression of the immediate early (IE) class of viral genes follows entry and is influenced by virion tegument proteins (virion transactivators). IE genes include viral functions that regulate gene expression by activating transcription and suppressing host repression systems, cell death, and major histocompatibility complex class I gene expression. As in all herpesviruses, different temporal classes of genes are interspersed across the HCMV genome. The IE genes are not clustered and map to diverse locations in the U_L, U_S, and IR_S/TR_S regions of the viral genome. Expression of the next set of genes, the delayed early (DE) genes, depends on the expression of regulatory IE gene products. DE genes control the initiation of viral DNA replication and a wide range of host-cell modulatory functions. Viral DNA synthesis initiates on the viral genome at oriLyt and relies on six core virus-encoded DNA synthesis proteins well as additional functions that facilitate this process. Expression of late (L) genes occurs last and includes a majority of virion structural proteins, a great many of which are herpesvirus core functions. DE and L gene classes also include as many as 100 immunomodulatory functions that impact the host cell and the immune response of the host, only a fraction of which have been studied (**Table 1**).

The replication cycle of HCMV is slow, requiring 48–72 h to begin the release of progeny, with a switch from E to L phase being delayed until 24–36 h post infection (hpi) and maximum levels of virus release starting at 72 –96 hpi. The basic features of HCMV capsid formation and maturation are likely to be common to all herpesviruses. Encapsidation of viral DNA is under the control of a set of viral proteins that package and cleave viral DNA molecules into preformed capsids. Seven herpesvirus core encapsidation proteins likely act as a complex to process a concatemeric DNA template via cleavage/packaging (*pac*) sites located within the terminal *a* sequences, and following the insertion of genome-length viral DNA, cleave to produce a filled nucleocapsid. The nucleocapsid follows a complex two-stage envelopment and egress process that starts in the nucleus and leads to virion release by exocytosis at the plasma membrane. This process depends upon many core herpesvirus functions and starts with primary envelopment at the inner nuclear membrane followed by a de-envelopment event at the outer nuclear membrane, a process that releases the nucleocapsid into the cytoplasm (**Figure 2**). Secondary envelopment occurs in the cytoplasm at ERGIC membranes with the resulting vesicles transporting mature virions to the cell surface using the cellular exocytic pathway. Dense bodies form in the cytoplasm,

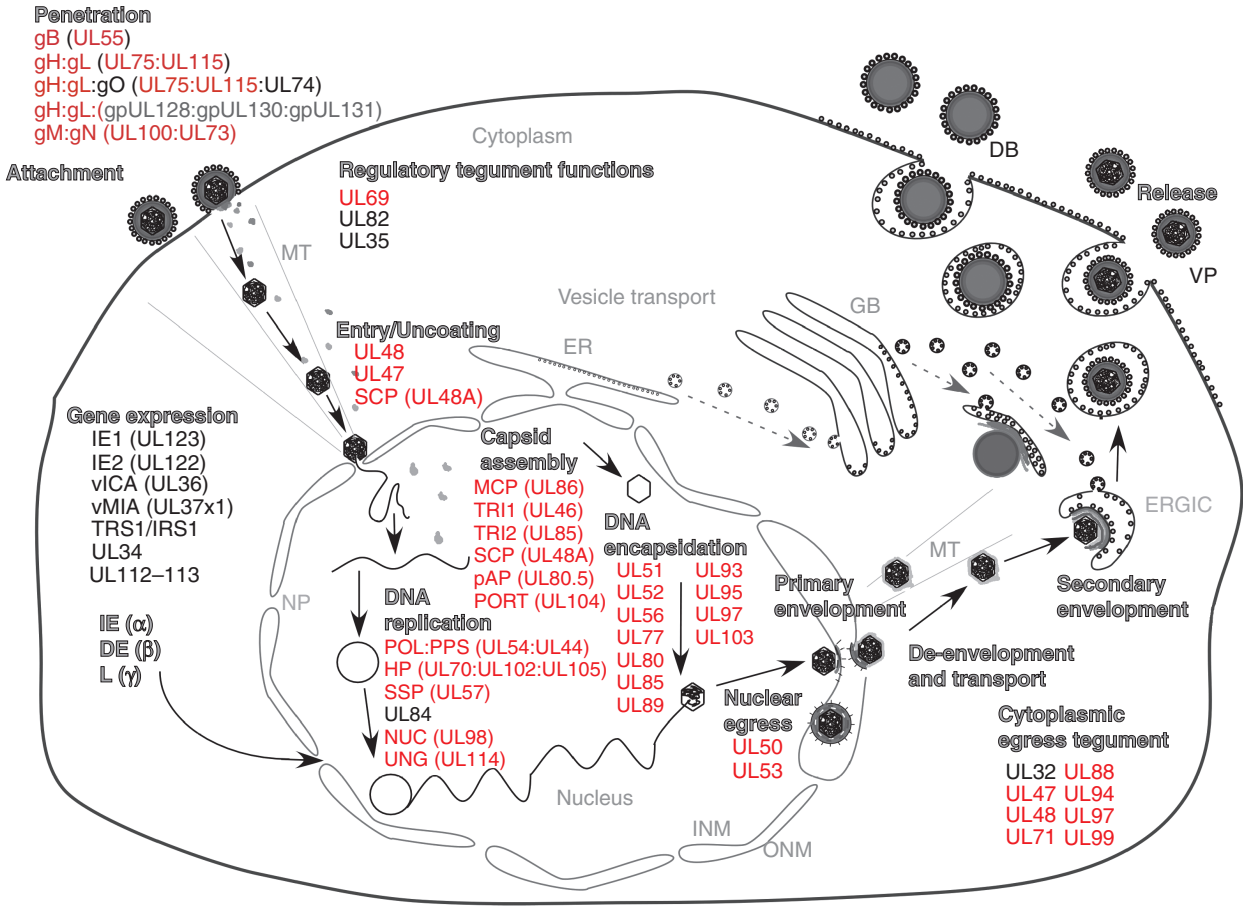

Figure 2 Summary of the HCMV replication pathway with focus on herpesvirus core (red) and betaherpesvirus-conserved (black) gene products playing known or predicted roles in replication. Major steps in productive replication are indicated in large gray outlined font, and black arrows indicate the procession of steps with individual functions identified by abbreviated names. The entry pathway shown employs direct fusion at the plasma membrane (attachment and penetration) although an endocytic pathway may also be important in certain cell types. Entry requires gB, gH:gL, possibly with gO, or gpUL128-gpUL130-gpUL131, and gM:gN.Virion tegument functions (UL69, UL82, UL35) are involved in regulation. UL47, UL48, and SCP are predicted to mediate transport on microtubules, docking at nuclear pores, and release of virion DNA from the capsid into the nucleus. Transcriptional regulation of viral and host-cell gene expression is mediated by IE genes (IE1, IE2) or DE genes (UL34, UL35, UL112-UL113). Cell death suppression is mediated by IE gene products vICA and vMIA. DNA replication depends on several core proteins (POL:PPS, HP, SSB, NUC, and UNG) as well as one betaherpesvirus-specific function (UL84). Capsid assembly uses core functions MCP, TRI1:TRI2, SCP, PORT, and pAP. Preformed capsids likely translocate to sites of DNA replication where several core proteins (UL51, UL56, UL77, UL80.5, UL85, UL89, UL93, UL95, UL97, UL103 gene products) are likely to be involved in encapsidation of viral DNA. Nuclear egress is likely to be controlled by UL50 and UL53 gene products, which are core proteins. Cytoplasmic egress (black arrows) and secondary (final) envelopment are controlled by core functions (UL47, UL48, UL71, UL88, UL94, UL97, UL99 gene products) as well as one betaherpesvirus-specific protein (UL32 gene product). Nucleocapsids are likely transported on microtubules and virion envelope glycoproteins follow vesicle transport to sites of final envelopment in the cytoplasm. Golgi body (GB), microtubules (MTs), and ER and ERGIC, as well as both virus particle (VP) and dense body (DB) final release steps are identified in the cytoplasm. Nuclear pores (NPs), inner nuclear membrane (INM), and outer nuclear membrane (ONM) are identified in the nucleus. The cellular vesicle transport pathway from the ER to GB is also designated (dashed gray arrow).

following only the cytoplasmic steps (**Figure 2**). Once maturation starts, infected fibroblasts continue to produce virus at peak levels for several days, depending on the viral strain and constellation of cell-death suppressors encoded by the strain. Based on systematic mutagenesis, about 80 viral genes play important roles in replication, with roughly 45 being essential for replication in fibroblasts.

Evolution

HCMV has a 236 kbp genome and the capacity to encode in excess of 166 gene products, including several gene families (**Figure 1**). This is considerably more than HHV-6 and HHV-7, whose smaller genomes (145–162 kbp) encode an estimated 84 or 85 gene products. Cytomegaloviruses from a wide variety of host species conserve the same 70

[a]Commonly annotated ORFs of HCMV (see **Figure 1**). Based on the replication properties of HCMV mutant viruses, most genes are dispensable in cell culture (normal type). Viruses with mutations that influence replication efficiency exhibit one of three broad growth deficient phenotypes: failure to replicate (†), very poor replication (¥), or slight replication defect (¶) when assayed in human fibroblasts. Mutations of putative HCMV ORFs UL60 and UL61 are interpreted as disrupting *ori*Lyt rather than any protein-coding ORF. Certain mutant virus phenotypes vary depending on viral strain and strain variant tested.

[b]Betaherpesvirus-common genes are in italics, and include 40 herpesvirus core functions, labeled as 'core'. Gene family, characteristics, and functional information are provided for HCMV and a blank indicates the lack of information.

[c]Abbreviations: fam, family; pp, phosphoprotein; teg, tegument; gp, glycoprotein; mem-gp, membrane gp; env-gp, envelope gp, TM-gp, transmembrane gp; sec, secreted; put, putative; GPCR, G-protein-coupled receptor; 7TM, seven transmembrane-spanning; IE, immediate early.

[d]Functional information is speculative in some cases.

betaherpesvirus-common genes, as do HHV-6 and HHV-7. Betaherpesviruses exhibit the greatest divergence observed in the herpesviruses, with even the most closely related primate cytomegaloviruses exhibiting differences in gene content and different CMV strains containing a subset of strikingly variable genes. Human roseoloviruses and HCMVs lack detectable DNA sequence homology. The deduced protein-coding capacity of cytomegaloviruses is also highly diverged, although a set of betaherpesvirus-conserved proteins emerges from bioinformatic analysis of potential protein-coding regions and greater levels of conservation are observed in cytomegaloviruses of closely related host species. The diversity of genes observed in biologically related viruses may be a product of immune clearance pressure through co-evolution with particular hosts. Each betaherpesvirus appears to have co-evolved with its host species and exhibits little genetic evidence of cross-species transmission.

Pathogenesis and Latency

HCMV transmission is via contact with virus-positive body fluids and requires direct contact with infectious material, as is the case with most human herpesviruses. HCMV is shed for prolonged periods of time in urine, saliva, tears, semen, and cervical secretions, as well as in breast milk. HCMV transmission rates are highest where contact with body fluids occurs, such that HCMV is an important sexually transmitted disease as well as an infection that is transmitted among children in day-care centers and from young children to parents and other care providers. Thus, two distinct types of exposure are associated with horizontal transmission of HCMV: sexual activity among adults and direct contact with urine or saliva from young children. Children in day-care centers, who frequently transmit virus to each other through casual contact, continue to shed virus in saliva and urine for years without symptoms. Day-care workers have markedly increased rates of HCMV infection as do parents of young children who attend day-care centers, where transmission rates of 10% or greater per year have been reported. Hygiene is thought to play a role in transmission, and regular hand washing has been recommended to reduce transmission. Although shedding of HCMV is common among hospitalized individuals, medical-care professionals who are known to use good hygiene practices do not exhibit any increased risk of HCMV infection. Horizontal transmission may also occur through blood transfusion, blood and marrow (hematopoietic cell) allograft transplantation, and in the clinically important setting of solid organ transplantation from HCMV seropositive donors to naive recipients.

HCMV is transmitted vertically during pregnancy, as well as during the birthing process or from mother's milk. Transplacental transmission is a characteristic of HCMV and possibly roseoloviruses, and is not observed with alphaherpesviruses or gammaherpesviruses. Primary

infection has been reported to occur in 1–4% of pregnant women, and is associated with a significant risk for transplacental transmission. Between 20% and 40% of newborns delivered by women with primary infection are HCMV infected, compared to between 1% and 2% of newborns delivered by women with past infection. Primary infection is associated with more severe forms of congenital disease, although disease occurrence has been well documented in both settings. Transmission at birth as well as through mother's milk helps maintain HCMV infection in the population, with 25–50% of infants nursed by seropositive mothers acquiring HCMV by 1 year of age. Importantly, there are no known disease sequelae associated with intrapartum or postpartum acquisition of HCMV in healthy term newborns.

Although serotypes of HCMV have not been useful for epidemiology, various molecular genetic approaches that assess viral genome sequence variation have been used to differentiate viral strains in circulation. Comparison of polymerase chain reaction (PCR)-amplified segments of specific, highly variable genomic regions and protein-coding genes has been most useful, notably the noncoding genomic L–S junction (*a* sequence) as well as genes UL144, UL146, UL73, and UL74. To date, no particular viral strain has been unambiguously linked to any clinical disease.

HCMV appears to reside latent in progenitor cells of the myeloid lineage and to reactivate when these progenitors are stimulated by pro-inflammatory cytokines. HCMV is persistently detected in saliva approximately 3–5% of the time. Based on the distribution and levels of viral DNA, natural latency occurs in bone marrow-derived myelomonocytic cells that give rise to macrophages and dendritic cells, with approximately 0.01–0.001% of cells infected and each cell carrying two to ten genome copies of HCMV DNA. Little is known about sporadic reactivation in immunocompetent individuals, which leads to shedding in saliva and other bodily fluids. However, reactivation in allogeneic transplant settings appears to follow the elaboration of pro-inflammatory cytokines that are a component of tissue rejection. Patients with compromised immunity to HCMV amplify virus to levels that become a clinical threat. HCMV reactivation also occurs in settings without allogeneic stimulation. Pregnancy appears to allow reactivation at levels that are not a threat to women but may be a threat to a developing fetus. Severely immunocompromised patients, such as terminal AIDS patients, appear to support sufficiently high levels of HCMV replication for disease to occur.

Clinical Features and Pathology

HCMV infection in the immunocompetent host is typically clinically silent. A small percentage of mononucleosis is due to HCMV, which is typically less severe than that caused by Epstein–Barr virus. Severe or systemic HCMV disease affecting one or more organs only occurs in immunocompromised hosts and has been known to unveil underlying immunodeficiency in individuals with a previously unrecognized immune deficit.

Congenital disease is the hallmark of HCMV pathogenesis and follows transplacental transmission to the fetus any time during pregnancy, and is a particular risk for woman with primary infection. Congenital disease remains the most important medical and public health concern for HCMV, and is difficult to identify because primary infection is typically asymptomatic. A significantly lower rate of congenital disease follows recurrent compared to primary maternal infection during pregnancy, providing the key evidence that universal vaccination would benefit the population. In addition, primary infection at an earlier gestational age is most likely to manifest as disease in the newborn. HCMV disease recognized at birth often reflects neuronal damage (hearing loss, retinitis, optic neuritis, microcephaly, or encephalopathy) as well as damage to the reticuloendothelial system (hepatomegaly, splenomegaly, petechiae, or jaundice). Prematurity and poor intrauterine growth are common among newborns with symptomatic congenital HCMV infection. Although the majority of infected newborns are asymptomatic at birth, some still develop sequelae, notably sensorineural hearing loss, over the first few years of life. Most newborns with congenital HCMV infection, even those severely affected at birth, survive; congenital HCMV infection takes its toll by affecting hearing, eyesight, and mental capacity.

Very low birth weight premature infants who acquire HCMV infection during birth or postpartum (from human milk or transfusion) may develop systemic disease that is distinct from conventional congenital disease. Risk factors include very low birth weight, exposure to multiple units of blood and birth to a seronegative mother (lack of passive immunity). Transfusion-associated HCMV disease in newborns has been controlled by the use of seronegative (or leukocyte-depleted) blood products. Whether or not transmission of HCMV from a mother's milk to a very low birth weight premature newborn should be prevented remains an area of controversy.

HCMV has become one of the most common opportunistic pathogens as allograft transplantation has grown and as the AIDS epidemic has unfolded. Solid organ and hematopoietic cell allograft recipients all receive strong post-transplant immunosuppressive therapy and AIDS patients progress to a T-lymphocyte deficit that provides an opportunity for HCMV to replicate to high levels and cause disease. Active infection arises from primary infection of naive individuals, reinfection with additional strains of virus, and reactivation of latent virus. This aspect of disease pathogenesis is complicated because HCMV

shedding and viremia are common in the face of impaired cellular immunity even when HCMV disease is absent. Clinically silent HCMV infection may predominate even in the face of antiviral prophylaxis, and may only progress to disease as T-cell-mediated immune surveillance becomes severely compromised, such as occurs in AIDS patients with very low CD4 T-cell counts.

Clinical manifestations of disease in solid organ transplant patients include systemic, febrile illness (CMV syndrome, with malaise, arthralgia and rash; neutropenia, thrombocytopenia, and elevated liver enzymes), as well as a direct or indirect impact on specific organs. This disease risk has been reduced but not eliminated by preemptive therapy or prophylaxis with antiviral drugs. Clinical detection of infection using assays for viral antigens or nucleic acids without the need for virus culture successfully reduced the incidence of acute HCMV disease in the first few weeks following transplantation. Preemptive therapy has been beneficial in other high-risk patients such as allogeneic blood and marrow (hematopoietic cell) transplantation where late-onset disease and indirect effects have become more prominent. The detection of HCMV antigens (usually pp65 antigenemia) or nucleic acids (usually PCR detection of viral DNA in plasma or leukocytes) in blood is used to implicate this virus in disease. Solid organ transplant recipients may acquire HCMV pneumonitis, or gastrointestinal lesions, hepatitis, retinitis, pancreatitis, myocarditis, and, in rare circumstances, encephalitis or peripheral neuropathy, whereas hematopoietic cell transplant recipients suffer HCMV pneumonitis or gastrointestinal disease. Establishing an etiologic role for HCMV requires detection of virus in affected tissue or bronchoalveolar lavage or quantitation of HCMV in blood or plasma. The principal indirect effects of HCMV, particularly during solid organ transplantation, include allograft rejection, vascular disease complications, and increased risk of opportunistic fungal and bacterial infections. Primary infection is most likely to lead to disease when a naive recipient receives an organ from an HCMV seropositive donor, although the particular organ and immunosuppression regimen also influence outcome.

Although antiviral prophylaxis has proved to be very effective in preventing HCMV disease in solid organ transplant recipients, late-onset HCMV disease may follow prophylaxis in as many as 5% of patients. Prophylactic or preemptive antiviral treatment in hematopoietic cell transplant recipients reduces the incidence of HCMV disease during the first 3–4 months to around 5%; however, late-onset disease, usually more than 100 days after transplant, remains a problem. In all clinical transplant settings, HCMV has been associated with chronic disease consequences that prophylaxis and preemptive therapy have not completely alleviated. In the nontransplanted individual, HCMV has been a suspected cofactor in atherosclerotic vascular disease and in autoimmune vasculitis.

Highly active antiretroviral therapy (HAART) reduces incidence of HCMV retinitis and gastrointestinal disease in AIDS patients due to reconstitution or preservation of cellular immune function, although HCMV remains a significant risk to human immunodeficiency virus (HIV)-positive individuals when CD4 T-cell counts drop to low levels.

Four antiviral agents are currently approved in the USA for treatment of HCMV disease, ganciclovir, valganciclovir, cidofovir, and foscarnet, with intravenous ganciclovir and orally administered prodrug valganciclovir being first choices in most settings. These two are also common choices for prophylaxis and preemptive therapy. All of the anti-HCMV drugs have potentially significant toxicity and are limited to use in patients with disabling or life-threatening disease risk. Thus, additional drugs are under development. Prolonged use of any investigational or licensed drug may select for resistant virus, but drug-resistant mutants have not been observed to circulate in the population.

Immune Response, Prevention, and Control

Prevention of HCMV infections during pregnancy to reduce congenital disease risk is an important public health goal, and universal vaccination during childhood is believed to be the appropriate route to achieve this control. Attempts to develop live, attenuated, killed, and subunit vaccines over the past 30 years have not yet resulted in success. The Centers for Disease Control and Prevention (CDC) currently recommends that parents and caregivers of young children be informed of how HCMV is transmitted and of hygienic measures that reduce transmission, particularly to women who care for young children and may become pregnant.

Natural HCMV infection is highly immunogenic, resulting in broad humoral antibody and cellular T-lymphocyte responses that persist for life. The parameters of CD4 and CD8 T-lymphocyte responses vary with age and other characteristics, but the continued high levels of response in a majority of infected individuals suggests that virus antigen provides a continuous immunogenic stimulus throughout life. In addition to the adaptive immune response, innate cellular clearance by natural killer (NK) cells appears to be important in the initial stages of infection.

HCMV encodes a very large array of gene products that deflect intrinsic host-cell antiviral responses mediated at the transcriptional level through activation of the interferon pathways or cell death. In addition, this virus encodes a wide range of functions aimed at disarming the innate NK cell response as well as the effectiveness of adaptive humoral and T-cell responses. These

functions provide an impression that this virus survives in tight balance with host immune clearance mechanisms, and are summarized in **Table 1**. In addition, accumulating evidence from animal models of HCMV pathogenesis implicates pro-inflammatory viral gene products in creating the appropriate environment to allow efficient growth and dissemination to important tissue sites to assure transmission to new hosts.

Future Perspectives

Although there have been tremendous gains in knowledge of HCMV molecular biology and pathogenesis, this virus continues to be a very important cause of disease especially for immunocompromised hosts and for the fetus. To date, antiviral chemotherapy has been only partially successful in controlling HCMV infection in transplant and other immunocompromised patients and there remains a need for vaccination to reduce the incidence of congenital HCMV infection. An important goal for future research will be to translate the large and growing body of basic knowledge of HCMV biology into improved treatments and effective vaccines.

Introduction

This chapter provides a general description of the molecular biology of human cytomegalovirus (HCMV) and highlights a number of specific features concerning the virus and its replication cycle. It is necessary to point out that most studies on the molecular biology of HCMV have utilized highly passaged, genetically deficient laboratory strains grown in human fibroblast cells. Although the findings are anticipated to apply in large part to wild-type strains grown in fibroblast and other cell types, and therefore to be relevant to the clinical situation, there are probably important differences to be discovered in the future.

Properties of the Virion

Typical of the herpesvirus group, the virion of HCMV (species *Human herpesvirus 5*, subfamily *Betaherpesvirinae*, family *Herpesviridae*) is approximately 230 nm in diameter and is composed of a DNA-containing capsid, surrounded by a less structured tegument layer, and bounded by a trilaminate membrane envelope. The capsid is isosahedral, has a diameter of approximately 110 nm, and is made up of four principal protein species that are organized into 162 capsomeres (150 hexamers plus 12 pentamers) and 320 triplexes located between the capsomeres. By analogy with herpes simplex virus type 1 (HSV-1), one of the pentamer positions is occupied by a portal complex (a dodecamer of the portal protein) through which DNA enters and leaves the capsid. The capsomeres are approximately 20 nm in length and 15 nm in diameter, have a channel about 3 nm in diameter that is open at the exterior end, possess favored cleavage planes along the longitudinal axis, and have short, spicule-like protrusions, probably representing the triplexes, extending out symmetrically and resulting in a pinwheel appearance of the capsomere viewed end on. The tegument region is approximately 50 nm thick and includes seven relatively abundant virus-encoded protein species, five of which are phosphorylated. The virion envelope is estimated to be 10 nm thick and contains at least 10 abundant protein species. Both the tegument and envelope contain a substantial number of

less abundant virus-encoded and host-cell proteins. In addition, the virion has been reported to contain phospholipids (phosphatidylcholine, phosphatidylethanolamine, and phosphatidylinositol) and polyamines (spermidine and spermine). The properties of the virion DNA and proteins are described below.

Properties of the Genome

The genome of HCMV is composed of a linear, double-stranded DNA molecule with a size of 236 kbp in wild type virus. Thus, it is over 50% larger than that of HSV-1, and the largest among the human herpesviruses. It is a class E genome, like that of HSV-1, consisting of a long unique (U_L) and a short unique (U_S) sequence, both of which are flanked by much shorter inverted repeat sequences that enable U_L and U_S to invert relative to each other and give rise to the four structural isomers of the genome found in virions. The origin of DNA replication (*ori*-Lyt) has been localized to a 3–4 kbp region near the center of U_L. Like *ori*-L, one of three duplicated origin sequences in the HSV-1 genome, the HCMV *ori*-Lyt region is located adjacent to the promoter for the early, single-stranded DNA-binding protein (encoded by gene UL57). HCMV *ori*-Lyt includes a 2.4 kbp sequence that has no homology with other described virus DNA replication origins and contains direct and inverted repeat sequences. This region contains consensus cyclic AMP (cAMP) response elements and other transcription factor-binding sites, and 23 copies of the sequence AAAACACCGT that are conserved near the homologous *ori*-Lyt of simian cytomegalovirus (SCMV).

The complete nucleotide sequence of the high passage strain AD169 was the first to be determined for HCMV, with a size of 229345 bp. It has a G + C content of 57.2 mol%, and was assessed as containing 189 protein-coding open reading frames (ORFs), some of which are spliced and some of which are duplicated in the inverted repeats. The low passage strain Toledo was found to contain an additional ~15 kbp at the right end of U_L containing 19 additional ORFs. Analysis of the complete 235645 bp sequence of the low passage strain Merlin and a reevaluation of the genetic content of strain AD169 have indicated that wild-type HCMV contains ~165 protein-coding genes. The wild-type genome contains 13 families of related genes, many with members clustered into blocks and encoding predicted or recognized glycoproteins (e.g., the RL11, US6, and US27 families). Taken together, these gene families represent ~40% of the total gene number and in part account for the comparatively large size of the HCMV genome. It is also worth noting that the HCMV genome contains homologs of several cellular genes, including surface receptors such as class I major histocompatability (MHC) antigens, G protein-coupled receptors (GPCRs), and a tumor necrosis factor receptor.

Properties of the Proteins

HCMV proteins share the general pattern of expression characteristic of the herpesvirus group. Immediate early (IE or α), early (E or β), and late (L or γ) proteins are synthesized sequentially from corresponding mRNAs whose transcription is regulated in a temporal cascade. IE proteins are required to regulate transcription from their own promoters and those of subsequently expressed genes. E proteins include many of the enzymes and regulatory factors needed to carry out the synthesis of progeny DNA and proteins. L proteins include most of the virion structural proteins. Members of all three classes have been described for HCMV, though only a small number of the proteins encoded by HCMV have been identified. Those that have been reported include both nonvirion and virion species and their properties are briefly described below.

Nonvirion Proteins

Many of the recognized nonvirion proteins are made at early times after infection and localize to the nucleus. The first of these to appear is the major IE protein (IE1, encoded by UL123), a 72 kDa phosphoprotein that, together with products of a second IE gene, IE2 (UL122), can transactivate HCMV E promoters. Both IE1 and IE2 are expressed from spliced transcripts generated using the major IE promoter. In addition, the IE2 gene gives rise to a family of proteins ranging in size from 23 to 86 kDa that are generated by differential splicing and translational start sites. IE2 proteins can repress the major IE promoter by acting on a sequence immediately upstream of the transcription initiation site. Other IE proteins are encoded by genes IRS1, TRS1, US3, and UL36–38, and can act synergistically with IE1 and the US3 protein to regulate both cellular and virus gene transcription.

The E proteins include the 140 kDa virus DNA polymerase (encoded by UL54), a 140 kDa nuclear single-stranded DNA-binding protein (DB140; UL57), and a set of closely related nuclear phosphoproteins (UL112). Like its homologs in other herpesviruses, the DNA polymerase has an associated 3′-specific nuclease activity. Like its homolog (UL29) in HSV-1, UL57 is located adjacent to *ori*-Lyt, and its product DB140 localizes to discrete foci within the nuclei of infected cells and accumulates in the cytoplasm under conditions of inhibited virus DNA synthesis. UL112 encodes a set of four E, nuclear,

DNA-binding phosphoproteins (34, 43, 50, and 84 kDa) that appear to be produced by alternate splicing, are related to each other by their common N-terminal sequence, and are differentially phosphorylated. Expression of these proteins appears also to be regulated at both the transcriptional and post-transcriptional levels. The functions of these proteins are not known, and they may have a role in DNA replication or gene regulation.

Another nonvirion nuclear DNA-binding phosphoprotein is distinguished by its high abundance and kinetics of synthesis. The ~52 kDa species, DB52, is the product of gene UL44. On the basis of its reduced but not eliminated synthesis under conditions of inhibited virus DNA replication, DB52 is classified as a delayed-early (DE or γ_1) protein. Expression of this gene is under different promoter control at early and late times of infection, and there is evidence that its expression is also post-transcriptionally regulated. DB52 and its SCMV homolog bind to DNA *in vitro* and *in vivo* and associate with the virus DNA polymerase to enhance its activity, analogous to the HSV-1 UL42 protein. DB52, like the HSV-1 UL42 protein, has the structure of a homotrimeric sliding clamp similar to that of the cellular processivity factor, proliferating cell nuclear antigen. Three other proteins that function in virus DNA replication or processing are a phosphotransferase (encoded by UL97), and the ATPase (encoded by UL89) and its partner subunit (encoded by UL56) that constitute an apparent homolog of the bacteriophage DNA cleavage/packaging complex, terminase.

Several other nonvirion HCMV proteins have recently been shown to interfere with the MHC class I antigen presentation system (i.e. the US3, US6, and US11 proteins). These proteins are thought to help the virus-infected cell escape recognition and destruction by immune surveillance, and provide a mechanism for virus persistence in the immune-competent host. It is viewed as likely that wild-type HCMV encodes many proteins involved in modulating the host response to infection.

Virion Proteins

Estimates of the number of protein species in HCMV virions depend on the techniques used. Classical approaches utilizing sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) have detected a total of 30–35 protein species. The characteristics of the most abundant of these proteins, including size, charge, carbohydrate and phosphate content, and deduced locations in the particle, are summarized in **Table 1** and described below. Virions have also been reported to contain several enzymatic activities (including protein kinase, DNA polymerase, DNase, and topoisomerase II), and several host proteins (including PP1 and PP2A phosphatases and a 45 kDa cellular actin-related protein), although it is not known whether these are specific associations. A larger number of proteins have been detected by a mass spectrometric analysis of virions, amounting to species encoded by 59 recognized HCMV genes and over 70 host proteins. The sensitivity of this technique is sufficiently high to raise questions about whether all these proteins are specifically incorporated into virions, and whether they are present in all virions.

The capsid shell is composed of four abundant protein species referred to as the major capsid protein (MCP), the minor capsid protein (mCP), the mCP-binding protein (mCP-BP), and the smallest capsid protein (SCP). Formation of the capsid shell is coordinated by precursors of an internally located maturational protease (assemblin) and assembly protein (pAP), which serve a scaffolding role and are present in nascent intranuclear capsids (e.g., B capsids) and in noninfectious enveloped particles (see below), but not in virions. These internal scaffolding proteins are the only abundant capsid proteins known to be post-translationally modified (**Table 1**).

The bulk of the protein mass of the virion tegument is contributed by its seven principal protein species. The largest of these, called the high molecular weight protein (HMWP), is the homolog of HSV-1 VP1/2 (encoded by HSV-1 UL36), and is an active ubiquitin-specific cysteine protease. HMWP forms heterooligomers with the HMWP-binding protein (HMWP-BP) encoded by the adjacent gene. Neither HMWP nor HMWP-BP is detectably phosphorylated or glycosylated. The basic phosphoprotein (BPP or pp150) and the upper matrix (UM or pp71) and lower matrix (LM or pp65) proteins account for the greatest protein mass of the tegument constituents and are highly phosphorylated, both *in vivo* and *in vitro*, by the virion-associated protein kinase. BPP is distinguished among the virion proteins by having the highest density of O-linked *N*-acetylglucosamine residues, which are attached at a single site or tight cluster of sites. UM is a transacting inducer of IE gene transcription that may be functionally analogous to the α-*trans*-inducing factor of HSV-1. LM appears to be an important component in cellular immunity and there are reports that it has an associated protein kinase activity. The '24K protein' (pp28) is also phosphorylated and, like its HSV-1 homolog UL11, forms oligomers (with the protein encoded by UL94). HMWP and BPP are thought to make direct contact with the capsid.

The virion envelope contains at least 10 protein species. The high degree of size and charge heterogeneity among this group has complicated their analysis. The most abundant species are distributed among three glycoprotein complexes (gCI, gCII, and gCIII), each of which is disulfide linked. The complex gCI consists of three forms

Table 1 Principle proteins of the HCMV virion

Descriptive name	*Predicted M_r*[a]	*Observed M_r*[b]	*Modification*[c]	*Charge*[d]	*Gene*[e]

[f]Present in immature capsids and noninfectious enveloped particles but absent from virions.
[g]Assemblin (A) is derived from a 74 kDa precursor (encoded by UL80a), and is autoproteolytically converted to amino (A_N) and carboxyl (A_C) portions.

of glycoprotein B (gB). HCMV gB is synthesized as a 130–160 kDa, cotranslationally N-glycosylated precursor that undergoes at least four further modifications: (1) its 17–19 predicted N-linked oligosaccharides are converted from nontrimmed to trimmed high-mannose forms, and then a portion is further modified to complex structures; (2) O-linked carbohydrates are added; (3) the C-terminal region of the molecule is phosphorylated; and (4) the protein is cleaved between Arg460 and Ser461 to yield an intramolecularly disulfide-linked heterodimer composed of a highly glycosylated 115–130 kDa N-terminal fragment (gB_N), and a less extensively modified 52–62 kDa C fragment (gB_C). This gB_N–gB_C heterodimer can form intramolecular disulfide crosslinks, yielding a complex with the composition $(gB_N–gB_C)_2$.

Early studies of the complex gCII identified proteins with M_rs of 50–52 and >200 kDa representing forms of the integral membrane protein glycoprotein M (gM). These proteins have similar peptide maps indicating that they are closely related, and the 52 kDa component is comparatively highly O-glycosylated and sialylated. Subsequently, the 50–60 kDa glycoprotein N (gN, UL73) was recognized as a second component of gCII.

The complex gcIII was initially characterized as composed of glycoprotein H (gH) and glycoprotein L (gL; not listed in **Table 1**). HCMV gH is an 86 kDa species that is less extensively N-glycosylated than gB and its oligosaccharides are not processed beyond the high-mannose structure. It has been proposed to mediate virus–host membrane fusion during the initial steps of virus infection, and its intracellular trafficking associates with gL. A third component, the highly sialylated, O-glycosylated virion glycoprotein O (gO), was later shown to be specified by UL74. Recently, using strains of HCMV that more closely reflect wild-type virus, an alternative complex consisting of gH, gL, and two small proteins encoded by UL128 and UL130 has been implicated in tropism for nonfibroblast cell types.

Physical Properties

Infectivity of HCMV is eliminated by exposure to 20% ether for 2 h, by heating at 65 °C for 30 min, by exposure to ultraviolet light (4000 erg s^{-1} cm^{-2}; 400 μJ s^{-1} cm^{-2}) for 4 min, by acidic pH (<5), and by treatment with low concentrations of either ionic or nonionic detergents. Infectivity is also reduced following sonication, pelleting by ultracentrifugation, and repeated cycles of freezing and thawing.

Replication

General features of the HCMV replication cycle are typical of the herpesvirus group. Following virus adsorption and entry into the cell, the DNA is transported to the nucleus where it is replicated and packaged into preformed capsids. Maturation of the nucleocapsid involves acquisition of the tegument constituents followed by envelopment, which has been observed at both nuclear and cytoplasmic membranes.

DNA Replication

HCMV DNA is replicated in the nucleus. Parental DNA appears to circularize soon after entering the cell, but maximal rates of progeny DNA synthesis do not occur until approximately 3 days after infection. The 'endless' concatemeric nature of progeny DNA is consistent with a rolling circle mechanism of DNA replication. However, the finding that virus DNA synthesis proceeds bidirectionally from *ori*-Lyt under conditions inhibition of replication by ganciclovir ([9-[2-hydroxy-1-(hydroxymethyl)-ethoxy]methyl]guanine) is not easily reconciled with this model, and perhaps indicates an intermediate stage of replication based on a theta mechanism. Unit-length genomic DNA is released from the concatemers by cleavage at a specific site located in the *a* repeat elements, 30–35 bp from a herpesvirus group-common cleavage/packaging region referred to as the herpes pac homology sequence.

Characterization of Transcription

The pattern and control of HCMV gene expression shares many features with that of HSV-1. As during translation, transcription of the HCMV genome is temporally regulated into three major kinetic classes. The first class of mRNAs made are transcribed from input DNA and are referred to as IE (or α) RNAs. Their expression requires no preceding virus protein or DNA synthesis, and they are operationally defined as those RNAs that can be made in the presence of inhibitors of protein synthesis. The most abundant IE RNAs are transcribed from the major IE promoter. These transcripts are related to each other by alternate splicing patterns and encode IE1 and multiple forms of IE2. The promoter region for this transcription unit is one of the strongest known, presumably due to its high content of consensus binding sites for host-cell transcription factors such as nuclear factor 1, CAAT-binding protein, and SP1, and the large number of repeat sequences that contain cyclic AMP response elements and that may interact with additional DNA-binding proteins. Transcription from this region is enhanced by UM, whose function appears to be analogous to that of the HSV α-*trans*-induction factor. Lower abundance IE RNAs arise from genes IRS1, TRS1, US3, and UL36–38.

Expression of E (or β) RNAs requires the preceding synthesis of IE proteins, but does not require virus DNA synthesis. Thus, E RNAs are made in the presence of inhibitors of virus DNA synthesis, but not in the presence of inhibitors of protein synthesis. Both IE and E genes appear to be transcribed by host-cell RNA polymerase II. Expression of L (or γ) RNAs requires the preceding synthesis of both IE and E virus proteins, as well as synthesis of virus DNA. The possibility that post-transcriptional events may be involved in controlling HCMV RNA processing and translation is suggested by the presence of some E RNAs that are not translated until late times of infection.

Characterization of Translation

HCMV RNAs are translated by the host-cell protein-synthesizing system. Virus-specific proteins that may augment the host system (e.g., initiation or elongation factors) have not yet been identified. Each virus protein species appears to be encoded by a unique mRNA. Cells infected with HCMV do not show the generalized early shut-off of cell protein synthesis that occurs in HSV-1-infected cells. There are, nevertheless, very early changes in the metabolism of HCMV-infected cells that include stimulated transcription of some host genes (e.g., heat shock protein 70, ornithine decarboxylase, thymidine kinase, creatine kinase, and cyclooxygenase 2), decreased transcription of other host genes (e.g., fibronectin), and changes similar to those induced by the GPCR signaling pathway (e.g., decreased intracellular Ca^{2+} stores and increased levels of intracellular cAMP).

Post-Translational Modifications

Modifications of HCMV proteins include phosphorylation, glycosylation, and proteolytic cleavage. Phosphorylation has been detected on IE (e.g., IE1 and IE2), E

(e.g., UL112 protein) and L (e.g., DE nonvirion UL44 protein; late virion tegument (UL32, UL82, and UL83) proteins), and capsid (AP) proteins, all of which localize to the infected cell nucleus. At least some of these phosphorylations are likely to be catalyzed by reported virus-coded protein kinases. Glycosylation typifies many of the virion envelope glycoproteins and includes both N-linked (high-mannose and complex structures) and O-linked oligosaccharides. The only nonenvelope virion protein that has been demonstrated to be glycosylated is BPP, which has O-linked *N*-acetylglucosamine. Glycosylation of HCMV proteins is most likely carried out by host cell systems. The third modification that has been described for HCMV proteins is proteolytic cleavage. There are two maturational endoproteolytic cleavages, in addition to glycoprotein signal sequence cleavages. The first of these cuts between Arg460 and Ser461 in envelope gB and is catalyzed by a calcium-dependent cellular, furin-like proteinase. The other is a cleavage between residues Ala308 and Ser309 of the capsid assembly protein precursor (pAP). This latter cleavage is catalyzed by the genetically related, virus-encoded proteinase, assemblin (A), and is essential for the production of infectious virus.

Cytopathology

The mechanisms of cell recognition, binding, and penetration by HCMV are not yet understood, but there are at least five envelope proteins that may be involved: (1) a 'disintegrin-like' domain in virion envelope gB interacts with cellular integrins; (2) β_2-microglobulin is present on virions and may interact with cell-surface MHC proteins; (3) virion envelope gH interacts with a 90 kDa cell protein that may also be involved in binding or penetration; and (4) a highly O-glycosylated envelope glycoprotein complex (gcII) is able to bind heparin, and this interaction could promote early virus–cell interaction as proposed for cellular heparin and HSV-1. Different entry mechanisms may operate for different cell types.

Assembly of the capsid and DNA replication and packaging take place in the nucleus. As with HSV-1, some tegument constituents are presumed to be added to the maturing nucleocapsid in the nucleus, with envelopment and de-envelopment occurring as the tegument-coated capsid transits the two leaflets of the nuclear membrane into the cytoplasm. Further addition of tegument proteins is then thought to precede secondary envelopment at vesicle membranes in the infected cell cytoplasm.

The cytopathic effects of HCMV are distinctive. Early after infection, a transient cell rounding occurs, followed by overall enlargement (cytomegalia) and by the appearance of basophilic intranuclear inclusions, which gradually enlarge to fill and distort the nucleus into an elongated or kidney-shaped form late in infection. These intranuclear inclusions contain virus DNA, proteins, and capsids, and are thought to be nucleocapsid assembly sites. Late in infection, the cytoplasm contains numerous enveloped and nonenveloped capsids, large (>500 nm 'black holes') and smaller (250–500 nm 'dense bodies') electron-dense aggregates, and a large eosinophilic spherical region adjacent to the nucleus that exhibits strong F_C binding.

Release of HCMV from the cell results in three kinds of enveloped particles being freed into the growth medium of cultured fibroblasts: (1) virions; and two aberrant particles referred to as (2) noninfectious enveloped particles, which closely resemble virions in structure and composition but have no DNA and contain the capsid assembly protein that is absent from virions; and (3) dense bodies, which are solid, 250–600 nm spherical aggregates of LM that contain no DNA and are surrounded by an envelope layer.

Glossary

Blepharoconjunctivitis Inflammation of the eyelid and conjunctiva.
Dacryoadenitis Inflammation of the lacrimal gland.
Iridocyclitis Inflammation of the iris and ciliary body.
Meibomian gland Modified sebaceous glands lining the eyelid margin that provide the lipid layer of the preocular tear film.
Retinochoroiditis Inflammation of the retina and choroid (uveal) layers of the eye.

Introduction

The eye contains diverse tissues intricately linked to subserve visual function (**Figure 1**). The ocular adnexae – periorbita, eyelids and lashes, lacrimal and meibomian glands – produce, spread, and drain the preocular tear film, physically protect the sensitive ocular mucosa, and cushion the globe. The redundant conjunctiva with its low-viscosity tear film allows rapid multidirectional eye movements. Lymphoid tissues within the conjunctiva and lacrimal glands furnish acquired immune defense. The cornea and its tear film fashion the major refractive surface of the eye. The sclera forms the wall of the globe and scaffolds the intraocular tissues. The eye's lens provides additional refractive power and filters ultraviolet light. The iris diaphragm dynamically regulates the amount of light incident upon the retina, and together with the choroid and optic nerve head provides immune effector cells to the interior of the eye. The retina transduces light energy into neural signals; retinal function is requisite for vision. The vascular choroid nourishes the outer layers of the retina. The anterior (aqueous) and posterior (vitreous) humors provide internal pressure sufficient for maintenance of normal anatomic relationships, nourish the interior ocular tissues, provide immunosuppressive factors necessary to the maintenance of immune deviation, and during infection act as conduits for the distribution of inflammatory cells derived from the iris, ciliary body, and optic nerve head.

Eye infection by viruses most often follows direct contact with virus externally, either from infected secretions in the birth canal (herpes simplex virus, human papillomavirus), on fomites (adenovirus), or airborne particles (rhinovirus), or is acquired during viremia (human cytomegalovirus, measles virus). Other mechanisms of ocular viral infection include extension from contiguous adnexal disease (herpes simplex virus), spread from the upper respiratory tract via the nasolacrimal duct (rhinovirus), and transplacental passage of infectious virus (rubella virus). Rarely, ocular infection may disseminate elsewhere (enterovirus 70).

Acute viral infection produces stereotypic changes in ocular target tissues. Infection of the eyelid skin induces the formation of vesicles and ulcers. Viral infection of the conjunctiva results in vasodilatation, serous discharge, hyperplasia of conjunctival lymphoid follicles, and enlargement of the corresponding draining lymph nodes. Severe conjunctival infection can cause permanent scarring of the globe to the eyelids and turning in of the eyelashes against the eye. Viral infection of the corneal epithelium induces punctate epithelial cytopathic effect evident biomicroscopically as isolated swollen epithelial cells (punctate epithelial keratitis) and loss of individual epithelial cells (punctate epithelial erosions). When extensive, the punctate erosions may coalesce to form confluent epithelial ulcers with dendritic, dendritiform, or geographic morphology. With herpetic infection, corneal anesthesia can ensue, and in the absence of epitheliotropic neural growth factors, corneal epithelial integrity is impaired. Reduced corneal clarity and progressive sterile ulceration may result. Corneal stromal infection induces white blood cell recruitment; subsequent corneal scarring, vascularization, and lipid deposition may permanently reduce vision. Intraocular infection manifests in inflammatory cell deposits on the posterior surface of the cornea and on the vitreous scaffold, and in free-floating leukocytes and biomicroscopically visible protein spillage into the normally cell-free and protein-poor aqueous humor. Iridocorneal and iridolenticular adhesions may develop and lead to glaucoma and cataract. Retinal infection concludes with necrosis and lost function. Viral encephalitis and meningitis can result in cranial nerve inflammation and secondary dysfunction of vision and extraocular motility.

Classical viral pathogenic mechanisms of latency, reactivation, and carcinogenesis all can be demonstrated in the eye. Herpes simplex virus causes recurrent lytic epithelial keratitis when viral reactivation within sensory ganglia of the first division of the fifth cranial nerve gives rise to virus in the preocular tear film. Necrotizing herpes stromal keratitis follows viral reactivation within the cornea stroma. Intraepithelial neoplasia and invasive squamous cell carcinoma of the conjunctiva and cornea

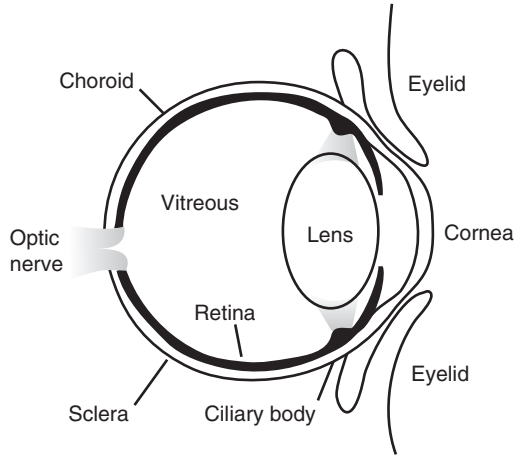

Figure 1 Cross section of the human eye.

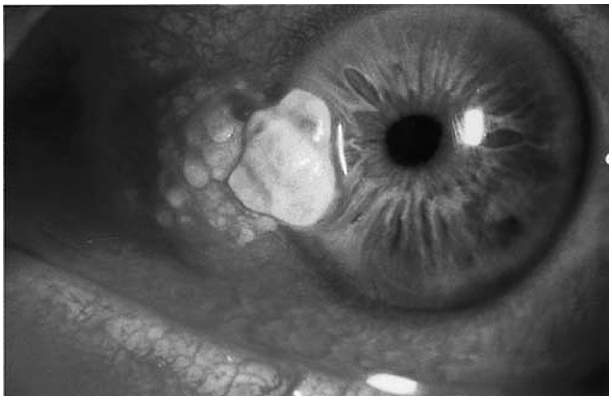

Figure 2 Squamous cell carcinoma of the corneal limbus is associated with infection by human papilloma virus types 16 and 18.

(**Figure 2**) have been associated with human papilloma virus types 16 and 18. When infected with oncogenic human papillomaviruses, corneal limbal stem cells can provide a persistent source of dysplastic ocular surface epithelium. Molecular mimicry has also been demonstrated as an immunopathogenic mechanism in ocular disease. Systemic infection with hepatitis C virus is associated with autoimmunity against a corneal stromal antigen and peripheral ulcerative keratitis. In a murine model of herpes simplex infection, non-necrotizing stromal keratitis accompanies T-cell reactivity against a corneal protein antigenically similar to a herpes simplex coat protein.

Ocular Immunology of Relevance to Viral Infection

Tissue diversity within the eye and adnexa compel varied means of innate immune defense. The eye's external surfaces (conjunctiva and cornea) encounter viruses by both airborne and contact routes. The eyelids, an intermittent barrier, periodically wipe the eye's surface free of debris and spread and drain the preocular tear film. The ability of the tear film to nonspecifically impede primary infection by viruses is unknown, although such mechanisms are well established for bacterial pathogens. An inhibitory effect of goblet cell-derived and intrinsic mucins and meibomian gland-derived lipids on viral adsorption to the ocular surface is speculative. Early in infection, aqueous tears from the main and accessory lacrimal glands furnish proinflammatory cytokines, and the conjunctival blood vessels provide both soluble and cellular components of innate immunity. After viral infection is established, aqueous tears carry lacrimal gland-derived monospecific secretory immunoglobulin A.

The constitutive defense armaments of the cornea and conjunctiva differ. The normal cornea is considered an immune-privileged site due to the high success rate of corneal transplantation; it lacks blood vessels, lymphatics, resident lymphoid cells, and Langerhans cells, expresses Fas ligand on its surface epithelium, and demonstrates reduced delayed hypersensitivity responses. Because corneal inflammation and subsequent scar reduce vision, corneal function is best served by its reduced immunologic responsiveness, also known as immune deviation. Necrotizing inflammation presupposes infection beneath the surface epithelium, and follows chemokine synthesis by infected corneal stromal fibroblasts. In contrast to the cornea, the conjunctiva is well endowed with blood and lymphatic channels, lymphoid cells, and Langerhans cells, and demonstrates classical delayed hypersensitivity responses. The immunology of the interior eye is less well established, but immune deviation appears to extend beyond the cornea to the aqueous and vitreous humors and to the central retina.

Ocular Disease Caused by RNA Viruses

Conjunctivitis is probably the most common viral ocular syndrome, and typically accompanies upper respiratory infections due to RNA viruses (**Table 1**). Rhinovirus, influenzavirus, respiratory syncytial virus, and parainfluenzavirus conjunctivitis typically are mild and self-limited, and most patients do not seek medical attention. More serious are the keratitis, uveitis, and retinitis caused by some RNA viruses. For example, influenzavirus infection of the respiratory tract, usually associated with a mild and short-lived conjunctivitis, less commonly causes inflammation in the lacrimal gland, cornea, iris, retina, optic and other cranial nerves.

Like influenzavirus, other RNA viruses can infect virtually every ocular tissue. For instance, rubella virus when acquired *in utero* may have devastating consequences for the eye. Characteristic features include

microphthalmos, corneal haze, cataracts, iris hypoplasia, iridocyclitis, glaucoma, and 'salt-and-pepper' pigmentary retinopathy. Rubella virus can be cultured from the lens of infected neonates at the time of cataract extraction. Congenital ocular abnormalities due to rubella, like those in other organ systems, are much worse when maternal infection ensues earliest in pregnancy.

In contrast to rubella virus, measles (rubeola) virus infection *in utero* rarely causes significant ocular disease. The classic triad of postnatally acquired measles – cough, coryza, and follicular conjunctivitis – can be accompanied by Koplik spots on the conjunctiva and a mild epithelial keratitis. Less common are optic neuritis, retinal vascular occlusion, and pigmentary retinopathy. Measles

keratopathy, a major source of blindness in the nonindustrialized world, typically presents as corneal ulceration in a malnourished child. A rare and fatal complication of measles virus infection, subacute sclerosing panencephalitis (SSPE), occurs in about 1 per 100 000 cases, and often years after clinically apparent measles. Along with devastating central nervous system damage, ocular abnormalities occur commonly in SSPE, including central retinal (macular) hyperpigmentation and inflammation, optic nerve atrophy, peripheral retinitis, and ocular motility disorders. Cortical blindness can occur in the absence of ocular involvement.

The most common ocular complication of mumps virus infection is dacryoadenitis, and this may occur concurrently with parotid gland involvement. Aseptic meningitis, associated oculomotor palsy, and optic neuritis also occurs. Follicular conjunctivitis, epithelial and stromal keratitis, iritis, trabeculitis, and scleritis have all been reported within the first 2 weeks after onset of parotitis.

Acute hemorrhagic conjunctivitis (AHC), caused predominantly by enterovirus type 70 and coxsackievirus A24 variant, but also by adenovirus type 11, is one of the most dramatic ocular viral syndromes. Sudden onset of follicular conjunctivitis associated with multiple petechial conjunctival hemorrhages characterizes AHC. The hemorrhages may become confluent and appear post-traumatic. In approximately 1 out of every 10 000 cases due to enterovirus type 70, a polio-like paralysis can ensue. Neurologic deficits are permanent in up to one-third of the affected individuals.

Human immunodeficiency virus (HIV) is the etiologic agent of the acquired immune deficiency syndrome (AIDS). Although HIV can be cultured from the retinas of individuals with AIDS, and has been shown to be present in the donated corneas of deceased AIDS patients, a direct relationship between local viral infection and ocular disease remains to be established. One example is the dry eye so common in AIDS patients. It is not known whether primary HIV infection of the lacrimal gland, immune deficit-induced potentiation of another virus such as Epstein–Barr virus within the lacrimal gland, or a putative HIV-induced neuro-immune-endocrine defect can account for AIDS-related dry eye. However, the severe immunosuppression of AIDS results in a host of other ocular diseases (discussed below).

Ocular Disease Caused by DNA Viruses

DNA viruses (**Table 2**) are responsible for most significant ocular viral infections in the industrialized world. Even the protean ocular manifestations of the HIV, an RNA virus, result largely from reduced immunity to DNA viruses.

Adenovirus is probably the most common DNA virus to cause eye disease. Three common ocular syndromes have been identified. Simple follicular conjunctivitis occurs with infection by many adenovirus types and may be subclinical. Pharyngoconjunctival fever typically follows infection with adenovirus types 3, 4, and 7. As the name implies, patients have pharyngitis, conjunctivitis, and fever, and may be misdiagnosed as having influenza. Epidemic keratoconjunctivitis, most often caused by adenovirus types 8, 19, and 37, is a highly contagious syndrome with significant morbidity. The conjunctivitis can be severe (**Figure 3**); associated inflammatory conjunctival membranes can permanently scar the eyelids to the globe. Corneal involvement begins as a punctate epithelial keratitis and may proceed to a large central epithelial ulcer. Stromal keratitis presents about 2 weeks after the conjunctivitis as multifocal subepithelial corneal infiltrates, and causes both foreign body sensation and reduced vision. The stromal infiltrates may resolve spontaneously, but can become chronic, require long-term treatment with corticosteroids, and cause persistent visual morbidity. A fourth ocular syndrome occasionally associated with adenovirus infection, AHC (discussed above), may be caused by adenovirus type 11. Interestingly, adenovirus type 11 also causes acute hemorrhagic cystitis. Follicular conjunctivitis (clinically indistinguishable from adenovirus conjunctivitis) can also be caused by Newcastle disease virus, an RNA virus that gives rise to fatal epidemics in poultry and infects the birds' human handlers.

The human herpes viruses are preeminent among DNA viruses in eye disease with at least seven of the eight known human herpes viruses associated with ocular disorders. Herpes simplex virus type 1 (HSV-1) is the most common herpes virus to cause eye disease, and herpes simplex keratitis is the most common cause of infectious blindness in the industrialized world. HSV-1 causes self-limited and relatively benign infections of the

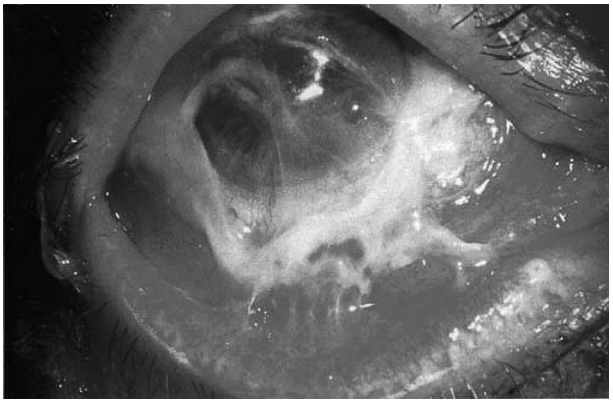

Figure 3 Epidemic keratoconjunctivitis. Infection with adenovirus serotype 19 has resulted in severe ocular surface inflammation.

eyelids, the conjunctiva, and the corneal epithelium, but infections of the corneal stroma, uvea, and retina may result in chronic or recurrent blinding stromal keratitis, uveitis, and retinal necrosis, respectively. Elevation of intraocular pressure due to involvement of the trabecular meshwork is not uncommon and may help to differentiate herpetic uveitis from noninfectious causes. Postnatally acquired HSV-2 ocular infection, less common than HSV-1, causes disease similar in most respects to HSV-1. Neonatal herpes simplex infection, acquired during transit through the birth canal and usually due to HSV-2, commonly causes vesicular blepharitis and conjunctivitis, but can also cause permanent visual loss due to keratitis, chorioretinitis, optic neuritis, and encephalitis of the visual cortex.

Varicella zoster virus, the etiologic agent of chickenpox and shingles, rarely causes keratouveitis with primary infection (chickenpox). However, vision-threatening keratitis, uveitis, and, less commonly, retinal necrosis are complications of varicella zoster virus reactivation in the distribution of the fifth cranial nerve (zoster ophthalmicus). Lid ulceration with frank tissue loss or lid malposition leads to corneal exposure and ulceration. Optic neuritis and cranial nerve paresis can accompany onset of the zoster rash. Sectoral iris atrophy is pathognomonic for zoster ophthalmicus. Postinfectious corneal anesthesia and secondary sterile corneal ulceration may follow herpes simplex types 1 and 2, but are most severe in zoster ophthalmicus. Chronic scleritis, keratitis, uveitis, and glaucoma may ultimately limit the visual acuity.

Acute systemic infection with Epstein–Barr virus may cause conjunctivitis and epithelial keratitis. Stromal keratitis occurs but is difficult to differentiate clinically from herpes simplex keratitis, and the true incidence of Epstein–Barr viral keratitis is unknown. Reports of uveitis and retinochoroiditis are unconfirmed. Delayed-onset optic neuritis following infectious mononucleosis is not uncommon.

Human cytomegalovirus (CMV) typically causes infectious retinitis (**Figure 4**) in immunocompromised patients with $CD4^+$ T-cell counts of less than $50\,\text{cells}\,\text{ml}^{-1}$. Although not the most common ocular complication of AIDS, CMV retinitis is the most common cause of blindness in AIDS patients. CMV retinitis in AIDS patients can be controlled but not cured. In contrast, congenital CMV infection in an otherwise normal fetus results in various degrees of retinochoroiditis, but is not progressive postnatally.

Human papillomavirus (HPV) causes a range of conjunctival tumors ranging from venereally acquired benign papillomas (HPV types 6 and 11) to invasive squamous cell carcinoma (**Figure 2**) (HPV types 16 and 18). Venereal papillomas are clinically similar to those of the larynx and anogenital tract. Ocular surface squamous neoplasia (conjunctival intraepithelial neoplasia and invasive squamous cell carcinoma) are most similar to dysplastic intraepithelial and invasive squamous lesions of the uterine cervix. Papillomatous eyelid neoplasms due to HPV also occur, and can be benign or malignant.

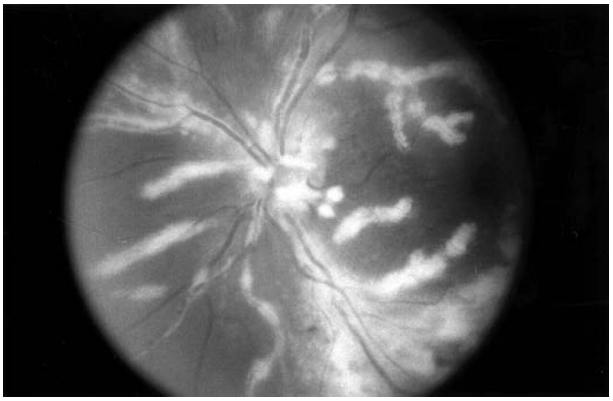

Figure 4 Cytomegalovirus retinitis. Discrete areas of perivascular necrosis and hemorrhage are typical.

Molluscum contagiosum virus is a poxvirus that may infect the eyelid skin or less commonly the conjunctiva. Skin lesions typically appear as elevated nodules with umbilicated centers, and may be multiple and quite large in HIV-infected patients. Molluscum lesions of the eyelid are fairly common in children, and can be associated with a follicular conjunctivitis that resolves with incisional or excisional biopsy of the lid lesion.

Prior to eradication, smallpox virus infection was associated with pustular blepharoconjunctivitis, secondary lid scarring, and stromal keratitis. In nonindustrialized nations, secondary bacterial infection of smallpox keratitis was a major source of blindness. Vaccination against smallpox virus with vaccinia virus was occasionally complicated by inadvertent autoinoculation of vaccinia into the eye, with potential for a severe blepharoconjunctivitis, keratitis, and globe perforation.

Ocular Complications of AIDS

Tay-Kearney and Jabs (1996) classified the ocular complications of HIV infection into five broad categories: (1) HIV retinopathy, (2) opportunistic ocular infections, (3) ocular adnexal neoplasms, (4) neuro-ophthalmic lesions, and (5) drug-induced manifestations.

HIV retinopathy is seen in over half of AIDS patients; cotton wool patches, or multifocal infarcts of the retinal nerve fiber layer, are the most common ocular sign of AIDS. Intraretinal hemorrhages occur less often. HIV can

be cultured from the retina of AIDS patients, but a direct relationship between retinal infection and AIDS retinopathy has not been established.

Some ocular infections, including CMV retinitis (**Figure 4**), *Pneumocystis carinii*, fungal, and mycobacterial choroiditis, and microsporidial keratoconjunctivitis are seen almost exclusively in AIDS. CMV retinitis is a major cause of morbidity in AIDS patients. Other infections, such as toxoplasmosis retinochoroiditis, ocular syphilis, herpes zoster ophthalmicus, and molluscum contagiosum of the eyelids are seen in immunocompetent as well as immunosuppressed individuals, but may be more severe and leave more profound deficits in HIV-infected patients. Herpes zoster ophthalmicus in young patients may be the first clinical clue to HIV infection. Acute retinal necrosis due to herpes simplex virus types 1 or 2, or varicella zoster virus, occurs more commonly in HIV-infected than in otherwise normal patients and can result in unilateral or bilateral blindness despite antiviral therapy.

Kaposi sarcoma of the eyelids or conjunctiva, associated with human herpes virus 8 infection, is exceedingly uncommon in immunocompetent individuals, but is probably the most common adnexal tumor in AIDS patients. Non-Hodgkin's lymphomas of the orbit, although rare overall, occur more frequently in AIDS patients than in the general population. Recently, squamous cell carcinoma of the ocular surface (conjunctiva and cornea) has been suggested as a marker for AIDS, but whether HIV infection potentiates HPV-induced carcinogenesis in the eye remains speculative.

Neuro-ophthalmic lesions in AIDS may occur directly due to HIV infection of the central nervous system, but most commonly are caused by cryptococcal meningitis or other opportunistic infections. Retinitis and uveitis due to anti-HIV medications can be confused with opportunistic intraocular infections.

Conclusion

Diverse ocular tissues act in concert to create vision. All of the tissues and structures within the eye are susceptible to viral infection, with consequences ranging from mild discomfort to severe pain and blindness, and almost all known human viruses cause ocular disease. Often, the same virus can infect widely disparate tissues within an eye. Classical viral pathogenic mechanisms are readily demonstrated in the eye, but the fine functions of ocular tissues within the visual axis (cornea, anterior chamber, lens, vitreous, and macula) compel altered immune responsiveness. The eye is uniquely affected by viral infection and provides an exceptional model for studies of viral pathogenesis and immunity.

Human Herpesviruses 6 and 7

U A Gompels, University of London, London, UK

© 2008 Elsevier Ltd. All rights reserved.

Introduction

The roseoloviruses human herpesviruses 6 and 7 (HHV-6 and HHV-7) infect almost all babies to give an 'infant fever', sometimes with rash (then termed 'exanthema subitum' or 'roseola infantum'), and persist throughout the host's lifetime. Infections with these viruses are generally regarded as benign and self-limiting, although severe complications have been recorded, with occasional associated fatalities, during some primary as well as secondary, reactivated infections in immunosuppressed (human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS) or transplantation) patients. These viruses infect and can remain latent in leukocyte stem cells and neuronal cell types, with lytic replication in CD4+ T-lymphocytes. Immunomodulatory gene products can aid persistence and contribute to pathogenesis. There are two sides to this. On the one hand, studies on such a widespread, well-adapted virus allow a greater understanding of human immunity to infection and the possible development of new immunotherapies. On the other hand, recent associations of HHV-6 (in particular) with neurological disease, including 'status epilepticus', encephalitis, and multiple sclerosis (MS), have led to reevaluations of the pathogenic potential of the roseoloviruses. To date, there are no licensed vaccines or antiviral treatments available.

History and Classification

The first isolates of HHV-6 were characterized in 1986–88 in the USA (strains GS and Z29) and the UK (strain U1102), followed by Japan (strain HST). Using reagents derived from these laboratory strains, it was found that there are two strain groups, termed variants, HHV-6A (strains GS and U1102) and HHV-6B (strains Z29 and HST). Subsequently, HHV-6B was shown to be more prevalent in these countries, and most of the available data concern this variant. In comparison, HHV-6A appears to be an emergent infection. Complete genome sequences were derived from plasmid clones for HHV-6A (strain U1102; 159 kbp; accession X83413) and HHV-6B (strain Z29; 162 kbp; accession AF157706) in 1995 and 1999, respectively. These laboratory strains have subsequently been denoted as the prototype reference strains. They were isolated from viruses reactivated from adult immunosuppressed HIV/AIDS patients from African countries: HHV-6A strain U1102 from Uganda and HHV-6B strain Z29 from the Democratic Republic of Congo. Other laboratory strains include HHV-6A strain GS, the first report of HHV-6 infection, which was isolated from an adult HIV/AIDS patient in the USA; HHV-6A strain AJ, from an adult HIV/AIDS patient in the UK; and HHV-6B strain HST, from a pediatric patient with 'exanthema subitum' in Japan. HHV-6B strain HST is the only isolate from primary childhood infection to have been sequenced completely (accession AB021506), and partial genome sequences are available for HHV-6A strains GS and AJ.

HHV-7 was isolated in 1990 from an immunocompetent blood donor. Infections with this virus appear less severe, although the virus is as widespread as HHV-6 and persists at higher levels in the blood (possibly lacking 'true latency'), with frequent secretions in saliva as with HHV-6. HHV-7 can reactivate latent HHV-6 infections. Both viruses appear to give rise to 'exanthema subitum', although HHV-6 infection is earlier and predominates. The genomes of two strains of HHV-7 have also been sequenced: JI (145 kbp; U43400) and RK (153 kbp; AF037218).

The species *Human herpesvirus 6* and *Human herpesvirus 7* are classified in genus *Roseolovirus*, subfamily *Betaherpesvirinae*, family *Herpesviridae*, and are related to genus *Cytomegalovirus* in the same subfamily. The human virus that is most closely related to HHV-6 and HHV-7 is therefore human cytomegalovirus (HCMV). The DNA sequences of the HHV-6A and HHV-6B variants are very closely related overall (>95%), with most variation located in repetitive sequences at the ends of the genomes. Hypervariable loci are also present in other regions of the genome mostly near the ends, and include genes encoding the viral chemokine vCCL (U83), immediate early transcriptional regulators (U86 and U90), glycoprotein gQ (U100), and, at the center of the genome, glycoprotein gO (U47). These regions of substantial variation presumably contribute to the different biological properties of the variants. Comparisons of the genomes of HHV-6B strains Z29 and HST show less variation (1–2%).

Geographical Distribution

Serological studies show that HHV-6 and HHV-7 are widespread throughout the world, with over 95% of adults infected. However, the geographical distribution of HHV-6A and HHV-6B is difficult to establish. There is currently no serological assay that can distinguish between the variants, since the genes encoding immunodominant proteins

belong largely to the well-conserved group. The variable genes, which are diagnostically attractive, do not encode consistently immunogenic proteins. Thus, current estimates of the distribution of HHV-6A and HHV-6B have been derived using conventional polymerase chain reaction (PCR) of virus DNA or reverse transcription-polymerase chain reaction (RT-PCR) of virus RNA from tissue, blood, saliva, or cerebrospinal fluid (CSF) samples, with the use of additional techniques such as quantitative PCR, restriction endonuclease digestion, and sequencing of variable genes. In analyses of specific patient groups in North America (USA), Europe (UK), and East Asia (Japan), HHV-6B causes most (>97%) of the primary pediatric infections that give rise to HHV-6-associated infant fever with or without the 'exanthema subitum' rash. HHV-6A is detected, but as a minor component in mother–child pairs. In studies of adult bone marrow transplantation (BMT) and solid organ transplantation patients in the USA and the UK, the distribution of the variants seems similar to that in childhood infections, with primarily HHV-6B identified. In contrast, HHV-6A and HHV-6B were shown to be equally prevalent in hospitalized febrile infants in southern Africa (Zambia). Thus, there appear to be geographical differences in the distribution of HHV-6A and HHV-6B.

Biological differences may also be driven by certain variable genes, thus compounding any differences in geographic distribution. For example, in comparison to HHV-6B, HHV-6A infections are more neurotropic and more prevalent in CSF samples and congenital infections, as well as in early infections of infants less than 3 months old. In analyses of adult lung samples in the USA, both HHV-6A and HHV-6B were detected with equal prevalence. Some analyses have detected HHV-6A DNA in sera but not in peripheral blood mononuclear cells (PBMCs). Thus, the biological compartmentalization of the variants *in vivo* may differ, contributing an additional dimension to the geographical distribution of the variants.

Cellular Tropism, Laboratory Culture, and Latency

HHV-6 and HHV-7 are T-lymphotropic and neurotropic viruses. They have both been adapted to grow in CD4+ T-leukemic cell lines: for example, J-JHAN (Jurkat), HSB2, and Molt-3 cells for HHV-6; and SupT-1 cells for HHV-6 and HHV-7. However, higher titers of both HHV-6 and HHV-7 are obtained in activated cord blood lymphocytes or mononuclear cells (CBLs or CBMCs) or in peripheral blood lymphocytes (PBLs) or PBMCs. Screening of these cells is required prior to use, as infection with laboratory strains can result in reactivation of resident latent virus from adult blood and occasionally from cord blood.

CD4+ T-lymphocytes are permissive for replication and virus production, as shown *in vitro* and *in vivo* during viremia from acute infection. Infection results in cell death by necrotic lysis, with associated apoptosis in bystander cells. Lytic replication results in a characteristic cytopathic effect of ballooning cells (cytomegalia) and fused, multinucleated cells (syncytia). Studies *in vitro* show that CD4+, CD8+, and γδ T-lymphocytes can be infected, particularly by HHV-6A, which may have a wider tropism. HHV-7 binds to CD4 on T-lymphocytes, contributing to cellular tropism. HHV-6 binds to CD46, a ubiquitous receptor, and there may also be a specific co-receptor.

Similar to HCMV, and a feature of the betaherpesviruses in general, latency occurs within myeloid subsets or bone marrow progenitor cells. There is also evidence, particularly for HHV-6A, for replication in glial cells, including oligodendrocytes, astrocytes and a microglial cell type with similarities to monocytic/macrophage cells, which may also be a site of persistence in the central nervous system (CNS). HHV-7 circulates at higher levels than HHV-6, and can reactivate HHV-6. Both HHV-6 and HHV-7 can be shed asymptomatically in saliva, and salivary glands may be a site of persistence.

Recent studies indicate that 0.2% or 0.8% of blood donors in Japan or the UK, respectively, exhibit germline integration of HHV-6 genomes (either HHV-6A or HHV-6B). How this relates to latency or pathogenesis is being evaluated, but it can lead to high levels of virus DNA being detected in the blood (in cells and in sera due to cell breakage) in the absence of virus production, although a limited number of genes may be expressed. Germline integration can confound diagnoses by quantitative PCR, since in these individuals high levels of DNA do not correlate with viremia or symptoms. However, gene expression from the integrated genomes may contribute to chronic disease or immunity to HHV-6 infection.

Genome Organization

The roseolovirus genomes consist of a large unique region (U) flanked by a terminal direct repeat (DR).

The variation in size among the genomes is primarily due to differences in the size of DR. DR is itself bounded by smaller repeats (t) that are related to human telomeric repeats, and there is some suggestion that this arrangement may mediate a latent chromosome-like state or facilitate the rare integrations into the human genome that are observed (see above). At the ends of DR are 'pac' sequences for cleavage and packaging of unit-length genomes from replicative head-to-tail concatamers. Other repetitive sequences with known functions include the origin of lytic DNA replication (ORI) in the center of the genome. This combines features of ORIs in

betaherpesviruses (e.g., HCMV) and alphaherpesviruses (e.g., herpes simplex virus (HSV)). HHV-6 ORI is relatively large, as in HCMV, and contains binding sites for an origin-binding protein (OBP), as in HSV. HHV-6 and HSV each encode an OBP, whereas HCMV lacks a homolog to this gene.

The protein-coding regions predicted from the genome sequences (see **Figure 1**) are available in the sequence database accessions. The prototypic HHV-6 genome layout from HHV-6A strain U1102 is shown in **Figure 1**, with main differences between HHV-6 and HHV-7 as marked and cited below. Approximately 30% of the genome is

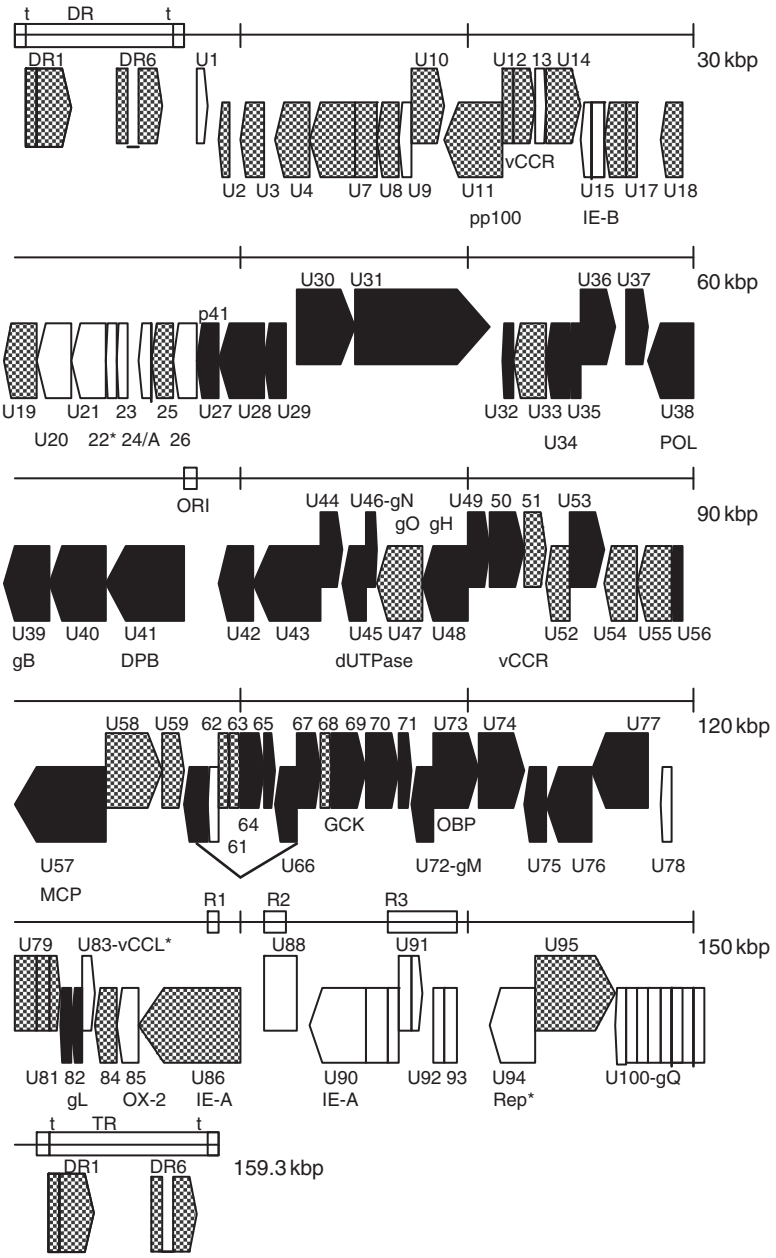

Figure 1 HHV-6 genome organization and locations of conserved genes. Protein-coding regions whose amino acid sequences are conserved among herpesviruses are indicated in black, those conserved only among betaherpesviruses are indicated as patterned, and those conserved in the roseoloviruses are indicated in white. HHV-6-specific genes are U22, U83, and U94 as asterisked, with additional possibly specific genes being U1, U9, U61, and U78. The U prefix is omitted from some gene names to enhance clarity. Repetitive sequences are marked: DR, terminal direct repeat; t, telomeric repeat; ORI, origin of lytic DNA replication; and R1, R2, and R3, locally repetitive sequences. Ancillary information is provided for certain genes mentioned in the text: p101, the major immunodominant tegument phosphoprotein; U94 Rep, the parvovirus Rep homolog and gene/replication regulatory latency gene; IE-A and IE-B, immediate early regulatory genes; POL, DNA polymerase; gB, gH, gL, gO, gM, gN, and gQ, envelope glycoproteins; vCCR, viral chemokine receptors; GCK, ganciclovir kinase; and chemokine vCCL.

taken up with genes encoding proteins that are conserved among mammalian and avian herpesviruses. These proteins dictate common features of replication, and include glycoproteins mediating virus entry by cell fusion, enzymes and accessory factors in the DNA replicase complex, and proteins for making the characteristic herpesvirus icosahedral nucleocapsid and packaging the genome into it. Proteins that are specific to betaherpesviruses are generally transcription factors controlling the gene expression cascade, functions for modulating the specificity of glycoproteins mediating virus entry by cell fusion, or proteins for modifying DNA virus replication. Functions specific to roseoloviruses that affect gene control and, in particular, immunomodulation presumably mediates latency and persistence.

Replication Cycle

Infection is initiated by virus binding to the cell, followed by penetration via virus-mediated cell fusion. As with other herpesviruses, HHV-6 and HHV-7 are first loaded onto the cell via proteoglycan interactions involving heparin or heparan sulfate. The herpesvirus-conserved gB and roseolovirus-specific gQ are involved at this stage. This is followed by membrane fusion mediated by the herpesvirus-conserved gH/gL complex. In HHV-6 and HHV-7, the gH/gL dimer also forms multimers, one with betaherpesvirus-specific gO, and the other with gQ (in two forms, gQ1 and gQ2). So far, no receptor has been identified for the gH/gL/gO complex, but the gH/gL/gQ1/gQ2 complex binds to the ubiquitous cellular receptor CD46 (which is also the measles virus co-receptor). The HHV-6A gH/gL/gQ1/gQ2 complex binds with much higher affinity than that of HHV-6B. HHV-7 additionally binds to the CD4 molecule (like HIV), but the virus attachment protein has not been identified.

Following transport of the nucleocapsid to the nucleus and release of the genome, expression of immediate early genes initiates the transcription cascade. The two spliced IE-A genes (U90 and U86) are positional counterparts of the well-characterized HCMV transcription factors, IE1 and IE2. U90 is particularly variable in sequence between HHV-6A, HHV-6B, and HHV-7. Like the corresponding region in HCMV, this major immediate early gene region is subject to CpG suppression, which is indicative of gene control by DNA methylation. This appears to be a common strategy for betaherpesviruses, which are latent in myeloid cells.

DNA replication is initiated at ORI utilizing a conserved replicase complex modified by the U55 protein, which corresponds to HCMV replication protein UL84, and also by the HHV-6-specific replication modulator, the U94 Rep protein. U94 Rep appears to be a latency-specific factor, and its absence from HHV-7 possibly contributes to the 'leaky latency' observed for this virus. The pac sites at the ends of the genome mediate cleavage of concatamers into unit-length genomes, which are then packaged into preformed nucleocapsids composed of herpesvirus-conserved capsid proteins. The virus buds through the nuclear membrane utilizing herpesvirus-conserved functions, and probably exits via the de-envelopment–re-envelopment pathway involving the *trans*-Golgi network (TGN), as has been shown for alphaherpesviruses.

Immunomodulation

HHV-6 and HHV-7 can have both direct and indirect modulatory effects on the immune system to favor persistence in immune cells. Direct effects include lysis of infected CD4+ lymphocytes during virus replication. In addition, apoptosis of bystander cells has been shown for both HHV-6- and HHV-7-infected cells. Indirect effects include modulation of the receptors on immune cells, thus affecting their function or specificity in immune activation or signaling. HHV-6 downregulates CD3 expression. Whereas HHV-7 downregulates CD4 expression, HHV-6 upregulates it. A protein encoded by both HHV-6 and HHV-7 (U21) downregulates major histocompatibility complex class I expression, which can lead to immune evasion of the antiviral TH1 cytotoxic T-cell response. A number of cytokines are dysregulated by HHV-6 infection, with IL-2 downregulated and IL-10, IL-12, TNFα, and IL-1 upregulated.

Like other primarily blood-borne herpesviruses, roseoloviruses engage the chemokine inflammatory system either to effect immune evasion or enhance virus dissemination. Homologs of chemokine receptors (vCCRs) are encoded by genes U12 and U51, and mimic properties of the human receptors in mediating immune cell traffic either constitutively, in homing to the lymph node, or inducibly, in the inflammatory response to infection. The HHV-6 vCCRs are betachemokine receptors that bind novel combinations of betachemokine ligands, including those with specificity for monocytic/macrophage cell types. Signaling by the U51 vCCR is affected by binding of different ligands and by G-protein levels in the cell. Early in infection when the U51 vCCR is produced, signaling leads to downregulation of the human CCR1-, CCR3-, and CCR5-specific chemokine Rantes/CCL5. In contrast, the HHV-7 vCCRs appear to mimic the constitutive homing chemokine receptors. HHV-6 infection can also mimic the constitutive receptor CCR7, which could allow homing of infected cells to sites of ligand secretion in the lymph node.

The HHV-6 U83 gene encodes a chemokine, vCCL. This gene is hypervariable between HHV-6A and HHV-6B but absent from HHV-7, and thus is a candidate for contributing to differences in virulence. HHV-6A vCCL has a high potency for human CCR1, CCR4,

CCR5, CCR6, and CCR8, which are present on mature monocytic/macrophage and T-cell subsets (TH2, skin homing) and immature dendritic cells. HHV-6B vCCL has a low potency for human CCR2 present on monocytes. These activities could aid immune evasion and virus dissemination, thus contributing to differences in tropism between the variants. They may also aid persistence via the chemoattraction of cell types for efficient antigen presentation and immune control.

In vivo reactivation of HHV-6 in BMT patients can lead to inhibition of outgrowth of cellular lineages. This is supported by *in vitro* data. HHV-6 infection is associated with monocyte dysfunction and suppression of macrophage maturation from bone marrow cultures. Similarly, HHV-6 infection can result in suppression of differentiation and colony formation from hematopoietic progenitor cells. For HHV-7, infection results in inhibition of megakaryocyte survival or differentiation.

Pathogenesis and Disease Associations

Infant Fever with or without Rash

HHV-6 and HHV-7 infect up to 95% of infants. Both HHV-6A and HHV-6B cause primary infant fever, and most infections occur following a drop in maternal immunity after 6 months of age. In the USA, HHV-6B accounts for 97% and HHV-6A for 3% of these infant infections. However, further studies in the USA and the UK show that in less common, earlier infections acquired either congenitally, during delivery, or heritably from germline integration, HHV-6A infections are more frequent, with a prevalence similar to that of HHV-6B. In southern Africa, infant febrile infections detected by PCR analysis of whole blood also indicate equal prevalence. Studies on acquisition of HHV-6B show that infection is symptomatic, with a fever of longer duration than other infections being the most common symptom (3–4 days, 39.4–39.7 °C in various studies). This is a frequent cause of referrals to physicians or hospital. HHV-7 is acquired later, in early childhood, with similar symptoms. As HHV-7 can reactivate HHV-6, the infections can be difficult to distinguish.

The main route of transmission appears to be spread by secretion of reactivated or persistent virus in the saliva from parents or siblings. Congenital infections with HHV-6, but not HHV-7, occur in 1% of births, a prevalence similar to that of HCMV, although HHV-7 has been detected in the placenta. Infections appear as asymptomatic compared to HCMV, although there is one report of neonatal HHV-6B infection associated with neurological disease, seizures, and mental retardation.

A minority of infants have other symptoms or complications, which may be mild or severe. Up to 10% have a skin rash similar to that of measles or rubella, which can confound diagnoses of those infections. This macular or papular rash spreads on face or trunk or both, and has previously been called 'exanthema subitum', 'roseola infantum', or sixth disease. The mean age for acquiring HHV-6 with rash is 7 months. Although this is primarily a benign, self-limiting disease, severe and occasionally life-threatening complications can develop, including lymphadenopathy, diarrhea, myocarditis, myelosuppression, and neurological disease. Indeed, HHV-6 has been reported to account for a third of childhood febrile seizures and direct or indirect mechanisms (via fever) are being evaluated. In the USA, where childhood infections by HHV-6B predominate, links with 'status epilepticus' have been suggested, HHV-6-associated childhood encephalitis cases can occasionally be fatal. The complications previously associated solely with HHV-6 rash are also found in HHV-6 infant fever without rash, and thus up to 90% of symptomatic HHV-6 infections may be undiagnosed or unrecognized.

Immunocompromised People

Solid organ transplantation

Owing to efficient and widespread early childhood transmission of HHV-6 and HHV-7, infections in the adult are primarily reactivations of latent virus, particularly in immunocompromised people such as transplantation patients. Where monitored, co-infections with HCMV present with more severe pathology ('CMV disease'), with a subgroup of delayed graft rejections in liver or kidney transplantation patients. HHV-6-linked encephalitis has occasionally been recorded in these patients, and also in cardiac and heart/lung transplantation patients. Immune suppression using monoclonal antibody to CD3 enhances HHV-6 reactivation and CMV disease; this treatment can also enhance HHV-6 replication *in vitro*. Where symptomatic correlates have been made, HCMV has a greater influence than HHV-6, and HHV-6 has a greater effect than HHV-7. Anecdotal correlates of HHV-6 infection in this context include fever, rash, pneumonitis, encephalitis, hepatitis, and bone marrow suppression. However, it is rare that HCMV reactivates in an HHV-6- or HHV-7-negative patient, as HHV-6 usually reactivates first, then HHV-7 concurrent with HCMV. Thus CMV disease is usually contingent on roseolovirus reactivation. An immunomodulatory role has been presented for HHV-6 reactivations that correlate with increased opportunistic infections, including those associated with HCMV and fungi. Occasional primary infections in the adult have been observed in rare HHV-6- or HHV-7-naive patients who become infected via the donor organ and experience more severe symptoms.

Bone marrow and hematopoietic stem cell transplantation

HHV-6 reactivation is associated with disease in BMT and hematopoietic or cord blood stem cell transplantation (SCT). HHV-6B predominates in Europe and the USA,

where typing has been done, reflecting the prevalence of this variant in primary infections of children there. Half of the patients have HHV-6 reactivations 2–4 weeks post-transplantation, with both direct and indirect immunomodulatory effects. Direct effects of reactivation can lead to HHV-6-associated encephalitis and reduced outgrowth of progenitor lineages, called 'bone marrow suppression' or stem cell inhibition. Indirect immunomodulatory effects leading to HCMV reactivation have also been recorded. The presence of virus DNA in the blood has been demonstrated by quantitative PCR, prior to encephalitis or CNS disease developing by 2–3 weeks post-transplantation. The highest levels were shown for cord blood SCT. Retrospective studies have shown that both HHV-6 reactivation and the use of monoclonal antibody to CD3 are independent risk factors for the development of encephalitis. Amnesia, delirium, or 'confusion' following HHV-6 reactivation have been reported, with estimates of 40% mortality for HHV-6-linked encephalitis in SCT patients. Further investigations are required, and should include possible complications in future stem cell therapy; prospective studies are underway to assess neurological involvement in BMT and SCT.

HIV/AIDS

Like HIV, both HHV-6 and HHV-7 can infect and kill or remain latent in CD4+ T-lymphocytes as well as monocytic/macrophage cells. In addition to direct effects via reactivation of HHV-6 and HHV-7, there may also be indirect interactions between these viruses. As the CD4 count in blood decreases with AIDS progression, so does detection of HHV-6 and HHV-7. However, in studies of disseminated reactivated infections, increased levels of HHV-6 DNA in various organs correlate with higher levels of HIV, suggesting interactions during AIDS progression. HHV-6 reactivations have been identified with HIV in lymph nodes, and have been associated with the early phases of lymphadenopathy syndrome. Individual case studies have recorded HHV-6A-associated fatalities in HIV/AIDS patients from pneumonitis and encephalitis. Furthermore, HHV-6-associated retinitis (on its own or in association with HCMV) has been identified in HIV/AIDS patients. However, the use of antiretroviral therapy in some countries has restored immune control of opportunistic infections such as HCMV, and probably HHV-6 and HHV-7.

Studies *in vitro* and in animal models point to possible mechanisms of interaction between HIV and HHV-6. HHV-6A has been shown to reactivate HIV from latency in monocytes *in vitro*. Ongoing studies of HHV-6A co-infection with simian immunodeficiency virus (SIV) in monkey models show enhanced disease. HHV-7 binds to CD4 and can compete with HIV *in vitro* for interaction with this receptor, and so inhibit infection. HHV-6A can induce CD4, thus enhancing infection with HIV in different cell types *in vitro*, whereas HHV-6A chemokine U83A can bind to CCR5, the HIV co-receptor, and inhibit infection. However, the HHV-6A U51 vCCR can bind, sequester, and downregulate the CCR5 ligand and the HIV-1 inhibitor, Rantes/CCL5, and thus enhance HIV-1 infection. Expression of the other HIV-1 co-receptor, CXCR4, is downregulated by HHV-6 infection and may inhibit progression. Thus, complex interactions between HIV-1 and HHV-6 may either inhibit or enhance HIV-1, depending on virus strain, specific gene expression, cell type, and stage of the lytic/latent life cycle.

Neuroinflammatory Disease and Persistence in the Brain

HHV-6 and HHV-7 have been identified as commensals in the brain, with latent or persistent infection in the CNS, and it is a major challenge to distinguish these silent infections from any locally activated ones associated with neurological disease. This problem is further complicated by the rare occurrence of germline integration of HHV-6A or HHV-6B as noted above. In studies of postmortem brain samples, HHV-6 has been identified more frequently than HHV-7 (*c.* 40% compared to 5%). Where genotyped, 75% of the HHV-6 was HHV-6B, reflecting the greater prevalence of this variant in childhood infections in the populations studied (China and the UK).

In the case of encephalitis, most data concern HHV-6, where active infections have been detected by a combination of identifying virus DNA in the CSF and sera and, where biopsies are available, by *in situ* hybridization in order to detect expression of lytic genes in various temporal classes. RT-PCR of virus RNA in blood may also identify specific viremia, but may often miss relevant localized reactivations in the CNS. Encephalitis associated with HHV-6A and HHV-6B has been identified as a rare complication during primary infection in childhood, and in adults. As described above, SCT and BMT patients are at most risk, since frequent HHV-6 infection/reactivation is linked with life-threatening HHV-6-associated encephalitis; further prospective studies are required.

Links with other neurological conditions have been described, including that of HHV-6B with 'status epilepticus' noted above, and prospective studies are underway. Evidence for active lesions associated with mesial temporal lobe specific regions of the brain, particularly the hippocampus, has been presented and evaluated for links with mesial temporal lobe epilepsy. Interestingly, this region of the brain is also associated with memory, and virus reactivation here may correlate with observations of amnestic periods linked with HHV-6 reactivations in some SCT and BMT patients. Neurological symptoms associated particularly with HHV-6A reactivations have also been linked with subsets of chronic fatigue syndrome patients (and in some cases termed HHV-6A encephalopathy), but the data are conflicting and prompt further studies.

Multiple sclerosis

Roseoloviruses have also been linked with a subset of MS patients, in particular the active HHV-6A infections in a subset of the relapsing remitting form of the disease, and in some studies they have been correlated with exacerbations. These HHV-6A infections occur in countries where the most prevalent childhood infections would be HHV-6B, although there are also some data for multiple reactivations along with HHV-6B or HHV-7. Thus, HHV-6A infections linked with MS could represent rare primary infections occurring during adulthood with this more neurotropic variant. Alternatively, an underlying condition may permit infection with multiple strains.

There is some evidence supporting mechanisms that link HHV-6 with MS. In one study, T-cells from MS patients had lower frequencies of activity against the immunodominant HHV-6 p101 (or pp100) protein (U11), suggesting defects in virus clearance. Furthermore, *in situ* hybridization and immunostaining of biopsy material from MS lesions showed the presence of HHV-6 DNA in oligodendrocytes, lymphocytes, and microglia, plus antigen expression in astrocytes and microglia. Studies on an oligodendrocyte cell line showed some productive infection with HHV-6A but abortive infection with HHV-6B; similar results were found using progenitor-derived astrocytes. *In vitro* studies on glial precursor cell infection by HHV-6 suggest that early virus proteins act in cell cycle arrest, thus inhibiting differentiation to the myelin-producing oligodendrocytes essential for repair of demyelination. In a study conducted in the USA, β-interferon treatment of MS patients resulted in lower amounts of detectable HHV-6 in sera. β-interferon also inhibited growth of HHV-6 cell culture. It has been suggested that tests with antiviral agents such as ganciclovir (GCV) will be required to examine the role of HHV-6 in MS. This will require careful selection of patients and use of appropriate controls, particularly if HHV-6 contributes only to a subsection of this disease.

Immune Response, Diagnosis, and Control

Protective Immunity

In immunocompetent people, HHV-6 and HHV-7 infections give rise to lifelong protective immunity. However, subsequent infections with multiple strains, either HHV-6A or HHV-6B, have been recorded even during early primary infection, with milder or no symptoms. Prior infection with HHV-6 does not prevent infection with HHV-7, but it may provide some cross-protective immunity.

Neutralizing antibodies can be generated after primary infection. Targets include gB as well as the gH/gL/gQ complex. As with other infections, not all antibodies are neutralizing, and thus high serological titers do not always correspond to protection against infection.

Cellular immunity also develops in response to these infections. It is usually HHV-6- or HHV-7-specific, but sometimes cross-reactive. HHV-6- or HHV-7-specific CD4+ T- and NK-cell clones have been isolated, as well HHV-6 antigen-specific clones to p101. Thus, efficient cellular immunity develops after infection, and immunomodulation of lymphoid and myeloid cells may contribute to a possible strategy for effective persistence.

Control

Compounds with activity specifically against HHV-6 are not available and require development. However, HHV-6 and HHV-7 share with HCMV genes encoding proteins involved in replication, and these serve as targets for certain antiviral compounds. Thus, many drugs that are active against HCMV and other herpesviruses also show some activity against HHV-6 and HHV-7. These include GCV, foscarnet, and cidofovir. Acyclovir, which is used to treat alphaherpesvirus, and sometimes gammaherpesvirus, infections, is not effective *in vitro* against HHV-6 or HHV-7, as these viruses do not have the thymidine kinase gene required for activity. The oral prodrug form of GCV (valganciclovir, vGCV) has some anecdotal efficacy during virus reactivations in BMT patients, but is not as efficacious as it is with HCMV, and some HHV-6 or HHV-7 antigenemia can still be observed after vGCV prophylaxis. However, as for HCMV, HHV-6 GCV-escape mutants have been observed *in vivo* in transplantation patients, indicating that there is some efficacy against virus replication. Mutations occur in gene U69, which encodes the homolog of the HCMV GCV kinase (GCK), or in gene U38, which encodes the DNA polymerase (POL). *In vitro*, the HHV-6 GCK is tenfold less active than that of HCMV, which perhaps explains the differences in response between these two betaherpesviruses. Prospective clinical trials are required to demonstrate clinical efficacy *in vivo*, and are underway with vGCV for herpesvirus-associated CNS disease.

Glossary

Host cell A cell that has been infected by a virus.
Provirus A virus that has integrated itself into the DNA of a host cell.
Viral load A measure of the severity of a viral infection which is reported in nucleic acid copies per milliliter of blood.
Viral tropism The specificity of a virus for a particular host tissue.
Virion A single virus particle.

Introduction

In 2006, there were an estimated 39.5 million people worldwide living with human immunodeficiency virus (HIV). An estimated 4.3 million new infections arose in 2006, with 65% of those in sub-Saharan Africa. Acquired immune deficiency virus (AIDS)-related infections accounted for about 2.9 million deaths in 2006 and over 25 million deaths since the syndrome was first recognized in 1981. AIDS is now recognized as one of the most destructive pandemics in recorded history, and with no effective vaccine or cure, treatment of the disease relies on antiretroviral therapy.

The life cycle of HIV begins with the attachment of the virion to the target cell via CD4 binding followed by binding to co-receptor, CCR5 or CXCR4. The viral lipid membrane then fuses to the host cell membrane, allowing the viral core, encapsidating HIV RNA and enzymes, to enter the host cell cytoplasm. HIV RNA subsequently undergoes reverse transcription into DNA, a process mediated by reverse transcriptase. The viral DNA enters the host cell nucleus and is integrated into the cellular DNA by the enzyme integrase. At this point, the provirus may remain latent for up to several years. When the host cell receives a signal to become active, the proviral DNA is transcribed into mRNA. The mRNA is

transported out of the nucleus and is translated into polyproteins. The polyproteins assemble to form an immature virus particle, which then buds out from the host cell. The enzyme protease cleaves these polyproteins into functional proteins, creating a mature virus.

Currently, 25 antiretroviral drugs are available, targeting three steps of the HIV life cycle: a fusion inhibitor, reverse transcriptase (RT) inhibitors (including two classes, nucleoside reverse transcriptase inhibitors (NRTIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs)), and protease inhibitors (PIs). Additional agents are being developed to target other steps in the viral life cycle. See **Table 1** for a list of antiretroviral drugs in development.

Most HIV patients are treated with highly active antiretroviral therapy (HAART), usually a combination of three antiretroviral agents. This treatment paradigm can often reduce a patient's viral load to below detectable levels for prolonged periods. The use of HAART over the past decade has led to significant declines in HIV-associated morbidity and mortality.

Entry Inhibitors

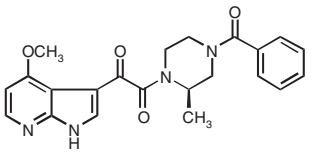
HIV entry into target cells is mediated by the envelope protein (Env), which is comprised of two glycoprotein subunits, the surface protein gp120 and transmembrane subunit gp41. Three distinct steps are required for the entry of HIV into host cells. First, the virus attaches to the cell surface via CD4 binding, changing the conformation of Env and exposing a co-receptor binding site on gp120, allowing the viral glycoprotein to bind to one of the co-receptors, CCR5 or CXCR4. The three gp41 glycoproteins in the trimeric envelope complex subsequently form a 6-helix bundle from interaction of the heptad repeat (HR-) 1 and HR2 domains present in the ectodomain of each subunit. The 6-helix bundle brings the viral and cellular membranes into close apposition and mediates their fusion. These three steps – attachment, co-receptor binding, and fusion – can be targeted by attachment inhibitors (including CD4 binding inhibitors), co-receptor binding inhibitors, and fusion inhibitors, respectively.

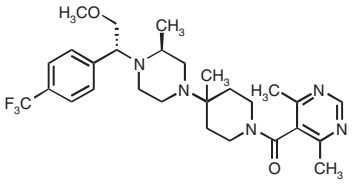
HIV entry inhibitors have recently exploded as potential therapeutic agents. The main reason for the great interest in this field is that entry inhibitors offer the opportunity to prevent infection of new target cells.

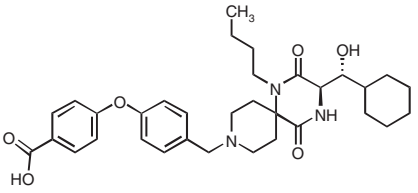
The CD4 receptor was identified in 1984 as the primary cellular receptor for HIV. Because gp120 is responsible for binding to the CD4 receptor on the surface of the host cell, the CD4–gp120 interaction is an attractive target for HIV therapy.

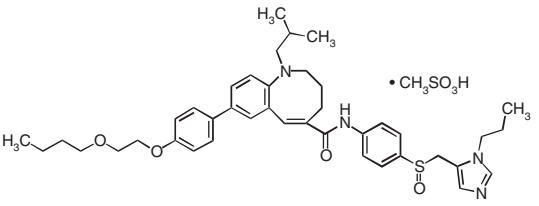
Several years after the discovery of CD4, it was determined that CD4 alone is insufficient to permit HIV infection. In 1996, CCR5 and CXCR4 were identified as the major co-receptors. It was determined that R5 tropic viruses, those which bind to CCR5, are involved in HIV transmission based on the discovery that CCR5Δ32 homozygotes are highly resistant to HIV infection. These individuals, mostly of northern European origin, have a 32 bp deletion in both copies of their CCR5 gene, which confers a recessive phenotype that is associated with resistance to HIV-1 infection and antibody production.

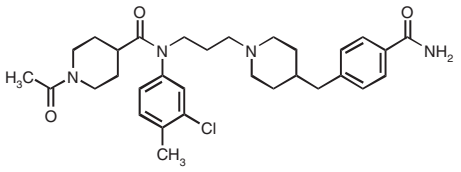
The CXCR4 and CCR5 co-receptors are appealing targets; however, their implementation will require viral phenotyping for co-receptor tropism. Patients infected with an X4 virus, for example, would need to be treated with a CXCR4-specific inhibitor.

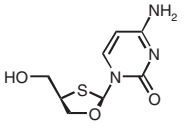


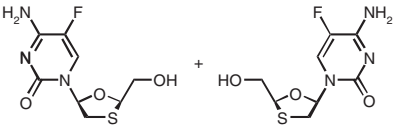








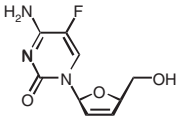


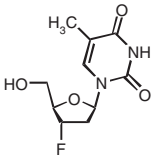


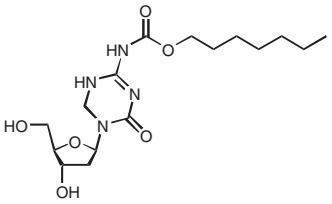
Maraviroc is a small molecule which became the first-in-class CCR5 antagonist and the first oral entry inhibitor with its FDA approval in August 2007 (**Table 2**). Maraviroc monotherapy including twice-daily doses of 300 mg led to a viral load reduction of 1.6 $\log_{10}$ copies ml^{-1}. In phase III studies, twice as many patients taking maraviroc along with optimized combination therapy as those taking a placebo with combination therapy had an undetectable viral load (less than 40 copies ml^{-1}) after 48 weeks.

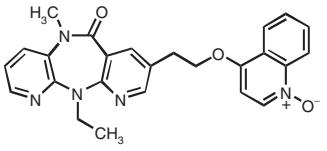
Several other attachment and co-receptor binding inhibitors are currently in development, and biological data have been reported for the drugs in more advanced stages. TNX-355 is a monoclonal antibody which inhibits the interaction between gp120 and CD4. Intravenous infusion of 10 mg kg^{-1} led to a viral load reduction of 1.33 $\log_{10}$ copies ml^{-1}. Vicriviroc and INCB9471 are small-molecule antagonists of the CCR5 receptor. Twice-daily dosing of 50 mg of vicriviroc resulted in a viral load reduction of 1.62 $\log_{10}$ copies ml^{-1}. INCB9471 has recently been reported to show a 1.9 $\log_{10}$ copies ml^{-1} viral load reduction with 14 days of monotherapy. Additionally, the viral load continued to drop for several days after discontinuation of therapy.

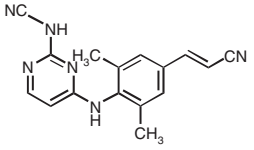
The field of fusion inhibitors is led by enfuvirtide, a biomimetic 36-amino acid peptide that was approved for use in March 2003 (**Table 2**). Enfuvirtide is based on the sequence of the HR2 region of gp41. When the drug binds to HR1, HR2 is unable to bind and fusion cannot occur.

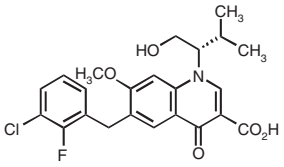


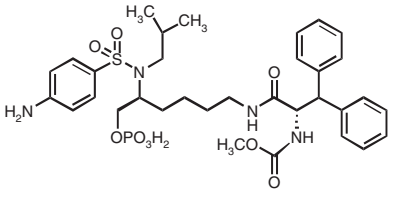












Enfuvirtide was shown to block virus-mediated cell-to-cell fusion with an IC_{90} of 1.5 ng ml^{-1}. A 15-day monotherapy study, with patients receiving 100 mg twice daily, resulted in an average plasma viral load reduction of 1.9 $\log_{10}$ copies ml^{-1}. The main disadvantage of enfuvirtide is its dosing regimen consisting of twice-daily subcutaneous injections. Furthermore, due to the complexity of its 106-step chemical synthesis, enfuvirtide is the most expensive antiretroviral drug on the market. Because of these obstacles, enfuvirtide is generally prescribed to patients for whom other antiretroviral agents have failed.

Table 1 HIV antiretroviral agents in clinical trials

Class	*Name*	*Structure*	*Phase of development*
Entry inhibitor (gp120-CD4)	BMS-378806		Phase I
Entry inhibitor (gp120-CD4)	TNX-355	Monoclonal antibody	Phase II
Entry inhibitor (CCR5)	Vicriviroc (SCH-D)		Phase II
Entry inhibitor (CCR5)	INCB9471	Structure not reported	Phase II

Reverse Transcriptase Inhibitors

Since the identification in 1983 of HIV as the etiological agent of AIDS, HIV RT has been one of the major targets for the development of antiretroviral drugs. HIV RT is a heterodimeric, RNA-dependent DNA polymerase (RdDp) that contains two subunits: the p66 catalytic unit and the p51 structural unit. Two classes of antiretroviral agents inhibit RT. These include NRTIs, which compete with normal 2′-deoxynucleoside triphosphates, and NNRTIs, which are allosteric, noncompetitive inhibitors of RT.

NRTIs are synthetic analogs of natural nucleosides that are incorporated into a nascent viral DNA chain. Because the NRTIs lack a 3′-hydroxyl group, incoming nucleotides are unable to form new phosphodiester linkages, therefore halting DNA replication (chain termination). NRTIs are administered as prodrugs, which must be phosphorylated to the active triphosphate before being incorporated into the DNA by HIV RT. Since these compounds enter the cell via passive diffusion, the prodrugs must be sufficiently lipophilic to penetrate the cell membrane.

Because NRTIs inhibit DNA polymerase, they can also affect normal cells. The drugs show much higher affinity for HIV reverse transcriptase compared to most human DNA polymerases; however, mitochondrial DNA polymerase is significantly inhibited by NRTIs. Various side effects of NRTIs can be attributed to mitochondrial dysfunction, including polyneuropathy, myopathy, cardiomyopathy, pancreatitis, bone-marrow suppression, and lactic acidosis.

Zidovudine, commonly known as AZT, was the first HIV drug approved by the FDA. AZT is a thymidine analog with an azido group replacing the 3′-hydroxyl group.

The azido group not only prevents binding of subsequent nucleosides to the DNA chain but also increases the lipophilicity of AZT, allowing it to easily cross the cell membrane.

Since the approval of AZT in 1987, six other NRTIs have come into the market: didanosine (ddI), zalcitabine (ddC), stavudine (d4T), lamivudine (3TC), abacavir (ABC), and emtricitabine (FTC). Zalcitabine is no longer manufactured as of February 2006. Although each of the NRTIs works by competitive inhibition of RT, they have significantly different dosing, toxicity, and resistance profiles (**Table 3**).

Several more NRTIs are in clinical trials. Apricitabine demonstrated a 1.65 $\log_{10}$ copies ml^{-1} viral load reduction after 10 days of 800 mg b.i.d. monotherapy. Other compounds in early clinical trials have not released efficacy data.

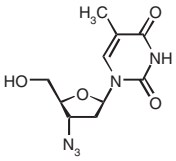
Nucleotide analogs, another type of RT inhibitors, are also available. While several nucleotide analogs are approved to treat various viruses, only tenofovir is approved for the treatment of HIV. Tenofovir is an acyclic nucleoside phosphonate analog that displays increased efficacy owing to its ability to bypass the nucleoside kinase step of activation. Tenofovir and other nucleoside phosphonate analogs also show activity against a broad range of DNA viruses and retroviruses (**Table 3**).

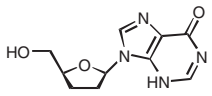
NNRTIs, on the other hand, are noncompetitive inhibitors that bind to a hydrophobic pocket near the polymerase active site. NNRTIs inhibit HIV-1 RT by locking the active catalytic site in an inactive conformation. Despite their structural diversity, most NNRTIs assume a similar butterfly-like structure consisting of two hydrophobic wings connected to a central polar body. The wing portions of the molecules contain significant π-electron systems and can act as π-electron donors to aromatic side chains of RT residues around the NNRTI binding pocket. Although NNRTIs bind at a common site on RT, they differ with regard to the exact amino acids of the binding site with which they interact. Therefore, NNRTIs show differences in their pharmacology and pharmacokinetic profiles, interactions with other drugs, and safety and toxicity profiles.

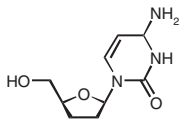
Four NNRTIs are currently licensed for clinical use: nevirapine, delavirdine, efavirenz, and etravirine. Nevirapine, a dipyridodiazepinone derivative, has been shown to reduce perinatal HIV transmission by 47% compared to treatment with AZT. However, the compound can cause life-threatening liver toxicity. Therefore, it is generally restricted to patients at lower risk for liver failure. Delavirdine is a bisheteroarylpiperazine derivative; it is not recommended as part of a first-line antiretroviral therapy program due to its inconvenient dosing regimen and lower efficacy compared to other NNRTIs. Efavirenz, a dihydrobenzoxazinone derivative, is the most commonly prescribed NNRTI due to its high efficacy, once-daily dosing, and relatively lower toxicity. Etravirine is second-generation NNRTI, a highly flexible diarylpyrimidine derivative with a higher genetic barrier to resistance than its precursors. It is the first NNRTI to demonstrate significant antiviral potency in patients with resistance to other NNRTIs.

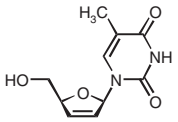
Several other NNRTIs are currently in clinical trials and promise higher potency while eliciting fewer drug-resistant HIV strains. BILR 355 BS is a second-generation dipyridodiazepinone derivative that shows antiviral activity against a wide range of recombinant NNRTI-resistant viruses. Rilpivirine, like etravirine, is a diarylpyrimidine derivative. It shows a median viral load reduction of 1.20 $\log_{10}$ copies ml^{-1} regardless of dose.

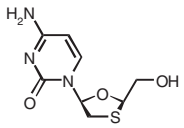
Integrase Inhibitors

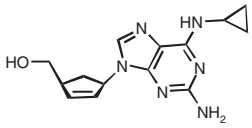


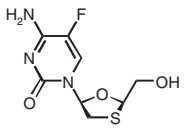








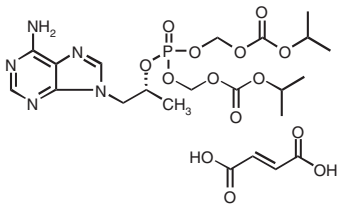


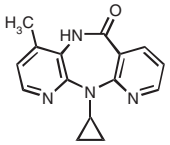


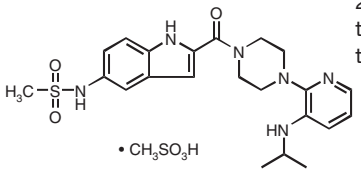
Following reverse transcription, HIV integrase mediates the integration of proviral cDNA by catalyzing two reactions. First, integrase mediates the endonucleolytic hydrolysis of the 3′ ends of the viral DNA. This 3′-processing step generates reactive nucleophilic hydroxyl groups. Integrase remains bound to the viral cDNA as a multimeric complex that bridges both ends of the viral DNA with intracellular particles called preintegration complexes (PICs). In the strand-transfer reaction, integrase mediates the nucleophilic attack of the viral 3′-hydroxyl cDNA across the major groove of the host DNA, resulting in a 5 bp stagger between the integrated viral and host DNA strands. The integration process is completed by DNA gap repair including a series of DNA polymerization, dinucleotide excision, and ligation reactions.

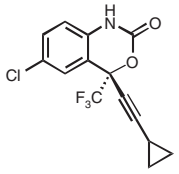
While integrase is essential for retroviral replication, there is no host-cell analog. Because integrase inhibitors do not interfere with normal cellular processes, they are an attractive target for antiretroviral agents. Integrase inhibitors were discovered as early as 1992, but not until 2007 was the first drug approved.

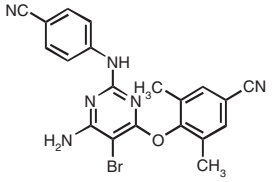
Raltegravir is a first-in-class integrase inhibitor that gained FDA approval in October 2007 (**Table 4**). Because it is the first integrase inhibitor on the market, raltegravir is efficacious even in patients with multidrug-resistant HIV. In phase III trials, raltegravir was found to reduce the HIV viral load to undetectable levels in nearly two-thirds of highly treatment-experienced patients after 16–24 weeks of combination therapy. While the initial approval is only for treatment-experienced patients, raltegravir may also prove to be an option for treatment-naive patients.











Two drugs in clinical trials, MK-0518 and GS-9137, and GSK364735 are shown in **Table 1**. GS-9137 is a dihydroquinoline carboxylic acid derivative which also acts by inhibition of strand transfer. GS-9137 displays a serum-free IC_{50} of 0.2 nM and has activity against viral strains resistant to NRTIs, NNRTIs, and protease inhibitors.

Table 3 FDA-approved reverse transcriptase inhibitors

Name and structure	*Dosing schedule*[b]	*Major toxicity*[b,c]	*Key mutations conferring resistance*[d]	*Impact of monotherapy*[e]
Zidovudine (AZT, Retrovir) 	300 mg tablet b.i.d.	Pancreatitis; lactic acidosis; hepatomegaly; anemia; myopathy; neutropenia	Thymidine analog mutations (TAMs): M41L, D67N/G, K70R, L210W, T215F/Y, K219E/Q/N T215 revertants: T215C/D/E/S/I/V T69 insertion mutations Q151M complex usually in combination with V75I, F77L, F116Y	1.0 $\log_{10}$ copies ml^{-1} decrease in viral load
Didanosine (ddI, Videx) 	200 mg tablet b.i.d. or 250 mg powder b.i.d.	Pancreatitis; lactic acidosis; hepatomegaly; peripheral neuropathy; optic neuritis	L74V/I K65R TAMs: M41L, D67N/G, L210W, T215F/Y, K219E/Q/N M184V/I	0.8 $\log_{10}$ copies ml^{-1} decrease in viral load
Zalcitabine (ddC, Hivid[a]) 	0.75 mg tablet t.i.d.	Pancreatitis; lactic acidosis; hepatomegaly; peripheral neuropathy; mouth and throat ulcers; neutropenia; stomatitis	T69A[f], L74V[g], K65R[h]	Less effective than either ddI or AZT
Stavudine (d4T, Zerit) 	40 mg capsule b.i.d.	Pancreatitis; lactic acidosis; hepatomegaly; peripheral neuropathy; lipodystrophy; hyperlipidemia; rapidly progressive ascending neuromuscular weakness	TAMs: M41L, D67N/G, K70R, L210W, T215F/Y, K219E/Q/N T215 revertants: T215C/D/E/S/I/V T69 insertion mutations Q151M complex usually in combination with V75I, F77L, F116Y	0.8 $\log_{10}$ copies ml^{-1} decrease in viral load
Lamivudine (3TC, Epivir) 	300 mg tablet daily or 150 mg tablet b.i.d.	Lactic acidosis; hepatomegaly	M184V/I K65R Q151M complex usually in combination with V75I, F77L, F116Y TAMs: M41L, D67N/G, L210W, T215F/Y, K219E/Q/N	Limited monotherapy data available
Abacavir (ABC, Ziagen) 	300 mg capsule b.i.d.	Hypersensitivity reaction which can be fatal	K65R L74V/I TAMs: M41L, D67N/G, L210W, T215F/Y, K219E/Q/N T69 insertion mutations	1.8 $\log_{10}$ copies ml^{-1} decrease in viral load
Emtricitabine (FTC, Emtriva) 	200 mg tablet q.d.	Lactic acidosis; hepatomegaly; hyperpigmentation	M184V/I K65R Q151M complex usually in combination with V75I, F77L, F116Y TAMs: M41L, D67N/G, L210W, T215F/Y	2.0 $\log_{10}$ copies ml^{-1} decrease in viral load

A 10-day study in treatment-naive and treatment-experienced patients resulted in mean HIV RNA decreases of 1.91 $\log_{10}$ copies ml^{-1} in patients receiving 400 or 800 mg monotherapy, or 50 mg boosted with 100 mg of ritonavir.

Protease Inhibitors

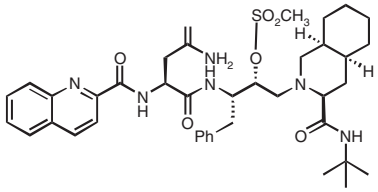
HIV protease is an aspartyl proteinase responsible for cleaving the Gag and Gag-Pol polyproteins in a late stage of the viral life cycle. Because there is no corresponding aspartyl protease that cleaves the Gag polyprotein in mammalian cells, HIV protease has been a popular target for antiretroviral drug development.

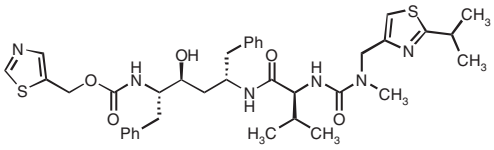
HIV PIs are peptidomimetic products that prevent cleavage of Gag and Gag-Pol protein precursors, preventing virions from maturing and becoming infectious. PIs bind to the protease site with high affinity due to their structural similarity to the tetrahedral intermediate formed during hydrolytic cleavage of a peptide bond in the natural substrate. First-generation PIs have a hydroxyethylene core which acts as a nonhydrolyzable transition state isostere. These compounds bind in the protease active site in a manner that mimics the transition state formed during peptide cleavage.

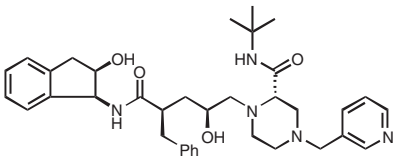
Although many peptidomimetic inhibitors of HIV protease have been reported since the first one in 1990, researchers have faced challenges regarding the physicochemical and pharmacokinetic properties of PIs. Many PIs exhibit poor bioavailability, a short plasma half-life, poor aqueous solubility, and high protein binding, and often require frequent dosing or high pill burden in order to achieve the necessary drug concentration. The newer PIs are starting to resolve these problems. The currently available PIs are shown in **Table 5**.

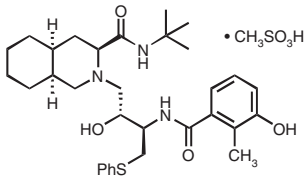
Saquinavir was the first HIV PI studied clinically; it was approved by the FDA in 1995. It was discovered as part of a strategy to find transition-state mimetics of the Phe-Pro peptide bond. The original formulation exhibited potent *in vitro* viral activity but very poor bioavailability in humans (3–5%). In 1997, the FDA approved a soft gelatin capsule formation that provided higher plasma levels and bioavailability.

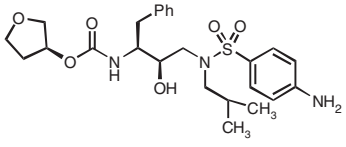
Ritonavir was discovered as a result of efforts to design inhibitors based on the C_2-symmetric structure of HIV protease. It shows better bioavailability than saquinavir and also inhibits cytochrome P450-3A4, a liver enzyme that normally metabolizes PIs. Therefore, ritonavir is administered in combination with other PIs in order to enhance their pharmacokinetic profiles.

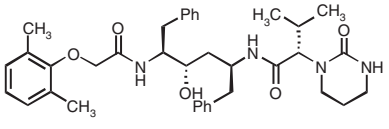








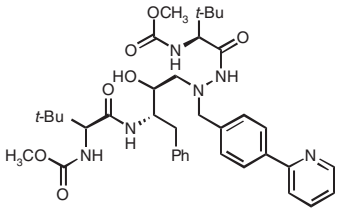


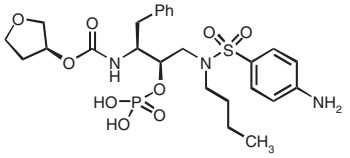


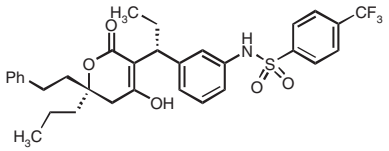
Indinavir resulted from a research program of mechanism-based drug design. The lead compounds preceding discovery of indinavir were modified to create smaller, less peptide-like structures with high water solubility and bioavailability. Nelfinavir was also discovered by rational design, which sought to maximize potency while improving on the pharmacokinetics of its predecessors.

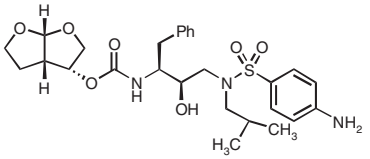
An analysis of the molecular weight distribution of marketed drugs revealed that most drugs with acceptable pharmacokinetic profiles have molecular weights under 600 Da. Amprenavir therefore emerged from a program seeking to maintain high potency while reducing inhibitor size. This compound has a sulfonylated secondary amino hydroxyethyl core, with one of the sulfonyl oxygens playing a key structural role in binding to the enzyme. While amprenavir was the first FDA-approved PI for twice-daily dosing, the 1200 mg dose required by its poor aqueous solubility was very inconvenient, and amprenavir was later superseded by its prodrug fosamprenavir.

Lopinavir is a second-generation PI inhibitor based on the structure of ritonavir. It is potent against ritonavir-resistant virus and tenfold more potent than ritonavir in the presence of human serum. Because lopinavir is rapidly metabolized, it must be co-dosed with ritonavir in order to achieve good oral bioavailability.









Atazanavir, an azapeptide PI inhibitor, is the first PI approved for once-daily dosing. It also appears to have a reduced effect on cholesterol and triglyceride levels as compared to other PIs.

Table 5 FDA-approved protease inhibitors

Name and structure	*Dosing schedule*[a]	*Major toxicity*[a]	*Key mutations conferring resistance*[b]	*Impact of monotherapy*[c]
Saquinavir (Invirase) 	Two 500 mg tablets b.i.d., boosted with ritonavir	Lipodistrophy; diabetes; increased bleeding in hemophiliacs; hyperlipidemia	G48V L90M ± G73S/C/T II84V I54V/T/L/M/A	0.7 $\log_{10}$ copies ml^{-1} decrease in viral load
Ritonavir (Norvir) 	Generally used as a boosting agent for other PIs, 100–400 mg q.d. or b.i.d. Maximum approved dose is 600 mg b.i.d.	Lipodystrophy; diabetes; increased bleeding in hemophiliacs; pancreatitis; paresthesias; hyperlipidemia; hepatitis	V82A/T/F/S I84V V32I I54V/T/L/M[d]	Limited monotherapy data available
Indinavir (Crixivan) 	400 mg capsule or 800 mg capsule b.i.d., boosted with ritonavir	Lipodystrophy; diabetes; increased bleeding in hemophiliacs; liver toxicity; kidney stones; jaundice; hyperlipidemia	V82A/T/F/S M46I/LI54V/T/M/L/A L90M	1.2 $\log_{10}$ copies ml^{-1} decrease in viral load[e]
Nelfinavir (Viracept) 	Two 600 mg tablets b.i.d.	Lipodystrophy; diabetes; increased bleeding in hemophiliacs; hyperlipidemia	D30N±N88D/S L90M±M46I/L I84V V82A/T/F/S	1.5 $\log_{10}$ copies ml^{-1} decrease in viral load
Amprenavir (Agenerase) 	24 50 mg capsules (1200 mg total) b.i.d.	Lipodystrophy; diabetes; increased bleeding in hemophiliacs; skin rash; oral paresthesias; hyperlipidemia		2.0 $\log_{10}$ copies ml^{-1} decrease in viral load[f]
Lopinavir (co-formulation with ritonavir is Kaletra) 	Administered with ritonavir in a single tablet. Two 200/50 mg (lopinavir/ritonavir) tablets b.i.d. or four 200/50 mg q.d.	Lipodystrophy; diabetes; increased bleeding in hemophiliacs; liver damage; hyperlipidemia	V82A/T/F/S I54V/L/M/A/T/SM46I/L I50V	1.9 $\log_{10}$ copies ml^{-1} decrease in viral load[g]

Because of the poor aqueous solubility of amprenavir, a more suitable analog was sought. Fosamprenavir, a phosphate ester prodrug of amprenavir, has excellent aqueous solubility due to the presence of the phosphate salt. Fosamprenavir is rapidly and extensively converted to amprenavir after oral administration and therefore maintains its positive pharmacokinetic profile.

Tipranavir, a nonpeptidic PI, shows excellent antiviral activity. However, its undesirable toxicity profile, including reports of hepatitis and hepatic failure, generally relegate this drug to salvage therapy for patients with resistance to other PIs.

Darunavir, the most recently approved PI, resulted from a drug discovery program aimed at replacing peptide segments of PIs with nonpeptidic isosteres – in particular, a bis-tetrahydrofuran system. The oxygen atoms in this portion of the molecule appear to form hydrogen bonds with aspartate residues in HIV protease. Because of these interactions, darunavir shows activity against a broad range of drug-resistant HIV strains.

Maturation Inhibitors

Recently, a new class of antiretroviral agents has been identified which blocks HIV-1 replication at a late step in the virus life cycle. PIs prevent the essential proteolytic processing of the Gag and Gag–Pol polyproteins, which leads to the structural maturation of the virus particle and activation of viral enzymes. Maturation inhibitors, on the other hand, act directly on the Gag protein by disrupting the conversion of the HIV capsid precursor p25 to the mature capsid protein p24. This results in the production of immature viral particles that have lost infectivity.

Bevirimat, also known as PA-457, is currently the only maturation inhibitor in clinical trials (**Table 1**). Bevirimat is a betulinic acid derivative, which exhibits a mean IC_{50} of 10.3 nM in assays using patient-derived WT virus isolates. The compound also retains a similar level of activity against a panel of virus isolates resistant to the three classes of drugs targeting the viral RT and PR enzymes. With an average 50% cytotoxicity value of 25 μM, the therapeutic index for bevirimat is *c.* 2500.

Combination Therapy

Antiretroviral agents are rarely used alone in treatment. Not only does monotherapy demonstrate inferior antiviral activity to combination therapy, but it also results in a rapid development of resistance. The most common antiretroviral regimens in treatment-naive patients generally contain two NRTIs along with one NNRTI or a single or ritonavir-boosted PI. Preferred regimens are shown below; patients who do not tolerate these combinations may try one of the alternative regimens. While these combinations are recommended by the Office of AIDS Research Advisory Council, each patient is encouraged to seek the optimal combination for his or her situation.

- Preferred
  - Atripla: efavirenz, tenofovir, emtricitabine
  - Atazanavir + ritonavir, tenofovir, emtricitabine
  - Fosamprenavir + ritonavir, tenofovir, emtricitabine
  - Lopinavir/ritonavir, tenofovir, emtricitabine
  - Efavirenz, zidovudine, lamivudine
  - Atazanavir + ritonavir, zidovudine, lamivudine
  - Fosamprenavir + ritonavir, zidovudine, lamivudine
  - Lopinavir/ritonavir, zidovudine, lamivudine

- Alternative
  - Nevirapine, abacavir, lamivudine
  - Atazanavir (unboosted), abacavir, lamivudine
  - Fosamprenavir (unboosted), abacavir, lamivudine
  - Fosamprenavir + ritonavir, abacavir, lamivudine
  - Lopinavir/ritonavir, abacavir, lamivudine
  - Nevirapine, didanosine, lamivudine
  - Atazanavir (unboosted), didanosine, lamivudine
  - Fosamprenavir (unboosted), didanosine, lamivudine
  - Fosamprenavir + ritonavir, didanosine, lamivudine
  - Lopinavir/ritonavir, didanosine, lamivudine

Conclusion

Significant progress in antiretroviral therapy has been made since AZT first hit the market in 1987. With 22 antiretroviral agents in four classes, patients have more choices than ever. Many of these new drugs also improve quality of life with more convenient dosing schedules and greatly improved tolerability.

Despite the important success of HAART, the evolution of many drug-resistant HIV strains has diminished the efficacy of antiretroviral therapy, and an ever-increasing number of patients have progressed to salvage therapy. An estimated 13% of adults receiving care in the USA exhibit resistance to all three drug classes, and 76% of patients show resistance to one or more drugs. Because so many individuals currently living with HIV infection are highly treatment experienced, there is a strong need for newer and more effective antiretroviral therapies.

Glossary

Pandemic An outbreak of an infectious disease that spreads across countries, continents, or even worldwide.
Zoonosis Transmission of a pathogen from one species to another (e.g., humans).

Introduction

Since the beginning of the 1980s, approximately 40 million people have been infected with the human immunodeficiency virus (HIV), the causative agent of the acquired immune deficiency syndrome (AIDS). To date, this multisystemic, deadly, and so far incurable disease has caused more than 20 million deaths. AIDS was first

described in 1981 in a group of homosexual men suffering from severe opportunistic infections. Two years later, a retrovirus was isolated from lymphocytes of AIDS patients and was later termed HIV. The two types, HIV-1 and -2, together with the simian immunodeficiency viruses (SIVs) found in nonhuman primates, delineate the genus of primate lentiviruses. Viruses of the genus *Lentivirus* preferentially replicate in lymphocytes and differentiated macrophages and often cause long-lasting and mostly incurable chronic diseases. In contrast to other retroviruses that require the breakdown of the nuclear membrane during mitosis for integration of the viral genome into host cell chromosomes, lentiviruses are uniquely capable of infecting nondividing cells, preferentially terminally differentiated macrophages and resting T cells.

Despite anti-retroviral therapy becoming more effective, infections with HIV remain one of the most devastating pandemics that humanity has ever faced. Unfortunately and despite enormous efforts, there is only limited hope that an effective vaccine will be developed in the near future and there are no other mechanisms available to stimulate the natural immunity against HIV. Another major drawback is the fact that the virus continues to persist even during prolonged therapy in latently infected host cells, classified as the viral reservoirs *in vivo*. Current anti-retroviral treatment is based on drugs that target either the viral enzymes, protease (PR) and reverse transcriptase (RT), or the envelope (Env) protein-mediated entry of the virus into the target cell.

Although introduction of highly active anti-retroviral therapy (HAART) in the mid-1990s, which involves the combination of different classes of both, PR and RT inhibitors, has led to a significant reduction in morbidity and mortality, an eradication of the virus from HIV-1-infected individuals has never been achieved. In addition, these antiviral drugs can induce severe adverse effects, particularly when administered in combination and over prolonged medication periods. A drawback to these treatments is that with the high mutation rate of HIV and replication dynamic, drug-resistant mutants are evolving. Cellular genes have much lower mutation rates, and a potential solution to this problem is to target cellular factors, enzymes, or complex mechanisms that are essential for replication of HIV in the host cells.

Genomic Organization and Replication of HIV

The *Retroviridae* belong to the huge group of eukaryotic retro-transposable elements. Retroviruses are distinguished from other viruses by their ability to reverse-transcribe their RNA genomes into DNA intermediates by using the enzyme RT. The provirus DNA genome is then integrated into the host cell chromosomes by action of the viral enzyme integrase (IN). All retroviruses contain at least three major genes encoding the main virion structural components that are each synthesized as three polyproteins that produce either the inner virion interior (Gag, group specific antigen), the viral enzymes (Pol, polymerase), or the glycoproteins of the virion Env. The genomic organization of HIV-1 is outlined in **Figure 1**. In addition to virus structural proteins and enzymes, some retroviruses code for small proteins with regulatory and auxiliary functions. In the case of HIV-1, these proteins comprise the two essential regulatory elements: Tat, which activates transcription, and Rev, which modulates viral RNA transport. In contrast, Nef, Vpr, Vif, and Vpu are nonessential for replication in certain tissue culture cells and are generally referred as accessory proteins (**Figure 1**).

According to the nomenclature defined by the International Committee on Taxonomy of Viruses (ICTV) convention, members of the *Orthoretrovirinae* contain RNA inside the virus particle and are released from the plasma membrane. However, the assembly of orthoretroviruses follows two different strategies: alpha-, gamma-, delta-, and lentiviruses (ICTV nomenclature) assemble on the inner leaflet of the plasma membrane and are released as immature virions. In contrast, betaretroviruses and spumaviruses first assemble in the cytoplasm to form immature particles that are then transported to the plasma (betaretroviruses) or internal (spumaviruses) membrane where virus budding occurs.

As with other retroviruses, the HIV replication cycle begins with virus attachment and penetration through the plasma membrane. The schematic replication cycle of HIV-1 is depicted in **Figure 2**. HIV binds to different cell receptors, among them the differentiation antigen, CD4, acting as primary receptor, as well as different specific chemokine receptors that act as co-receptors after binding to CD4. The first retroviral receptor ever identified was the CD4 T-cell receptor that was established in 1984 as the primary receptor for HIV-1 and -2 and SIV. However, the CD4 molecule alone is not sufficient to allow Env-mediated membrane fusion and virus entry, as certain primary isolates of HIV-1 preferentially replicate in T-cell lines (T-cell-line tropic, 'TCL'-tropic), while others establish productive replication only in macrophage cultures ('M'-tropic). Thus, a second class of HIV receptors was predicted and finally identified as a member of the G protein-coupled seven transmembrane domain receptor superfamily acting as so-called 'co-receptors' during HIV entry. Co-receptors, in general, function as cellular receptors for α- and β-chemokines. Two types of co-receptors arbitrate the disparity in cell-type tropism: the α-chemokine receptor CxCR4 that is typically present in T-cell lines, and the β-chemokine receptor CCR5 that is present on macrophages. It was shown that the genetic heterogeneity in co-receptor alleles determines the vulnerability to HIV infection and disease

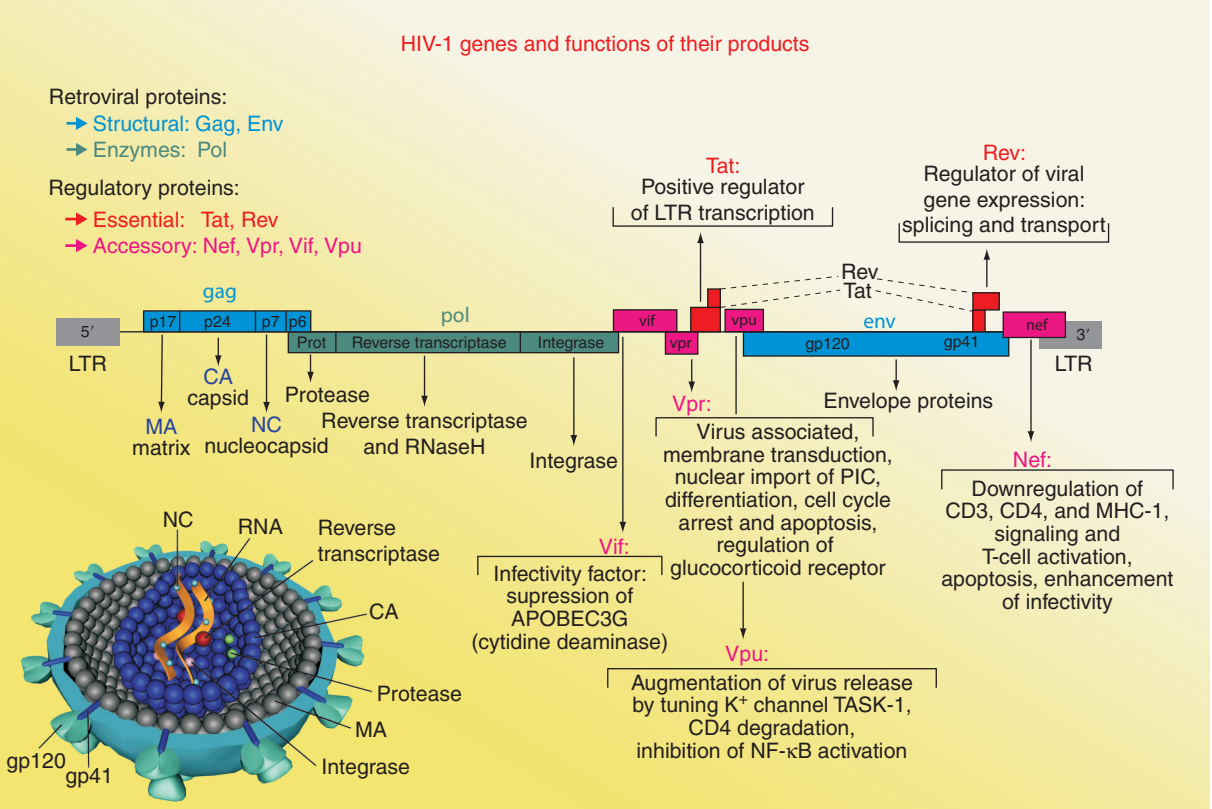

Figure 1 Genomic organization of HIV. This figure illustrates the complex organization of the HIV-1 genome comprising the standard retroviral elements for virus structure, *gag* and *env* (blue), the enzymes *pol* (green), and the six additional genes. These additional genes are either essential as *tat* and *rev*, or accessory as *vpr*, *vpu*, *vif*, and *nef*. The schematic model of the structure of the mature HIV-1 virus particle is given underneath.

progression. A well-characterized example is the identification of a truncated form of CCR5 (termed the 'CCR5/d32' mutation) that in its homozygous form almost completely protects individuals from HIV infection.

Virus entry starts with the so-called 'uncoating' of the virus which is the fusion between the virus and host cell membrane followed by the release of the viral core into the cytoplasm. Following this process, the viral RNA genome is transcribed by the reverse transcription complex (RTC) into double-stranded DNA, which, as part of the preintegration complex (PIC), is transported to the nucleus where the proviral genome is integrated into chromosomes. While there is evidence that the capsid (CA) molecules of the incoming virus are degraded via the ubiquitin proteasome system (UPS), the three virus proteins IN, matrix (MA), and accessory Vpr molecules together with the provirus genome form the PIC. Although the PIC components comprise various nuclear localization signals (NLSs), it is assumed that additional cellular and viral factors, including a central DNA flap that is formed during reverse transcription, facilitate the import of the PIC into the nucleus. It is worth noting that virus entry involves a number of consecutive and highly organized multistep events that might explain why approximately only 1 out of a 1000 mature HIV-1 particles are capable of establishing a productive infection.

After reverse transcription of the viral genome and nuclear import of the PIC, the proviral DNA is integrated into chromosomal DNA. Activation of HIV-1 long terminal repeat (LTR) promoter-driven retroviral gene expression, followed by export, transport, and splicing of the viral mRNA, the so-called late steps of the HIV-1 replication cycle are initiated at this point. These steps involve membrane targeting of Gag and Gag–Pol polyproteins, assembly, as well as budding and maturation of progeny virions. Upon activation of integrated provirus, viral mRNAs are processed and transported into the cytosol for translation of newly synthesized structural proteins that assemble at the plasma membrane into budding particles. The Gag polyprotein in HIV-1 and HIV-2 consists of different functional domains that mediate the recognition and binding of viral RNA, the membrane targeting of Gag and Gag–Pol polyproteins, virion assembly, and efficient particle release from the plasma membrane as the final step of virus budding. In general, the Gag polyprotein constitutes viral components that are both sufficient

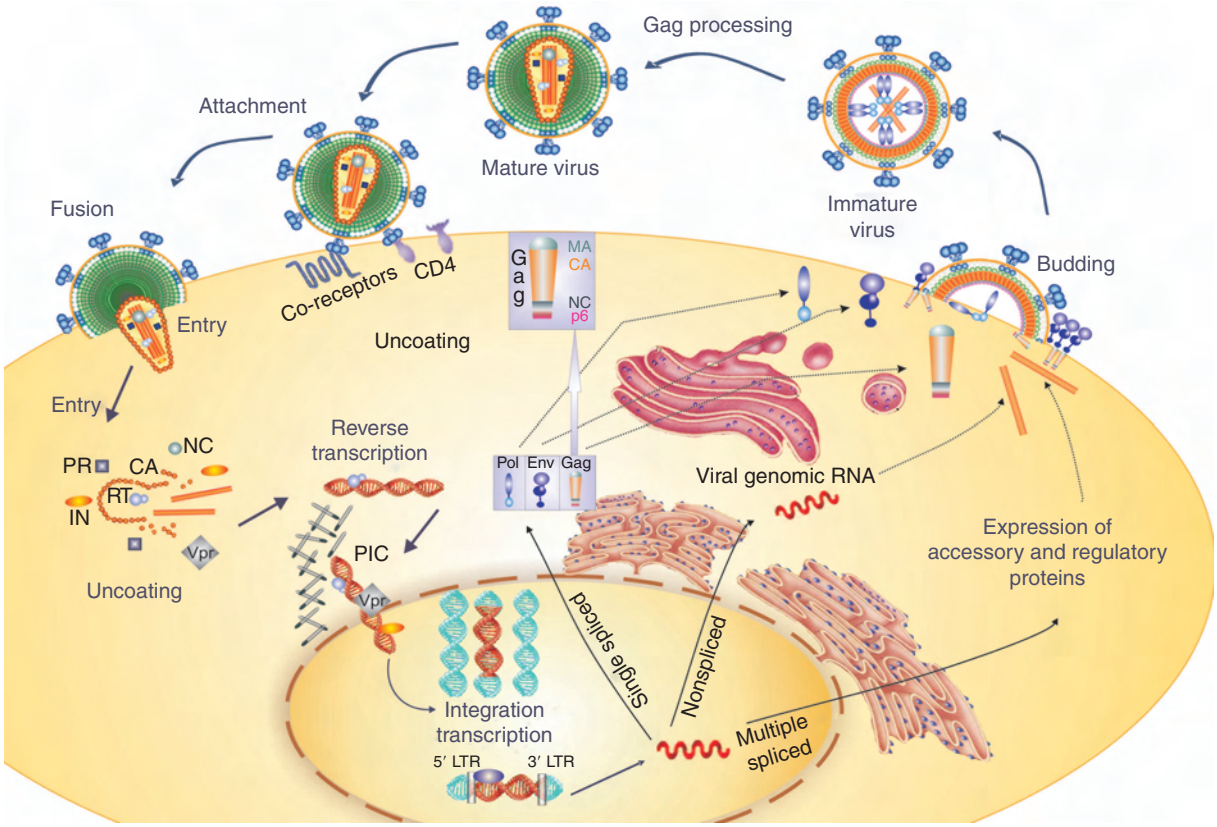

Figure 2 Replication cycle of HIV. Schematic overview of the different stages of the HIV-1 replication cycle.

and strictly required for virus particle assembly and budding, although further viral components such as the genomic RNA, the envelope, and the viral enzymes are required for production of infectious virions. The processing of the HIV-1 Gag polyprotein Pr55 by the viral PR generates the MA, CA, nucleocapsid (NC), as well as p6 proteins and the two spacer peptides, p2 and p1. The HIV-1 *pol*-encoded enzymes, PR, RT, and IN, are proteolytically released from a large polyprotein precursor, Pr160, the expression of which results from a rare frameshift event occurring during translation of Pr55. Like the Gag proteins, the Env glycoproteins are also synthesized from a polyprotein precursor protein. The resulting surface (SU) gp120 and transmembrane (TM) gp41 glycoproteins are produced by the cellular *protease* during trafficking of gp160 to the cell membrane. While gp120 contains the domains that mediate virus binding to CD4 and co-receptors, the gp41 anchors the trimetric complexes of TM/SU in the virus membrane and includes the determinants that regulate fusion between cellular and virus membranes during virus entry. The N-terminus of the extracellular ectodomain of gp41 harbors the so-called 'fusion peptide' that consists of a hydrophobic domain in concert with two helical motifs and regulates membrane fusion by formation of a six-helix bundle. The highly polymorphic SU protein gp120 is organized into five conserved domains (C1 to C5), and five highly variable domains that in most of the known SU sequences are concentrated near loop structures that are stabilized by disulfide bond formation.

In general, Gag proteins of different retroviruses exhibit a certain structural and functional similarity: MA mediates the plasma membrane targeting of the Gag polyprotein and lines the inner leaflet of the lipid bilayer of the mature virus particle, CA regulates assembly of Gag and forms the core shell of the infectious virus, and NC regulates packaging and condensation of the viral genome. In addition to these canonical mature retrovirus proteins, other Gag domains have been described, such as the HIV-1 p6 region that directs the incorporation of the regulatory protein Vpr into budding virions and governs efficient virus budding.

HIV particles bud from the plasma membrane as immature noninfectious viruses consisting predominantly of uncleaved Gag polyproteins. After virus release and in concert with PR activation which is autocatalytically released from the Gag–Pol polyprotein, processing of Gag and Gag–Pol polyproteins into its mature proteins and condensation of the inner core structure occurs that ultimately results in the formation of a mature

infectious virus. Besides PR and Env, at least two other viral factors are known to promote efficient virus release: the HIV-1-specific accessory protein Vpu and the p6 domain. While Vpu supports virus release by an ion channel activity, p6 contains at least two distinct late assembly (L) domains that are required for efficient separation of assembled virions from the cell surface by a yet-undefined mechanism that somehow involves the cellular multivesicular body (MVB) as well as the UPS.

Role of Cellular Factors in HIV Replication

From entry to release and maturation into infectious progeny virions, each individual step in the HIV replication cycle exploits cellular pathways. As for most other intracellular parasites, the replication of HIV-1 depends on the interaction with specific host cell factors, and some of these proteins are specifically incorporated into progeny virions. Conversely, replication of HIV-1 is blocked in cells of the infected host by the action of restriction factors that function as barriers to retroviral replication. These factors are part of the so-called 'innate immune system' for which several mechanisms are known to interfere with replication at different stages of the viral life cycle. HIV-1, however, has evolved strategies to undermine these antiviral responses and, as a consequence, successfully propagates in the specific host environment.

Well-characterized examples for host–virus protein interaction are the virus receptors (CD4 and chemokine receptors) which enable virus entry into specific host cells, the role of the chromatin-remodeling system, and the HMG I family proteins for proviral DNA integration, as well as the requirement of different factors of the endosomal protein trafficking and ubiquitination systems for virus release.

An important case of host–virus interaction is the role of the UPS in virus budding. Recent work has provided intriguing insight into the mechanism of how virus budding exploits the cellular machinery that is normally involved in vacuolar lysosomal protein sorting and MVB-biogenesis. In the case of HIV-1, the recruitment of these cellular factors to the virus assembly site is facilitated by the interaction between the primary L-domain of p6 with at least one important host factor, the tumor susceptibility gene product 101 (Tsg101), an E2-type ubiquitin ligase-like protein. The second L-domain at the C-terminus of p6 mediates the binding of Gag to AIP1/ALIX, a class E vacuolar protein sorting factor that also interacts with Tsg101. AIP1/ALIX also binds to late-acting components of the endosomal sorting complexes required for transport (ESCRTs) and is necessary for the formation of MVB at endosomal membranes. Further, in more recent studies, VPS37B was identified as a new component of the ESCRT that binds to Tsg101. There has been accumulating evidence that HIV-1 recruits the components of the MVB system to the budding machinery which follows two separate and cell-type-specific pathways: in T cells HIV-1 buds primarily from the cell surface, while in monocytes/macrophages the virus buds into vacuoles of the MVB system.

An example for the ability of HIV-1 to escape host cell restriction is the recently discovered relationship between the HIV-1 accessory protein Vif (virus infectivity factor), and APOBEC3G (apolipoprotein B mRNA editing enzyme catalytic polypeptide-like 3G). APOBEC3G is a member of the cellular cytidine deaminase DNA/RNA-editing enzyme family that has the unique capability of hypermutating retroviruses, including HIV-1, with terminal consequences. However, the antiviral effect of APOBEC3G does not correlate with the frequency of mutation induced by APOBEC3G, suggesting that cytidine deaminase activity is not the only underlying mechanism of the antiviral activity of APOBEC. Nevertheless, the resulting innate block in virus replication is counteracted by Vif, which in the virus producer cell binds to APOBEC3G, induces its polyubiquitination by an SCF-like E3 ubiquitin ligase (Cullin5-ElonginB+C), and finally initiates proteasomal degradation of APOBEC3G. It is assumed that by this mechanism Vif is precluding the presence of APOBEC3G in progeny virions.

A second family of proteins with anti-retroviral activity are proteins of the tripartite interaction motif (TRIM) family, exemplified by TRIM5α. TRIM proteins contain a series of three motifs comprising a RING-finger (really interesting new gene), a B-box, and a coiled-coil (CC) domain. Only TRIM5α contains an additional SPRY domain which mediates interaction with the viral CA and is mainly responsible for the species-specific restriction activity. It has been shown that TRIM5α blocks incoming retroviruses at an early step of virus replication, occurring sometime after virus entry and before reverse transcription is initiated, and this antiviral activity of TRIM5α is clearly CA dependent. The RING-finger acts as an E3-type ubiquitin ligase, suggesting that ubiquitination of incoming CA molecules leading to proteasomal degradation might be responsible for the antiviral activity. However, the molecular mechanisms employed by TRIM5α to restrict retroviral infection are still poorly understood and a matter of intensive debate.

HIV Regulator Proteins

While retroviruses share the same fundamental replication cycle and have the same basic genomic organization (e.g., the canonical *gag*, *pol*, and *env* genes), they vary in the content of additional small regulatory genes. These

proteins, except for Rev and Tat, dispensable for HIV-1 replication in certain cell lines *in vitro*, contribute enormously to pathogenesis and spread of HIV-1 *in vivo*.

The *trans*-Activator of Transcription (Tat) of HIV-1

It is now generally accepted that the HIV *trans*-activator (Tat) plays an important role in the pathogenesis of AIDS. Although originally described as an activator of the HIV-1 LTR promoter, Tat was later shown to regulate reverse transcription, to affect the expression of various cellular and viral genes, and to be released from infected cells. This so-called extracellular Tat, which acts as a cell membrane transducing peptide in the sense of a so-called 'trojan molecule', can affect neighboring cells, that are both uninfected and infected target cells. Indeed, there is accumulating evidence that Tat in its extracellular form plays a major role in AIDS-associated diseases like Karposi's sarcoma and HIV-associated dementia.

Tat can be expressed in two forms, as the 72-amino-acid one-exon Tat and as the 86–101-amino-acid (depending on the HIV-1 isolate) two-exon Tat expressed primarily early during infection. The 14–15 kDa Tat binds to an RNA stem–loop structure forming the Tat-responsive element (TAR) at the 5′ LTR region. It activates transcriptional elongation by stimulating the protein kinase TAK (Tat-associated kinase) resulting in hyperphosphorylation of the RNA polymerase II. In general, Tat stimulates the production of full-length HIV transcripts and is, therefore, essential for HIV replication.

The Regulator of Expression of Virion Proteins (Rev)

The compact organization of the HIV-1 genome and expression of all structural and regulatory proteins from a single promoter in the 5′-LTR requires a complex splicing regime of the primary transcript. The fully spliced mRNAs encoding Tat, Rev, and Nef are readily transported from the nucleus to the cytoplasm and, in consequence, these proteins are synthesized early in infection. However, the nuclear export of unspliced or single spliced mRNAs encoding structural proteins Gag and Env, the viral enzymes, as well as the accessory proteins Vif, Vpr, and Vpu, all require the activity of Rev. Hence, these proteins are expressed later during viral infection as the Rev concentration in the infected cell increases.

The Rev protein binds to the viral mRNAs via an arginine-rich RNA-binding motif that additionally serves as NLS required for the transport of Rev from the cytosol to the nucleus. Rev recognizes a stem–loop structure in the viral transcripts known as the Rev response element (RRE) that is located in *env*. After binding to RRE, Rev forms multimeric complexes of up to 12 monomers that are exported from the nucleus by interaction with nuclear export factors. These factors are recruited by a leucine-rich nuclear export signal (NES) located in the C-terminal region of Rev and promote the shuttling of the Rev–RNA complexes to the cytosol. Hence, Rev is required for the synthesis of viral proteins and is therefore essential for HIV replication.

The Lentivirus Protein R (Vpr)

Vpr is a virion-associated, nucleocytoplasmatic shuttling regulatory protein that is encoded by (and conserved among) primate lentiviruses, HIV-1, HIV-2, and the SIVs. Although dispensable for growth of HIV-1 in activated and dividing T cells, Vpr appears to play an important role in virus replication *in vivo*, since deletion of *vpr* and the related *vpx* genes in SIV severely compromises the pathogenic properties in experimentally infected rhesus macaques. Furthermore, HIV-2 and SIV also encode an additional Vpr-related protein, Vpx, that is believed to function synergistically with Vpr. The Vpr of HIV-1 is reported to exhibit numerous biological activities, including nuclear localization (based on the presence of at least two NLS), ion channel formation, transcriptional activation of HIV-1 and heterologous promoters, co-activation of the glucocorticoid receptor, regulation of cell differentiation, induction of apoptosis, cell cycle arrest, and transduction through cell membranes. Although significant amounts of Vpr (approximately 0.15-fold molar ratio to viral core proteins) are packaged into budding HIV-1 particles in a process dependent on Vpr's interaction with the C-terminal p6 domain of the Gag, the biological role(s) of virion-associated Vpr still remains to be fully elucidated.

The highly conserved 96-amino-acid Vpr has received considerable attention, and a number of biological functions have been attributed to its presence in various cellular and extracellular compartments. The most intensively investigated biological functions of Vpr are those affecting the translocation of the PIC of the incoming virus from the cytoplasm to the nucleus, and the arrest in the G_2 phase of the cell cycle. The nuclear targeting function of Vpr has been associated with productive infection of terminally differentiated macrophages by mediating integration of the proviral DNA into the host genome. It is assumed that Vpr causes dynamic disruptions in the nuclear envelope architecture that enables transport of the PIC across the nuclear membrane. Regarding the second function of Vpr, which leads to G_2 cell cycle arrest in HIV-1-infected T cells, it was suggested that this activity provides an intracellular milieu favorable for viral gene expression. Numerous cellular binding partners of

Vpr have been identified, and for some of these a specific role in G_2 arrest has been proposed. Nevertheless, the precise molecular mechanism underlying the Vpr-induced G_2 arrest remains unclear. A potential explanation for the obvious paradigm that Vpr prevents proliferation of infected T cells by arresting them in the G_2 phase was provided by the observation that viral gene expression is optimal in the G_2 phase and that Vpr can increase virus production by delaying cells at this stage of the cell cycle. Interestingly, there are sufficient amounts of Vpr in incoming virus particles to induce G_2 cell cycle arrest even prior to the initiation of *de novo* synthesis of viral proteins. The secondary structures in Vpr emerging from several analyses indicate the presence of an α-helix–turn–α-helix motif at the N-terminus and an extended amphipathic helical region at the C-terminus which might play a key role in self-association and the interaction of Vpr with heterologous proteins, such as p6, NC, Tat of the virus and the adenine nucleotide translocator of the mitochondrial pore.

Other studies suggest that the prolonged G_2 arrest induced by Vpr ultimately leads to apoptosis of the infected cell. Conversely, early anti-apoptotic effects of Vpr have been described which are superseded by its pro-apoptotic effects. These pro-apoptotic effects of Vpr may result from either effects on the integrity of the nuclear envelope or direct mitochondrial membrane permeabilization, perhaps involving Vpr-mediated formation of ion channels in biological membranes.

The HIV-1-Specific Virus Protein U (Vpu)

Vpu is exclusively encoded by HIV-1, with one exception – the HIV-1 related isolate SIV_{cpz} that encodes a Vpu-like protein similar in length and predicted structure to the Vpu from HIV-1 isolates. Vpu of HIV-1 represents an integral membrane phosphoprotein with various biological functions: first, in the endoplasmic reticulum (ER), Vpu induces degradation of CD4 in a process involving the ubiquitin proteasome pathway and casein kinase 2 (Ck-2) phosphorylation of its cytoplasmic tail (Vpu_{CYTO}). Second, Vpu augments virus release from a post-ER compartment by a cation-selective ion channel activity mediated by its transmembrane anchor (Vpu_{TM}). It was shown previously that Vpu can regulate cationic current when inserted into planar lipid bilayers and in *Xenopus* oocytes. Recent results indicate that the virus release function of Vpu_{TM} involves the mutually destructive interaction between Vpu and the K^+ channel TASK-1. Thus, the virus release function of Vpu might be mediated by tuning the activity of host cell ion channels at the cell membrane.

Structurally, Vpu is a class I oligomeric membrane-bound phosphoprotein composed of an amphipathic sequence of 81 amino acids comprising a hydrophobic N-terminal membrane anchor proximal to a polar C-terminal cytoplasmic domain. The latter contains a highly conserved region with the CK-2 phosphorylation sites that regulate Vpu's function in the ER. The current model of the structure and the orientation in the membrane of the N-terminal hydrophobic Vpu_{TM} provides evidence for water-filled five-helix bundles. However, more work is required to understand Vpu in its functional forms *in vivo* where it exists as the phosphoprotein in mulitprotein complexes involving CD4 and β-TrCP, a component of the SkpI, Cullin, F-box protein (SCF^{TrCP}) E3 ubiquitin ligase complex that regulates the ubiquitination and degradation of cellular proteins by the proteasome.

The Viral Infectivity Factor Vif

The 23 kDa phosphoprotein Vif represents a viral infectivity factor that is highly conserved among primate lentiviruses. Vif regulates virus infectivity in a cell-type-dependent fashion. Permissive cells like Hela, Cos, 293T, SupT1, CEM-SS, and Jurkat cells support HIV replication independent of Vif. In contrast, primary lymphocytes, macrophages, and certain cell lines like H9 cells require Vif for production of fully infectious viruses.

Until recently, the mechanism of how Vif supports formation of infectious virions remained mostly enigmatic. Several findings now support the intriguing hypothesis that at least one main function of Vif is to neutralize cellular cytidine deaminase APOBEC3G, which, in the absence of Vif, is encapsidated into progeny virions. It has been a long-known fact that Vif can act *in trans* when it is expressed in the virus-producer cell, but not in the target cell, indicating that Vif must be situated at the virus-assembly site. This model of a post-entry function for Vif is further supported by the observation that Vifs from diverse lentiviruses function in a species-specific mode. Several hypotheses have been put forward to explain the mechanism of Vif function: the activity of Vif might regulate reverse transcription and proviral DNA synthesis, Vif can support the formation of stable virus cores, or Vif might bind to viral RNA in order to support post-entry steps of virus replication. The discovery of the APOBEC3G–Vif interaction provides at least some explanation for these previous observations.

The Multifunctional Nef Protein

Originally, the 27 kDa N-terminal myristoylated membrane-associated phosphoprotein Nef was described as a 'negative factor' that suppresses the HIV LTR promoter activity. As one of the most intensively investigated HIV-1 accessory proteins, Nef has been shown to fulfill multiple functions during the viral replication cycle. In general, it is now widely accepted that inconsistent with its originally 'negative' nomenclature, Nef plays an important stimulatory role in the replication and pathogenesis

of HIV-1. The broad spectrum of Nef-associated activities so far described can be summarized in distinct classes: (1) modulation of cell activation and apoptosis; (2) change in intracellular trafficking of cellular proteins, particularly of cell receptor proteins like CD4 and major histocompatibility complex I (MHC-I); and (3) increase of virus infectivity.

Well characterized and one of the earliest observations in the course of studying the biology of Nef is the Nef-induced downregulation of cell surface CD4. This mechanism occurs on a post-translational level by augmentation of receptor internalization, where Nef binds to the adapter protein complex in clathrin-coated pits, followed by lysosomal degradation. Another influence on immune receptors is the Nef-mediated block in the transport of MHC-I antigen complexes to the cell surface, leading to the disturbance in the recognition of HIV-1 infected cells by cytotoxic T_{CD8}^{+} lymphocytes (CTLs). More recent studies also described downregulation of the co-stimulatory protein CD28 induced by Nef. It appears that the mechanisms by which Nef blocks cell surface expression of CD4, MHC-I, and CD28 are independent and can be genetically separated.

Nef is expressed relatively early in the HIV replication cycle, and there are reports that Nef is even incorporated into budding virions where it can be cleaved by the viral protease. Nef is present during almost all steps of the viral life cycle, which might explain the multiple functions deployed by this accessory protein. Major attention has been focused toward the Nef-mediated modulation of the T-cell signal transduction and activation pathways. Several lines of evidence supported the hypothesis that, by affecting T-cell receptors, Nef may support several aspects of the virus replication cycle, including regulation of apoptosis and immune evasion. Earlier studies in transgenic mice indicated Nef-dependent activation in T-cell signaling. Later studies indicate that Nef imitates T-cell receptor signaling motifs. The Nef-induced T-cell activation requires the tyrosine kinase Zap70 and the ζ-chain of the T-cell receptor. Further, Nef was shown to activate T cells by binding to the Nef-associated kinase, also known as the p21-activated kinase 2 (PAK2). In addition to the activation of T cells, Nef also induces cell death, since it was shown that expression of the death receptor Fas ligand (FasL) is activated by Nef, and that this upregulation might increase killing of lymphocytes attacking HIV infected cells.

A remarkable turn to our understanding of Nef function was offered recently when it was demonstrated that Nef proteins from the great majority of primate lentiviruses, including HIV-2, efficiently downregulate the T-cell receptor CD3 (TCD3), thereby suppressing activation and apoptosis in T cells. In contrast, *nef* alleles from HIV-1 and its closest related SIV isolates do not encode this activity. Hyperactivation of the immune system as caused by T-cell activation is now generally accepted as an important clinical marker of AIDS progression. Hence, downregulation of TCD3 and the resulting avoidance preceding T-cell activation yields viral persistence without damaging the host immune system and disease progression to AIDS. Thus, in contrast to HIV-1, SIV-derived Nef proteins are better described as persistence factors than as pathogenesis factors.

HIV Subtypes

Analysis of viral sequences allows HIV-1 to be classified into three distinctive groups, representing the HIV-1 lineages main (M), outlier (O), and non-M-non-O (N). It is assumed that each group resulted from an independent zoonotic transfer from chimpanzees, which were infected with SIV_{CPZ} into humans. In addition, eight HIV-2 lineages arose from separate zoonotic transfers from sooty mangabeys infected with SIV_{SM}. Most intriguingly, of these 11 zoonotic events that transferred primate lentiviruses from nonhuman primates to humans, only those resulting in the HIV-1 M-group finally led to the current global AIDS pandemic. Most of group O and group N strains originate from West Africa, especially Cameroon. However, the propagation of these strains was relatively restricted. HIV-2, predominantly A and B groups, is also for the most part endemic in West Africa, particularly in Côte d'Ivoire. In comparison to HIV-1, HIV-2 led to a relatively small number of infections in humans. It is conceivable that more transmissions from nonhuman primates to humans occurred, which, however, were not able to spread efficiently in the human population and therefore have never been detected. At least one reason for the low frequency of successful zoonotic events is that transmissions of primate lentiviruses across the species barrier can be controlled by the existence of species-specific restriction factors (e.g., TRIM5α, as detailed above) that act as barriers against retroviral transfers.

Glossary

Circulating recombinant forms These forms represent recombinant HIV-1 genomes that have infected three of more persons who are not epidemiologically related.
Endemic A classification of an infectious disease that is maintained in the population without the need for external inputs.
Epidemic A classification of a disease that appears as new cases in a given human population, during a given period, at a rate that substantially exceeds what is expected, based on recent experience.
Neighbor-joining method This clustering method constructs trees by sequentially finding of pairs of operational taxonomic units (OTUs) or neighbors that minimize the total branch length at each stage of clustering OTUs starting with a starlike tree.
Pandemic An epidemic that spreads through human populations across a large region (for e.g., a continent), or even worldwide.
Phylogenetic tree A phylogenetic tree, also called evolutionary tree, is a graphical diagram, showing the evolutionary relationships among various biological species of other entities that are believed to have a common ancestor, comparable to a pedigree showing which genes or organisms are most closely related. In a phylogenetic tree, each node with descendants represents the most common ancestor of the descendants, and the edge lengths in most trees correspond to time estimates. External nodes are often called operational taxonomic units (OTUs), a generic term that can represent many types of comparable taxa. Internal nodes may be called hypothetical taxonomic units (HTUs) to emphasize that they are the hypohetical progenitors of OTUs.
Prevalence The prevalence of a disease in a statistical population is defined as the total number of cases of the disease in the population at a given time, or the number of cases in the population, divided by the number of individuals in the population.

Introduction

Infectious diseases have been an ever-present threat to mankind. A number of important pandemics and epidemics arose with the domestication of animals, such as influenza and tuberculosis. Whereas the cause of some of the historic pandemics, such as the bubonic plague (the Black Death) that killed at least 75 million people, have been successfully eradicated, many others still cause high mortality especially in developing countries. Emerging infectious diseases continue to represent a major threat to global health. As such, HIV/AIDS is one of the most important diseases to have emerged in the past century. When on 5 June 1981, a report was published, describing five young gay men infected with *Pneumocystis carinii* pneumonia (PCP), no one could have imagined that 25 years later, more than 40 million people all over the world would be infected with the human immunodeficiency virus (HIV), the cause of the acquired immunodeficiency syndrome (AIDS). With more than 25 million deaths, HIV/AIDS continues to be one of the most serious public health threats facing humankind in the twenty-first century.

It is important therefore to identify where HIV came from, whether a natural host reservoir exists and how it was introduced into the human population. Today it is well established that human immunodeficiency viruses HIV-1 and HIV-2 are the result of several cross-species transmissions from nonhuman primates to humans.

West-Central African chimpanzees (*Pan troglodytes troglodytes*) are now recognized as the natural reservoir of the simian immunodeficiency viruses (SIVcpz*Ptt*), that are the ancestors of HIV-1. Similarly, HIV-2, which has remained largely restricted to west Africa, is the result of cross-species transmissions of SIVsmm from sooty mangabeys (*Cercocebus atys*).

Although it is clear now that HIV has a zoonotic origin, it remained for a long time less certain where, when, and how often these viruses entered the human population. In this article, we will describe in more detail the latest findings on the origin of HIV, more specifically of the three groups of HIV-1 (M, N, and O) and HIV-2.

Taxonomy, Classification, and Genomic Structure

Taxonomy

Human and *Simian immunodeficiency viruses* (HIV and SIV) belong to the genus *Lentivirus* of the family *Retroviridae*, characterized by their structure and replication mode. These viruses have two RNA genomes and rely on the reverse transcriptase (RT) enzyme to transcribe their genome from RNA into a DNA copy, which can then be integrated as a DNA provirus into the genomic DNA of the host cell. This replication cycle is common for all members of the family *Retroviridae*. As the name suggests, the genus *Lentivirus* consists of slow viruses, with a long incubation period. Five serogroups are recognized, each reflecting the vertebrate hosts with which they are associated (primates, sheep and goats, horses, cats, and cattle). A feature of the primate lentiviruses, HIV and SIV, is the use of a CD4 protein receptor and the absence of a dUTPase enzyme.

Classification

Classification of simian immunodeficiency viruses (SIVs)

SIVs isolated from different primate species are designated by a three-letter code, indicating their species of origin (e.g., SIVrcm from red-capped mangabey). When different subspecies of the same species are infected, the name of the subspecies is added to the virus designation, for example, SIVcpz*Ptt* and SIVcpz*Pts* to differentiate between the two subspecies of chimpanzees *P. t. troglodytes* and *P. t. schweinfurthii,* respectively. For chimpanzee viruses, the known or suspected country of origin is often included; for example, SIVcpzCAM and SIVcpzGAB are isolates from Cameroon and Gabon, respectively.

Currently, serological evidence of SIV infection has been shown for 39 different primate species and SIV infection has been confirmed by sequence analysis in 32 (see **Table 1**). Overall, complete SIV genome sequences are available for 19 species. Importantly, 30 species of the 69 recognized Old World monkey and ape species in sub-Saharan Africa have not been tested yet or only very few have been tested. Knowing that the vast majority (90%) of the primate species tested are SIV infected, many of the remaining species would be expected to harbor additional SIV infections. Only Old World primates are infected with SIVs, and only those from the African continent; no SIVs have been identified in Asian primate species. It is important also to note that none of the African primates naturally infected with SIV develop disease.

Classification of human immunodeficiency viruses (HIVs)

AIDS can be caused by two related lentiviruses; human immunodeficiency virus types 1 and 2 (HIV-1 and HIV-2). On the basis of phylogenetic analyses of numerous isolates obtained from diverse geographic origins, HIV-1 is classified into three groups, M, N, and O. Group M (for Major) represents the vast majority of HIV-1 strains found worldwide and is responsible for the pandemic; group O (for Outlier) and N (non-M–non-O) remain restricted to West-Central Africa. Group M can be further subdivided into nine subtypes (A–D, F-H, J, K), circulating recombinant forms (CRFs, CRF01–CRF32), and unique recombinants. The geographic distribution of the different HIV-1 M variants is very heterogeneous and differs even from country to country. Compared to HIV-1, only a limited number of HIV-2 strains have been genetically characterized and eight groups (A–H) have been reported.

Genomic Structure

All primate lentiviruses have a common genomic structure, consisting of the long terminal repeats (LTRs), flanking both ends of the genome, three structural genes, *gag, pol,* and *env* and five accessory genes, *vif*, *vpr*, *tat*, *rev,* and *nef*. Some primate lentiviruses carry an additional accessory gene, *vpx* or *vpu,* in the region between *pol* and *env.* Based on this genomic organization, we can distinguish between three patterns (**Figure 1**): (1) SIVagm, SIVsyk, SIVmnd1, SIVlho, SIVsun, SIVcol, SIVtal, and SIVdeb display the basic structure with three major and five accessory genes; (2) SIVcpz, SIVgsn, SIVmus, SIVden, SIVmon, and also HIV-1 harbor an additional accessory gene, *vpu*; HIV-1 and SIVcpz differ from the other members of this group by the fact that *env* and *nef* genes are not overlapping; (3) SIVsmm, SIVrcm, SIVmnd2, SIVdrl, and SIVmac, and HIV-2 harbor a supplemental accessory gene, *vpx*. For the remaining SIVs, SIVolc, SIVwrc, SIVasc, SIVbkm, SIVery, SIVblu, SIVpre, SIVagi, and SIVgor, full-length sequences are not yet available.

Table 1 Serological and/or molecular evidence for SIV infection in the African nonhuman primates

Genus	*Species*	*Common name*	*SIV*	*Geographic distribution*
Pan	*troglodytes*	Common chimpanzee	SIVcpz	West to East: Senegal to Tanzania
Gorilla	*gorilla*	Western gorilla	SIVgor[a]	Central: Cameroon, Gabon, Congo, Central Africa Republic
Colobus	*guereza*	Mantled guereza	SIVcol	Central: Nigeria to Ethiopia/Tanzania
Piliocolobus	*badius*	Western red colobus	SIVwrc[a]	West: Senegal to Ghana
Procolobus	*verus*	Olive colobus	SIVolc[a]	West: Sierra-Leone to Ghana
Lophocebus	*albigena*	Gray-cheeked managabey	?	Central: Nigeria to Uganda/Burundi
	aterrimus	Black crested mangabey	SIVbkm[a]	Central: Democratic Republic of Congo (DRC)
Papio	*anubis*	Olive baboon	?	West to East: Mali to Ethiopia
	cynocephalus	Yellow baboon	SIVagm-Ver[a]	Central: Angola to Tanzania
	ursinus	Chacma baboon	SIVagm-Ver[a]	South: southern Angola to Zambia
Cercocebus	*atys*	Sooty mangabey	SIVsmm	West: Senegal to Ghana
	torquatus	Red-capped mangabey	SIVrcm	West Central: Nigeria, Cameroon, Gabon
	agilis	Agile mangabey	SIVagi[a]	Central: northeast Gabon to northeast Congo
Mandrillus	*sphinx*	Mandrill	SIVmnd-1, SIVmnd-2	West Central: Cameroon (south of Sanaga) to Gabon, Congo
	leucophaeus	Drill	SIVdrl	West Central: southeast Nigeria to Cameroon (north of Sanaga)
Allenopithecus	*nigroviridis*	Allen's swamp monkey	?	Central: Congo
Miopithecus	*talapoin*	Angolan talapoin	SIVtal[a]	West Central: East coast of Angola into DRC
	ogouensis	Gabon talapoin	SIVtal	West Central: Cameroon (south of Sanaga)-Gabon
Erythrocebus	*patas*	Patas monkey	SIVagm-sab[a]	West to East: Senegal to Ethiopia, Tanzania
Chlorocebus	*sabaeus*	Green monkey	SIVagm-Sab	West: Senegal to Volta river in Burkina Faso
	aethiops	Grivet	SIVagm-Gri	East: Sudan, Erithrea, Ethiopia
	tantalus	Tantalus monkey	SIVagm-Tan	Central: Ghana to Uganda
	pygerythrus	Vervet monkey	SIVagm-Ver	South: South Africa to Somalia and Angola
Cercopithecus	*diana*	Diana monkey	?	West: Sierra-Leone to Ivory Coast
	nictitans	Greater spot-nosed monkey	SIVgsn	Central: forest blocks from West Africa to DRC
	mitis	Blue monkey	SIVblu[a]	East Central: East Congo to Rift-valley
	albogularis	Sykes's monkey	SIVsyk	East: Somalia to Eastern Cape
	mona	Mona monkey	SIVmon	West: Niger delta to Cameroon (north of Sanaga)
	campbelli	Campbell's mona	?	West: Gambia to Liberia
	pogonias	Crested mona	?	West Central: Cross River in Nigeria to Congo (east)
	denti	Dent's mona	SIVden	Central: south of Congo River
	cephus	Mustached guenon	SIVmus	West Central: Cameroon (south of Sanaga) to east of Congo River
	erythrotis	Red-eared monkey	SIVery[a]	West Central: Cross River in Nigeria to Sanaga in Cameroon, Bioko
	ascanius	Red-tailed monkey	SIVasc[a]	Central: South-East Congo to West Tanzania
	lhoest	l'Hoest monkey	SIVlho	Central: eastern Congo–Zaire to western Uganda
	solatus	Sun-tailed monkey	SIVsun	West Central: tropical forest of Gabon
	preussi	*Preuss's monkey*	SIVpre[a]	West Central: Cross river in Nigeria to Sanaga in Cameroon, Bioko
	hamlyni	Owl-faced monkey	?	Central: eastern DRC to Ruanda
	neglectus	de Brazza's monkey	SIVdeb	Central: Angola, Cameroon, Gabon to Uganda, western Kenya

[a]only partial sequences are available, ? only serological evidence for SIV infection.

Evolutionary History

HIV-2 and SIVsmm from Sooty Mangabeys

Shortly after the identification of HIV-1 as the cause of AIDS in 1983, the first SIV, SIVmac, was isolated from rhesus macaques (*Macaca mulatta*) at the New England Regional Primate Research Center (NERPRC). Retrospective research revealed that the newly identified SIV was introduced to the NERPRC by rhesus monkeys, previously housed at the California National Primate Research Center (CNPRC), where they survived an earlier (late 1960s) disease outbreak, characterized by immune suppression and opportunistic infections. A decade after the first outbreak, the story has been repeated in

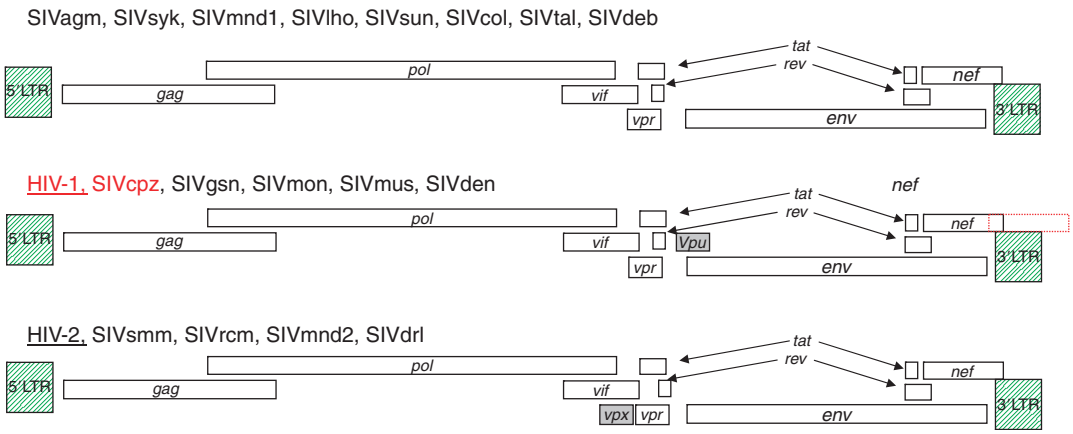

Figure 1 Genomic organization of the primate lentiviruses.

stump-nailed macaques (*Macaca arctoides*) in the same settings and 15 years later a lentivirus, called SIVstm, was isolated from frozen tissue from one of these monkeys. In both cases, the infected rhesus macaques had been in contact with healthy, but retrospectively shown SIVsmm seropositive sooty mangabeys at the CNPRC. The close phylogenetic relationship between SIVmac, SIVstm, and SIVsmm identified mangabeys as the plausible source of SIV in macaques. Since SIVmac induced a disease in rhesus macaques with remarkable similarity to human AIDS, a simian origin of HIV was soon suspected. The discovery in 1986 of HIV-2, the agent of AIDS in West Africa, and the remarkable high relatedness of HIV-2 with SIVsmm, naturally infecting sooty mangabeys in West Africa, reinforced this hypothesis.

In addition, the similarities in viral genome organization (the presence of *vpx*), the geographic coincidence of the natural range of sooty mangabeys and the epicenter of the HIV-2 epidemic in West Africa, as well as the fact that sooty mangabeys are frequently hunted for food or kept as pets, allowed the identification of SIVsmm from sooty mangabeys as the simian source of HIV-2.

HIV-1 and SIVcpz from Chimpanzees

The first SIVcpz strains, SIVcpzGAB1 and SIVcpzGAB2, were isolated from chimpanzees (*P. troglodytes*) in Gabon more than 15 years ago; of 50 wild-caught chimpanzees initially tested for SIVcpz infection, two (GAB1 and GAB2) harbored HIV-1 cross-reactive antibodies. Analysis of the SIVcpzGAB1 genome revealed the same genomic organization as HIV-1, including an accessory gene, named *vpu*, so far only identified in HIV-1. Furthermore, phylogenetic analysis indicated that SIVcpzGAB1 was more closely related to HIV-1 than to any other SIV. A few years later, a third positive chimpanzee, confiscated upon illegal importation into Belgium from the Democratic Republic of Congo (DRC, ex-Zaire), was identified among 43 other wild-caught chimpanzees. A virus, SIVcpzANT, was isolated and characterized, but this virus showed an unexpected high degree of divergence from the others. A fourth SIVcpz strain (SIVcpzUS) was obtained from a chimpanzee (Marilyn) housed in an American primate center and it was shown that SIVcpzUS was closely related to the SIVcpz strains from Gabon. Subspecies identification of the chimpanzee hosts revealed that the SIVcpzANT strain was isolated from a member of the *P.t. schweinfurtii* subspecies, whereas the other chimpanzees belonged to the *P.t. troglodytes* subspecies. These findings suggested two distinct SIVcpz lineages according to the host species: SIVcpz*Ptt*, from the West-Central African chimpanzees, and SIVcpz*Pts*, from eastern chimpanzees. HIV-1 strains are classified into three highly divergent clades, groups M, N, and O, each of which was more closely related to SIVcpz from *P. t. troglodytes* than to SIVcpz from *P. t. schweinfurthii*. These data pointed to the West-Central African subspecies, *P. t. troglodytes* as the natural reservoir of the ancestors of HIV-1.

Until recently, only a handful of complete or partial SIVcpz genomes have been derived. In addition to the four previously mentioned viruses, three other strains, SIVcpzCAM3, SIVcpzCAM5, and SIVcpzCAM13, have been identified in Cameroon and all clustered with the previously identified SIVcpz*Ptt* strains consistent with their species of origin. The discovery of HIV-1 group N in a Cameroonian patient in 1998 showed that HIV-1 N is closely related to SIVcpz*Ptt* in the envelope region of the viral genome, suggesting an ancient recombination event. This finding demonstrated the co-circulation of SIVcpz and HIV-1 N viruses in the same geographic area and provided additional evidence that the western part of Central Africa is the likely site of origin of HIV-1.

However, the number of identified SIV strains in chimpanzees was low, compared to that of other naturally occurring SIV infections. The major problem in studying SIVcpz infection in chimpanzees is their endangered status and the fact that they live in isolated forest regions. All

previously studied chimpanzees were among wild-caught but young and captive animals. They were initially captured as infants, mainly as a by-product of the bushmeat trade. Since the age of maturation of chimpanzees is around 9 for males and 10 for females, these infections were most probably the result of vertical transmission and do not reflect true prevalences among wild-living adult animals. Apparently, the frequency of vertical transmission is low among naturally infected primates, which can explain the low prevalence rates initially observed.

The recent development of noninvasive methods to detect and characterize SIVcpz in fecal and urine samples from wild ape populations boosted the search for new SIVcpz strains in the vast tropical forests of Central Africa. The first report of a full-length SIVcpz sequence obtained from a fecal sample, SIVcpzTAN1, was from a wild chimpanzee from the *P. t. schweinfurtii* subspecies in Gombe National Park, Tanzania. Subsequently, additional cases of SIVcpz*Pts* infections were documented in Tanzania (SIVcpzTAN2 to SIVcpzTAN5) and around Kisangani, northeastern DRC (SIVcpzDRC1). All the new SIVcpz*Pts* viruses formed a separate lineage with the initially described SIVcpzANT strain and suggest that the SIVcpz*Pts* strains are not at the origin of HIV-1 (**Figure 2**). A recent study in wild chimpanzee communities in southern Cameroon documented a prevalence of SIVcpz infection ranging from 4% to 35%, and identified 16 new SIVcpz*Ptt* strains. All of these newly identified viruses were found to fall within the radiation of SIVcpz*Ptt* strains from captive *P. t. troglodytes* apes, which also includes HIV-1 groups M and N, but not group O or SIVcpz*Pts* (**Figure 2**). The new SIVcpz*Ptt* viruses are characterized by high genetic diversity and SIVcpz*Ptt* strains were identified which are much more closely related to HIV-1 groups M and N than were any previously identified SIVcpz strains. Interestingly, the new SIVcpz*Ptt* viruses exhibited a significant geographic clustering and made it possible to trace the origins of present-day human AIDS viruses to geographically isolated chimpanzee communities in southern Cameroon.

HIV-1 and SIVgor from Gorillas

SIV infection has recently been described in western gorillas (*Gorilla gorilla*) in Cameroon. Surprisingly, the newly characterized gorilla viruses, termed SIVgor, formed a monophyletic group within the HIV-1/SIVcpz*Ptt* radiation, but in contrast to SIVcpz*Ptt*, they were most closely related to the HIV-1 group O lineage (**Figure 2**). However, the phylogenetic relationships between SIVcpz, SIVgor, and HIV-1 indicate that chimpanzees represent the original reservoir of SIVs now found in chimpanzees, gorillas, and humans. Given their herbivorous diet and peaceful coexistence with other primate species, especially chimpanzees, it remains a mystery by what route gorillas acquired SIVgor.

The data on SIV in wild chimpanzee and gorilla populations showed that distinct chimpanzee communities in southern Cameroon transmitted divergent SIVcpz to humans giving rise to HIV-1 groups M and N; and that chimpanzees transmitted HIV-1 group O-like viruses either to gorillas and humans independently, or first to gorillas which then transmitted the virus to humans. Additional studies are needed to determine if the other African great ape species, the eastern gorillas (*Gorilla berengei*) and the bonobo (*Pan paniscus*) harbor any SIV.

Cross-Species Transmission

Where?

HIV-1

Based on mitochondrial DNA sequences, common chimpanzees (*P. troglodytes*) are classified into four subspecies: *P. t. verus* in West Africa; *P. t. vellerosus*, restricted to a geographical area between the Cross River in Nigeria and the Sanaga River in Cameroon; *P. t. troglodytes* in southern Cameroon, Gabon, Equatorial Guinea, and the Republic of Congo; and *P. t. schweinfurtii* in the Democratic Republic of Congo, Uganda, Rwanda, and Tanzania. No evidence of SIV infection is found in *P. t. verus*, despite testing of more than 2000 chimpanzees, mostly captive animals exported to zoos or research centers in the US. Wild *P. t. vellerosus* apes have not been found to harbor SIVcpz, but only about 100 samples have been screened. The single reported SIV infection of *P. t. vellerosus*, SIVCAM4, was most probably the result of a cage transmission from a *P. t. troglodytes* ape, infected with SIVcpzCAM3. Since the three groups of HIV-1 (M, N, and O) all fall within the HIV-1/SIVcpz*Ptt*/SIVgor lineage, the cross-species transmissions giving rise to HIV-1 most likely occurred in western equatorial Africa. Furthermore, no human counterpart is found for SIVcpz*Pts* from *P. t. schweinfurtii*, which undermines the idea of a human-induced origin of HIV-1 by oral polio vaccine (OPV) programs in East-Central Africa in the late 1950s. It has been suggested that tissues derived from SIVcpz-infected chimpanzees, captured in the northeastern part of DRC were used for the polio vaccine production. However, this geographical region is situated in the middle of the *P. t. schweinfurtii* range and the characterization of a partial SIV genome (SIVcpzDRC1) from a wild chimpanzee in this region proved once more the inconsistency of the OPV theory (**Figure 2**).

The recent studies in wild chimpanzee communities in Cameroon, not only confirm the West-Central African origin of HIV-1, but also indicate that HIV-1 group M and N arose from geographically distinct chimpanzee populations. Phylogenetic analysis showed that all SIVcpz strains collected in southeast Cameroon formed a cluster with HIV-1 group M, whereas SIVcpz isolates from chimpanzee communities of a well-defined region in

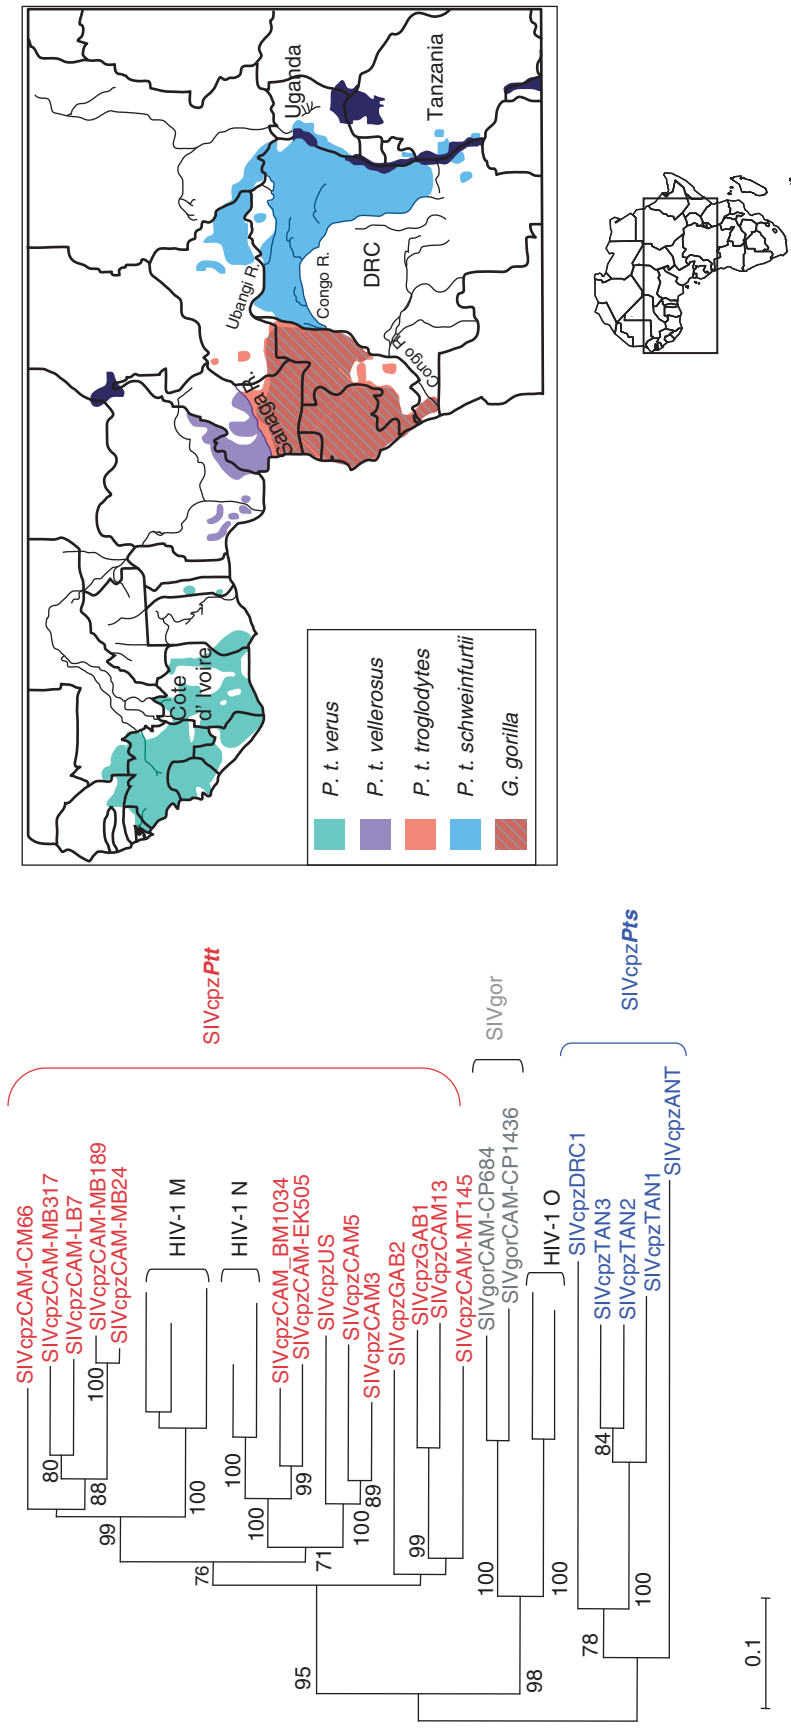

Figure 2 Natural range of chimpanzee subspecies and phylogeny of the HIV-1/SIVcpz/SIVgor lineage. The ranges of the four recognized chimpanzee subspecies are color-coded. The SIVcpz*Ptt* and SIVcpz*Pts* sequences in the phylogenetic tree are colored in red and blue, respectively, in accordance to the chimpanzee subspecies, illustrating that HIV-1 is more closely related to SIVcpz from West-Central African chimpanzees. The natural range for western gorillas (*Gorilla gorilla*) overlaps with the *P. t. troglodytes* range in West-Central Africa; SIVgor sequences are indicated in gray. The country of origin where SIVcpz strains were identified is indicated with a three-letter code: CAM for Cameroon, GAB for Gabon, TAN for Tanzania, DRC for the Democratic Republic of Congo, US for an animal in a primate center in the USA, and ANT for a captive animal in Antwerp, Belgium. This tree was derived by neighbor-joining analysis of partial *env*/*nef* nucleotide sequences. Horizontal branch lengths are drawn to scale.

south-central Cameroon clustered with the nonpandemic HIV-1 group N. It is also interesting to note that there is an uneven dissemination of SIV infection among chimpanzee populations, with the absence of SIV infection in some of them and with major geographical elements, like rivers, that can serve as important barriers.

As discussed above, HIV-1 group N resulted from an ancestral recombination event between divergent lineages. The discovery of such a recombinant virus in a geographically isolated chimpanzee community in southern Cameroon shows that HIV-1 N was already a recombinant in its natural hosts prior to its transmission to humans.

The origin of the third group of HIV-1, group O, remained uncertain until the recent identification of HIV-1 group O-like viruses in two different wild-living gorilla populations, in southern Cameroon (SIVgor). So all three HIV-1 groups seem to have their seeds in West-Central Africa. While HIV-1 group O infections remained restricted to West-Central Africa (Cameroon, Nigeria, Gabon, Equatorial Guinea) and HIV-1 N to Cameroon only, HIV-1 group M strains have spread across Africa and all the other continents.

HIV-2

A close phylogenetic relatedness is also observed between SIVsmm from sooty mangabeys (*Cercocebus atys*) and HIV-2 in West Africa. Sooty mangabeys are indigenous to West Africa, from Senegal to Ivory Coast, coinciding with the endemic center of HIV-2 (**Figure 3**). Eight groups (A–H) of HIV-2 have been described so far, but only subtypes A and B are largely represented in the HIV-2 epidemic, with subtype A in the western part of West Africa (Senegal, Guinea-Bissau) and subtype B being predominant in Ivory Coast. The other subtypes have been documented in one or few individuals only. Except for groups G and H, groups C, D, E, and F were isolated in rural areas in Sierra Leone and Liberia and these viruses are more closely related to the SIVsmm strains obtained from sooty mangabeys found in the same area than to any other HIV-2 strains. This suggests that the

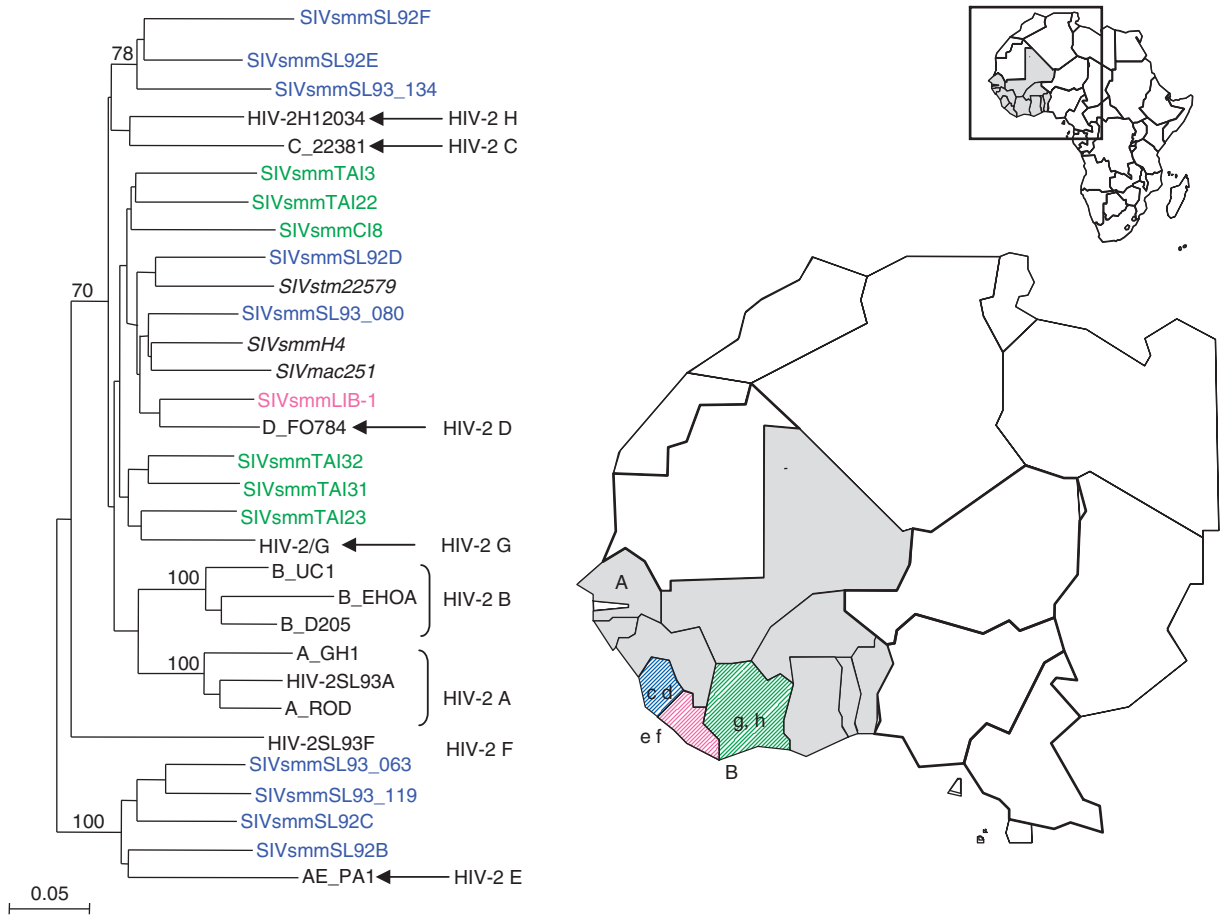

Figure 3 Geographic distribution of the different HIV-2 groups and phylogeny of the HIV-2/SIVsmm lineage. Countries where HIV-2 is endemic are colored in grey and overlap with the range of sooty mangabeys (*Cercocebus atys*) in West Africa. SIVsmm strains obtained from mangabeys in different regions are colored: green for Ivory Coast, blue for Sierra Leone, and pink for Liberia. SIVsmm strains isolated from mangabeys or macaques in US zoo's or primate centers are indicated in italic. This tree was derived by neighbor-joining analysis of partial *gag* nucleotide sequences from HIV-2 and SIVsmm sequences from West Africa. Horizontal branch lengths are drawn to scale.

different groups of HIV-2 must be the result of multiple independent cross-species transmissions of SIVsmm into the human population. Importantly, HIV-2 prevalence remains low and is even decreasing, since HIV-1 M is now predominating also in West Africa.

When?

It is clear now that each group of HIV-1 (M, N, and O) and HIV-2 (A–H) resulted from an independent cross-species transmission, followed by different viral evolution rates and possibly by one or more recombination events. HIV-1 group M can be further subdivided into subtypes, circulating recombinant forms and many unique recombinants, which had a heterogeneous geographical spread. The highest genetic diversity, in number of co-circulating subtypes and intrasubtype diversity has been observed in Central Africa, more precisely the western part of DRC, suggesting this region being the epicenter of HIV-1 M. Moreover, the earliest known HIV-1 virus, ZR59, isolated from an individual in Léopoldville (now Kinshasa) in 1959. The virus has been characterized as a member of HIV-1 M, subtype D. So, the common ancestor of this group should be dated prior to 1959. Molecular clock analyses estimated the date of the most recent common ancestor of HIV-1 group M around 1930 with a confidence interval of 1915–1941. A similar time frame is estimated for the origin of the HIV-1 group O radiation: 1920 with a range from 1931 to 1940. The oldest HIV-1 group O sample has been documented in a Norwegian sailor in 1964 infected in Cameroon (Douala), both groups show an exponential increase of the number of HIV infections during the twentieth century. However, the growth rate of HIV-1 group O ($r = 0.08$ [0.05–0.12]) is slower than the rate estimated for HIV-1 group M in Central Africa ($r = 0.17$). This is not surprising, considering the much lower prevalence of group O in Cameroon. Since the first identification of HIV-1 group N in 1998, about 10 group N infections have been described and all were from Cameroonian patients. The intra-group genetic diversity is significant lower for group N than for group M or O, which suggests a more recent introduction of the HIV-1 N lineage into the human population.

Similar analyses traced the origin of the pandemic HIV-2 groups A and B to be around 1940 with a confidence interval of ± 16 years, and around 1945 with a confidence interval of 1931–59, respectively.

How?

Although the precise conditions and circumstances of the SIVcpz and SIVsmm transmissions remain unknown, human exposure to blood or other secretions of infected primates, through hunting and butchering of primate bushmeat, represents the most plausible source for human infection. Also bites and other injuries caused by primates kept as pets can increase the probability of viral transmission. Direct evidence of human infection with other SIVs is not yet reported, but that retroviruses can jump from primates to humans has been documented for simian foamy viruses (SFV) and simian T-cell leukemia viruses (STLVs). For example, SFV infection has been detected in rural Central Africa among individuals who hunt monkeys and apes. The infection with SFV in an Asian man, who regularly visited an ancient temple, was most probably the result of a bite from a macaque. An analysis of the man's blood indicated the presence of an SFV strain similar to a strain from macaques living around the temple. So far, SFV has not been shown to cause disease in humans, but the long-term effects of SFV in humans are not yet known. These effects are well documented for SIV and its human counterpart HIV; the HIV-1 group M epidemic clearly illustrates the devastating results of a single cross-species transmission.

Other SIV Cross-Species Transmissions, Risk for Novel HIV?

A recent study on primate bushmeat in Cameroon revealed that about 10% is SIV infected and illustrates an ongoing exposure to a plethora of different SIVs. Today, 69 different nonhuman primate species are identified in Africa and for 32 species (47%) SIV infection could already be proved by genomic amplification of the virus. This means that, in addition to sooty mangabeys, chimpanzees, and possibly gorillas, at least 29 other primate species harbor SIV's, which poses a potential risk for transmission to humans, especially for those in direct contact with infected blood and tissues. Therefore, efforts to reduce exposure to SIV-infected primates should be a primary concern. However, the opposite is occuring; the bushmeat trade has increased significantly during the last few decades, especially through the development of the logging industry. As a consequence, roads are now penetrating the formerly isolated forest areas and create a free passage for transport of wood, bushmeat, people, and subsequently different pathogens. The surrounding villages change from modest, little communities to real trade centers, with up to several thousand inhabitants. In addition, human migration and social and economic networks support this industry. It is very likely that the estimated prevalence of SIV infection of wild monkey species is underestimated for three reasons: first, only half of the recognized species have been tested; second, for some species only a few monkeys were tested; and third, and the most important reason, the sensitivity of the available diagnostic tools, initially developed for HIV detection, may be inaccurate for the detection of divergent SIVs. The increasing magnitude of human exposure to SIVs, combined with socioeconomic changes, which

favor the dissemination of a plausible SIV transmission into the human population, could be the basis of novel zoonoses that lead in turn to novel HIV epidemics.

It is important to note that there is more needed than transmission of a virus to initiate an epidemic. After the virus has crossed the species barrier, adaptation to the new host is necessary to be able to spread efficiently within a population. The pathogenic potential of the virus and host genetic differences between individuals, as well as between species, determine susceptibility or resistance to further disease progression. In addition, environmental, social, and demographic factors play a major role in the further spread of new viruses.

Evolution of SIVs in their Natural Primate Hosts: The Origin of SIVcpz

With the increasing number of full-length SIV sequences from different primate species it becomes clear that cross-species transmissions and subsequent recombinations have occurred frequently among primates lentiviruses. Cross-species transmissions among co-habiting species in the wild has been observed between African green monkeys and patas monkeys in West Africa; between African green monkeys and baboons in southern Africa; and between different *Cercopithecus* species in Central Africa, that is, greater spot-nosed guenons (*C. nictitans*) and moustached (*C. cephus*) monkeys in Cameroon.

One of the most striking examples of cross-species transmission, followed by recombination, is SIVcpz in chimpanzees. Chimpanzees are known to hunt other primates for food, such as red-capped mangabeys (*Cercocebus torquatus*), greater spot-nosed guenons (*Cercopithecus nictitans*), and colobus monkeys (*Colobinae*). The isolation and characterization of the SIV genomes from the former monkey species revealed an unexpected high level of similarity between some parts of the SIVcpz genome and SIVrcm and SIVgsn. The 5′ region of SIVcpz (*gag*, *pol*, *vif,* and *vpr*) is most similar to SIVrcm, except for the accessory gene *vpx*, which is characteristic for the SIVrcm lineage, but absent in the HIV-1 and SIVcpz strains. The 3′ region of SIVcpz (*vpu*, *env,* and *nef*) is closely related to SIVgsn. Furthermore, SIVgsn is the first reported monkey virus to encode a *vpu* gene, the accessory gene characteristic of the HIV-1/SIVcpz lineage. Most probably, the recombination of these monkey viruses occurred within chimpanzees and gave rise to the common ancestor of today's SIVcpz lineages, which in turn were subsequently transmitted to humans. The cross-species transmission of this recombinant virus, or its progenitors, happened some time after the split of *P. t. verus* and *P. t. vellerosus* from the other subspecies, but possibly before the divergence between *P. t. troglodytes* and *P. t. schweinfurtii.*

The fact that gorillas are infected with an SIV from the SIVcpz lineage, represents a mystery, since only peaceful encounters have been documented among these sympatric apes. The evolutionary history of primate lentiviruses is complex and likely involved a series of consecutive interspecies transmissions, the timelines and directions of which remain to be deciphered.

Conclusion

We now have a clear picture of the origin of HIV and the seeds of the AIDS pandemic. SIVcpz, the progenitor of HIV-1, resulted from a recombination among ancestors of SIV lineages presently infecting red-capped mangabeys and *Cercopithecus* monkeys in West-Central Africa. HIV-1 groups M and O resulted from independent cross-species transmissions early in the twentieth century. The SIVcpz*Ptt* strains that gave rise to HIV-1 group M belonged to a viral lineage that persists today in *P. t. troglodytes* apes in south Cameroon. Most likely this virus was transmitted locally, but made its way to Kinshasa where the group M pandemic was spawned. HIV-1 group N, which has been identified in only a small number of AIDS patients from Cameroon, derived from a second SIVcpz*Ptt* lineage in south-central Cameroon and remained geographically more restricted. HIV-1 group O-related viruses are present in a second African great ape species, the western gorilla (*Gorilla gorilla*), but chimpanzees were the original reservoir of SIVgor.

Similarly, only HIV-2 group A and B play a major role in the HIV-2 epidemic, and most other groups (C–H) represent unique sequences found in a single patient. A possible explanation could be that some viruses were not able to adapt to the new host or that the environment was not suitable for epidemic spread.

Viral adaptation to the new host is one of the requirements for the generation of an epidemic, but also the interaction of sociocultural factors, such as deforestation, urbanization, and human migration, have been crucial in the emergence of the HIV-1 pandemic. While the origin of the HIV-1 and HIV-2 viruses has become clearer, important questions concerning pathogenicity and epidemic spread of certain SIV variants needs to be further elucidated.

Glossary

Apoptosis Programmed cell death.

Bystander cell death The death of HIV-uninfected cells.

CCR5 A G-protein-coupled, seven transmembrane spanning receptor for the chemokines RANTES (CCL5), MIP-1α (CCL3), and MIP-1β (CCL4) that is primarily expressed on T lymphocytes, dendritic cells, macrophages, and microglial cells.

CD4+ T lymphocytes (also called T-helper cells) Cells bearing CD4, a co-receptor of the T-cell receptor (TCR) complex, that recognize peptide antigens bound to MHC class II molecules and are important for both humoral and cellular immunity.

Cytotoxic T lymphocytes (CTLs) Cells that are capable of killing other cells. Most CTLs express CD8, a co-receptor of the TCR complex, and recognize antigenic peptides from cytosolic pathogens, particularly viruses, that are bound to MHC class I molecules.

Generalized immune activation The activation of all lymphocyte subsets in HIV infection, leading to increased cell death.

Mucosal-associated lymphoid tissue (MALT) The system of lymphoid cells found in the epithelia and lamina propria of the body's mucosal sites, including the gastrointestinal tract, lungs, eyes, nose, and the female reproductive tract.

Neutralizing antibodies Antibodies that can limit the infectivity of a pathogen or the toxic effects of a toxin by binding to the receptor-binding site on the pathogen/toxin and thus block entry into the target cell.

Simian immunodeficiency virus (SIV) Like HIV it is a single-stranded, positive-sense, enveloped RNA virus that is classified as a member of the genus *Lentivirus* of the family *Retroviridae*. The virus infecting chimpanzees (SIV_{cpz}) is the origin of HIV-1 and the virus infecting sooty mangabeys (SIV_{smm}) is the origin of HIV-2.

Introduction

The AIDS pandemic, with an estimated 40 million individuals infected with the causative agent, human immunodeficiency virus (HIV), is without question one of the key medical challenges of modern times. Twenty-four years after the first identification of HIV, the situation in the fields of AIDS research, prevention, and treatment reflects several major advances as well as a number of areas where the progress has been slow or nonexistent (**Table 1**). While the #1 challenge (low rate of treatment in developing countries, particularly sub-Saharan Africa) is, in essence, a reflection of the sociopolitical climate arising from a lack of stability, development, and health-care infrastructure in these countries, challenges #2 and #3 (absence of a preventative vaccine or a cure for HIV infection and AIDS) are a direct consequence of our incomplete understanding of the pathogenesis of HIV infection. Here we summarize the key advances that have improved our understanding of the mechanisms underlying the immunodeficiency that follows HIV infection.

While it is clear and universally accepted that HIV is the etiologic agent of AIDS and that the main

Table 1 Major achievements and remaining challenges in AIDS research

Major achievements in AIDS research:
1. Discovery and characterization of the etiologic agent.
2. Development of lab tests to monitor and prevent the infection via blood and blood products.
3. Definition of the origin of the epidemics.
4. Development of a large array of potent anti-HIV drugs, with consequent major reduction in mortality and MTCT in Western countries.

Major remaining challenges:
1. Abysmally low rate of treatment in developing countries.
2. Absence of a vaccine or a long-lasting microbicide.
3. Absence of a treatment that can eradicate infection.
4. Incomplete understanding of the pathogenesis of infection.

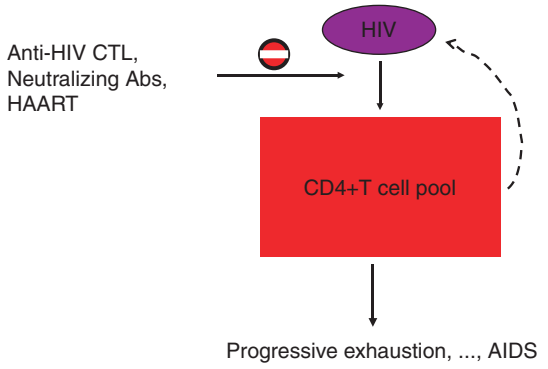

Figure 1 The classical or virus-centric model of AIDS pathogenesis.

pathophysiologic assault during HIV infection is the development of a state of chronic, progressive, and ultimately fatal immunodeficiency, several questions remain regarding the exact sequence and cause of the pathogenic events that define the progression from HIV infection to the development of AIDS. In particular, the precise mechanisms that underlie the progressive and generalized CD4+ T-lymphocyte depletion that represents the most striking and consistent laboratory finding in HIV-infected individuals as well as the best predictor of progression to AIDS are still unclear. While it is well established that HIV infects and kills CD4+ T lymphocytes, it is not known to what extent this direct effect of the virus contributes to the overall *in vivo* loss of these cells when measured against a series of indirect mechanisms of CD4+ T-lymphocyte depletion that are related to the state of generalized immune activation associated with HIV infection. Understanding the mechanisms responsible for the HIV-associated CD4+ T-lymphocyte depletion is a matter of utmost importance, as it is likely that greater knowledge of the immunopathogenesis of AIDS will pave the way for the implementation of novel therapeutic strategies.

Direct Cytopathic Effect of HIV on Infected CD4+ T Lymphocytes

A series of crucial discoveries made between 1983 (when HIV was first identified and proposed as the etiologic agent of AIDS) and 1996 (when highly active antiretroviral therapy, HAART, became available) resulted in a model for the pathogenesis of HIV infection that explains a large number of experimental and clinical findings (**Figure 1**). This model is based primarily on the following observations: (1) after transmission of HIV through either the sexual or intravenous route, the virus infects (using the CD4 molecule as well as one of the chemokine receptors CCR5 or CXCR4 as entry receptors) and then kills a subset of memory/activated CD4+ T lymphocytes; (2) the level of virus replication and the severity of CD4+ T-lymphocyte depletion are the key markers of disease progression from the initial asymptomatic phase of infection (lasting 2–15 years) to the phase characterized by constitutional symptoms and, eventually, the onset of opportunistic infections and cancer; (3) if HIV replication is controlled following the administration of antiviral drugs or spontaneously (in a small subset of HIV-infected individuals referred to as long-term nonprogressors, LTNP), the immunological damage induced by HIV is limited and survival improves dramatically. Collectively, these findings suggested that the pathogenesis of AIDS is mainly related to the direct, virus-mediated killing of CD4+ T lymphocytes that results in a slow but continuous erosion of the pool of these cells (**Figure 1**). This virus-centric model of AIDS pathogenesis was strengthened by the observations that HIV infection is associated with a high rate of virus turnover and a short lifespan of virus-infected cells. These studies were interpreted to mean that, in infected individuals, HIV kills large numbers of CD4+ T lymphocytes at a very fast pace, to the point that the compensatory drive to reconstitute the pool fails to maintain sufficient CD4+ T-lymphocyte numbers. Ultimately, this progressive depletion of CD4+ T lymphocytes results in the permanent loss of a key function of the human immune system, which in turn manifests itself as an increased susceptibility to opportunistic infections and neoplasms. It is important to note that, according to this model, the increased level of CD4+ T-lymphocyte proliferation that is consistently observed in HIV-infected patients is interpreted to be a homeostatic mechanism aimed at compensating for the loss of CD4+ T lymphocytes induced directly by HIV.

Further refinement of this model comes from studies defining the co-receptors used by HIV, in addition to CD4, to infect human cells. The main HIV co-receptor is the chemokine receptor CCR5 (CD195) that is used by the non-syncytium-inducing (NSI), macrophage-tropic

viruses that are preferentially transmitted from person-to-person and represent the majority of strains found in infected patients. CCR5 is expressed in a relatively small fraction (approximately 10–15%) of circulating and lymph node CD4+ T lymphocytes that mainly display a memory phenotype (i.e., CD45RO+), but is present on a much larger fraction of mucosal-associated memory CD4+ T lymphocytes. This latter finding is particularly important as it may explain why CD4+ T lymphocytes may be more severely depleted in mucosal tissues than in peripheral blood and lymph nodes (see below). The second important HIV co-receptor is CXCR4 (CD184), that is used by syncytium-inducing (SI), T-lymphocyte tropic viruses that are found in a minority of HIV-infected individuals, usually during advanced stages of disease. Interestingly, CXCR4 is expressed primarily by naïve CD4+ T lymphocytes, thus potentially accounting for the relative preservation of naïve CD4+ T lymphocytes during the early stages of HIV infection. These data are important not only for their elucidation of potential targets for therapeutic interventions aimed at blocking HIV entry (e.g., CCR5 inhibitors), but also because they help to explain the finding that not all subsets of CD4+ T lymphocytes are equally sensitive to HIV infection, such that depletion of memory/activated CD4+ T lymphocytes is associated with infection with CCR5-tropic viruses, and depletion of naïve CD4+ T lymphocytes is associated with CXCR4-tropic viruses.

Indirect Mechanisms of Immunopathogenesis during HIV Infection

The virus-centric model of HIV/AIDS pathogenesis outlined in the previous section has the unquestionable advantage of being fairly straightforward while still encompassing several important observations. More recently, however, this model, at least in its simplest formulation, has been challenged by a series of new insights into the experimental data. First, the long period of time between virus transmission and the development of AIDS in which the level of CD4+ T lymphocytes appears to be in a quasi-steady state is not compatible with the kinetics of a typical viral infection that should rapidly and exponentially consume all available target cells. The original assumption was that the long duration of the disease process is due to the regenerative capacity of the CD4+ T-lymphocyte compartment that is able to at least partially (or temporarily) compensate for the virus-induced killing of these cells. However, it is now believed that it would be too striking of a coincidence that in the vast majority of patients the rate of killing by HIV happens to be just slightly faster than the rate of production of new CD4+ T lymphocytes (and never slower, in which patients would remain healthy, nor significantly faster, in which patients would die within days to weeks). It was then shown that the fraction of infected CD4+ T lymphocytes was remarkably low (i.e., 0.01–1%) at any given time during the course of infection, thus raising the question of why the immune system cannot simply ramp up the production of new CD4+ T lymphocytes to compensate for the relatively limited losses induced by direct viral infection and killing. The further observations that, in fact, the majority of CD4+ T lymphocytes that die *in vivo* in HIV-infected patients appear to be uninfected (termed bystander cell death) and that, when rates of cell turnover are measured *in vivo* in HIV-infected patients, both CD4+ and CD8+ T lymphocytes show similarly elevated rates of death, together support a pathogenic model, whereby nonviral (or indirect) factors are primarily responsible for HIV disease progression. It is important to note that the increased rate of death of uninfected CD4+ T lymphocytes clearly indicates that direct killing by HIV cannot be the only mechanism involved in the depletion of CD4+ T lymphocytes seen in HIV-infected patients.

Taken together, the above-mentioned observations suggest that the pathogenesis of the HIV-associated CD4+ T lymphocyte depletion is a complex phenomenon and that the host response to the virus must play a key role. In particular, it has been proposed that the presence of a chronic generalized immune activation that involves all lymphocyte subsets is an important driving force in the loss of CD4+ T lymphocytes that is associated with progression to AIDS. This concept of HIV infection having a general effect on the host immune system is confirmed by the fact that a large number of functional abnormalities involving virtually all other immune cell types are associated with HIV disease progression. Importantly, several clinical studies have shown that, in HIV-infected patients, disease progression correlates better with markers of immune activation than with viral load. In this perspective, the observation of the short *in vivo* lifespan of HIV-infected CD4+ T lymphocytes has been re-interpreted as the result of their heightened state of activation that dooms them to die (via activation-induced apoptosis) rather than as a consequence of direct infection. As such, the impact of HIV infection on the lifespan of infected CD4+ T lymphocytes may be less dramatic than was originally proposed and it has now been hypothesized that HIV, in essence, jumps from one activated cell (that is destined to die of apoptosis) to another without changing the fate of these infected cells. It could thus be conceived that the number of available activated CD4+ T lymphocytes dictates, independently, both the level of virus replication and the overall rate of CD4+ T lymphocyte death, and that these two factors are correlated with one another only because they reflect the prevailing level of immune activation.

Further key support for the immune activation hypothesis derives from studies of the nonpathogenic

simian immunodeficiency virus (SIV) infections of natural hosts, such as sooty mangabeys (*Cercocebus atys*, SMs), African green monkeys (AGMs), mandrills, and numerous other nonhuman primate species. These natural SIV hosts are the origin of the human HIV epidemics through multiple episodes of cross-species transmission, with HIV-1 originating from the chimpanzee (*Pan troglodytes*) SIV_{cpz}, and HIV-2 originating from the SM SIV_{smm}. Naturally SIV-infected SMs are of interest also because SIV_{smm} is the source of the various rhesus macaque (*Macaca mulatta*)-adapted SIV_{mac} viruses (e.g., SIV_{mac239}, SIV_{mac251}) that are commonly used in laboratory studies of AIDS pathogenesis and vaccines. In natural SIV hosts, chronic high levels of virus replication and *in vivo* killing of CD4+ T lymphocytes are not associated with any signs of immunodeficiency in the setting of typically low levels of both immune activation and cellular immune responses to the virus. This phenotype suggests that natural SIV hosts have evolved to be disease-resistant without the acquisition of any special ability to control virus replication (via either immune or other mechanisms), but rather by an adaptation that attenuates the immune response to this retroviral infection (**Table 2**).

Interestingly, some recent findings may help to harmonize the classical (i.e., virus-centric) and immune activation models in that they support a more comprehensive model whereby the pathogenesis of HIV/AIDS involves both direct and indirect mechanisms (**Figure 2**). There are now thought to be two sequentially distinct phases in infection that involve very different pathogenic mechanisms. The first phase (acute infection) is characterized by a rapid, massive, directly HIV-mediated loss of memory CD4+ T lymphocytes that takes place mainly in mucosal tissues and may leave a profound scar on the overall function of the immune system. It is still unclear what determines the cessation of this brief early phase, although likely explanations include the consumption of available target cells and the generation of HIV-specific immune responses. The second phase (chronic infection) lasts typically for several years, and is characterized, in essence, by the immune system's struggle to both recover from the early injury (via activation of mechanisms of immune homeostasis) and control virus replication (via activation of humoral and cellular immune responses). Unfortunately, this latter endeavor proves almost always to be insurmountable as HIV is a pathogen of extraordinary genetic and structural plasticity allowing it to develop a series of highly effective strategies for immune evasion. The struggle of the second phase is characterized by the continuous generation of strong, though ultimately ineffective, immune responses to HIV, and by the attempt to maintain T-lymphocyte homeostasis in the face of massive T-lymphocyte loss due to both the direct effect of the HIV and bystander cell death. Sadly, this epic battle seems to end up inducing nothing but the very state of chronic immune activation that, as mentioned above, ultimately causes more damage than repair to the host immune system.

Table 2 Immunologic and virologic features of natural, nonpathogenic SIV infections vs. pathogenic HIV infection

	Natural SIVs	*HIV*
Chronic virus replication	Yes	Yes
Lack of immune control	Yes	Yes
Short lifespan of infected CD4+ T cells	Yes	Yes
Depletion of MALT CD4+ T cells	Yes	Yes
Systemic loss of CD4+ T cells	Rare	Yes
Generalized immune activation	No	Yes
Expression of CCR5 on CD4+ T cells	Low	High

Determinants of HIV Transmission and Early Replication

A clearer understanding of the host and viral factors determining the likelihood of virus transmission upon exposure and/or the course of infection after transmission will likely provide useful information for the design of new strategies to prevent HIV infection and AIDS. However, while some host factors regulating the risk of infection and disease progression have been identified, predicting the natural course of the infection remains very difficult at the level of the individual patient. Among the host genetic factors that have been shown to induce resistance to HIV infection, a predominant role has been ascribed to the 32 bp deletion in the CCR5 gene seen in 1% of Caucasian individuals. This deletion results in a frameshift mutation that causes the CCR5 protein to be completely absent from the surface of all cells. Thus, individuals homozygous for the Δ32 allele are resistant to transmission of CCR5-tropic viral strains (the overwhelming majority of viruses involved in horizontal sexual transmission). Other genes whose polymorphisms have been associated with some effect on HIV disease progression include SDF-1, CX3CR-1, CCL3, and many others. The clinical consequence of these discoveries is that small molecule antagonists or a monoclonal antibody directed against CCR5 are increasingly recognized as promising strategies to prevent HIV transmission.

The search for host factors associated with more effective immune responses to HIV (and, in fact, the identification of any type of correlate of immune protection) has proved much more frustrating. As of early 2007, it is still unclear whether and to what extent the immune response to HIV is capable of inducing absolute (i.e., by preventing infection) or relative (i.e., by lowering virus replication) resistance to virus transmission and early dissemination. While stronger and/or broader T-lymphocyte responses to the virus have been associated with better course of disease, it is still unclear whether this apparently more

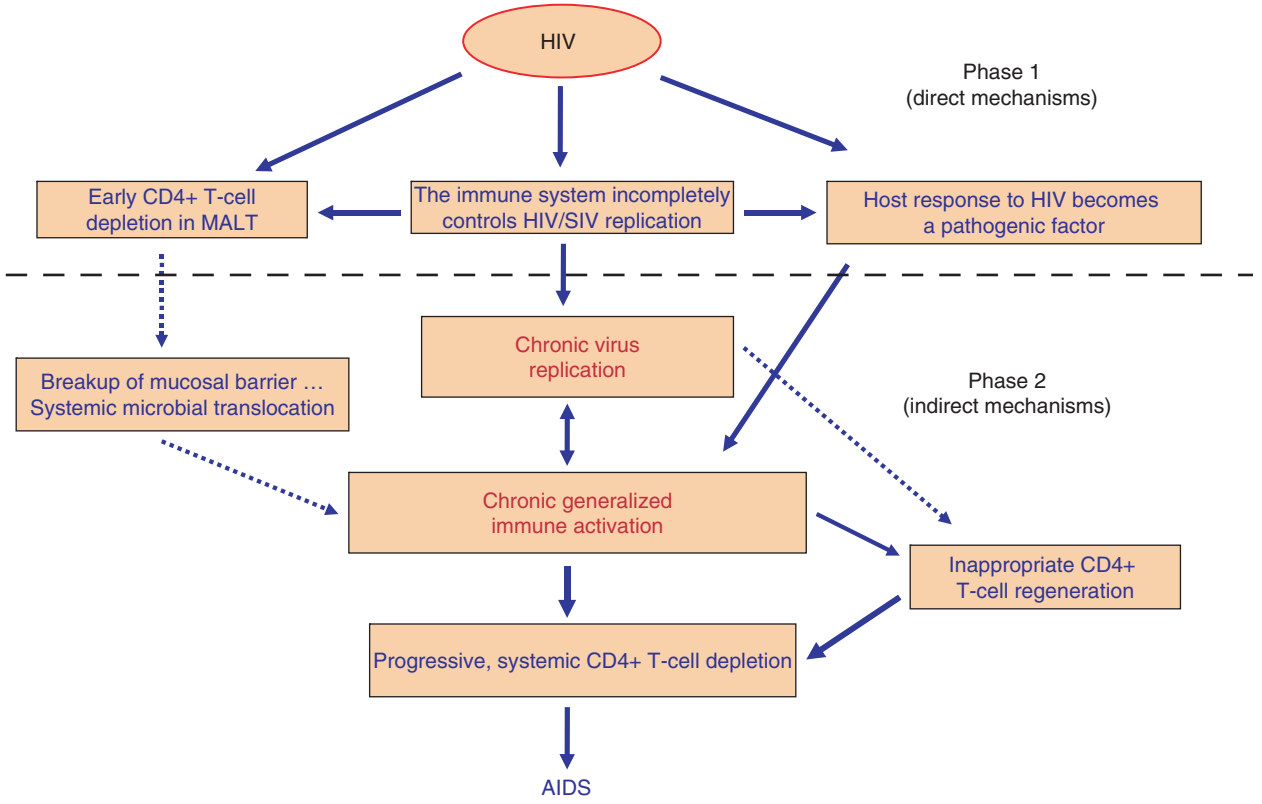

Figure 2 The biphasic model of AIDS pathogenesis. This model summarizes the key immunopathogenic events in acute and chronic infection that lead to progression to AIDS in HIV-infected individuals, taking into account both direct (virus-mediated) and indirect (immune activation-mediated) mechanisms.

effective immune response is cause or consequence of a more benign course of infection. Furthermore, the observation that natural SIV hosts, who are resistant to AIDS, show a low-level T-lymphocyte response to the virus and, more generally, an attenuated immune system activation clearly indicates that a strong host antiviral immune response is not necessary to lessen disease. While more studies are needed to fully elucidate the mechanisms underlying the lack of disease progression in natural SIV hosts, one clear message thus far is that co-evolution of SIV and its natural hosts have resulted in a happy equilibrium whereby the host immune function is preserved without any significant immune-mediated control of virus replication (**Table 2**).

Some recent advances in understanding what factors influence HIV-1 transmission come from recent studies of heterosexual transmission in Africa. One such study showed that the viruses that establish new infections encode an envelope surface glycoprotein (gp120) with a compact structure and reduced glycosylation that appears to be significantly more sensitive to antibody neutralization. To this end, it should be noted that the vast majority of gp120s isolated from patients with chronic HIV infection are resistant to neutralization by autologous sera. The implication of these findings for HIV vaccine development is significant, as they reveal a relative vulnerability of the HIV-Env glycoprotein in the very early phase of HIV infection. Also interesting is the finding that, in a cohort of discordant heterosexual partners (i.e., one HIV-infected and one HIV-uninfected) in Zambia, the sharing of HLA-B alleles is associated with a significant enhancement in the rate of transmission. This observation suggests that the foreign HLA molecules on virus-infected cells or the virus itself (acquired from the cell membrane) trigger protection against infection with a mechanism analogous to allogeneic transplant rejection; alternatively, transmission of viruses that have already escaped the cytotoxic T-lymphocyte (CTL) response may make infection more efficient in individuals with shared HLA alleles. While these reports shed some light on what type of adaptive immune response may control the spread of HIV infection, it is obvious that the virus appears to rapidly win the battle with the host immune system in the overwhelming majority of infected individuals.

When HIV first enters the body (most commonly via mucosal transmission but in certain instances through the bloodstream), the type and magnitude of the subsequent antiviral immune response is largely determined by immature dendritic cells (DCs), a cell type that is a component of the innate defense against mucosal penetration and

widespread dissemination of many pathogens. Importantly, the role of DCs in the early events of HIV infection is complex and not always beneficial (**Figure 3**). On the one hand, DCs take up HIV-1 via C-type lectin binding receptors and migrate to the draining lymph node where they prime HIV-specific immune responses by presenting HIV antigens to CD4+ T lymphocytes. On the other hand, DCs may also contribute to early HIV dissemination throughout the body, due to their migratory potential and the fact that the DC–CD4+ T lymphocyte contact often results in productive infection of CD4+ T lymphocytes. While manipulation of the DC–T lymphocyte interaction may conceivably improve the host immune response to HIV, our limited understanding of the molecular mechanisms responsible for this interaction hampers the design of simple interventions aimed at blocking the early dissemination of HIV infection.

The Acute/Early Phase of HIV Infection

The acute phase of HIV infection is characterized by a peak of virus replication that occurs coincident with a transient decline of circulating CD4+ T lymphocytes and the presence of a flu-like clinical syndrome. This acute infection lasts for approximately 2–3 weeks and ends at approximately the time of antibody seroconversion. Some recent elegant studies have highlighted the role of the mucosal-associated lymphoid tissue (MALT) in acute HIV infection. The MALT houses the majority of CD4+ T lymphocytes in the body, a large fraction of which express CCR5 and have an activated memory phenotype. A key feature of the early phases of HIV and SIV infections is the massive infection and depletion of MALT-associated CD4+CCR5+ memory T lymphocytes (**Figure 2**). HIV replication in activated CD4+CCR5+ memory T lymphocytes proceeds relatively unchecked for 2–3 weeks after transmission, resulting in large-scale depletion of these cells. During early pathogenic SIV infection of Asian macaques (i.e., non-natural hosts), up to 60% of memory CD4+ T lymphocytes in the intestinal lamina propria contain SIV-RNA at the peak of infection (day 10) and the majority of these cells are eliminated by day 14. Importantly, though, the best predictor of rapid disease progression may not be the extent of the early CD4+ T lymphocyte depletion from mucosal sites, but rather the ability to reconstitute the pool of memory CD4+ T lymphocytes in the MALT. MALT-associated memory CD4+ T lymphocytes are an integral component of the mucosal immunological barrier against invading pathogens,

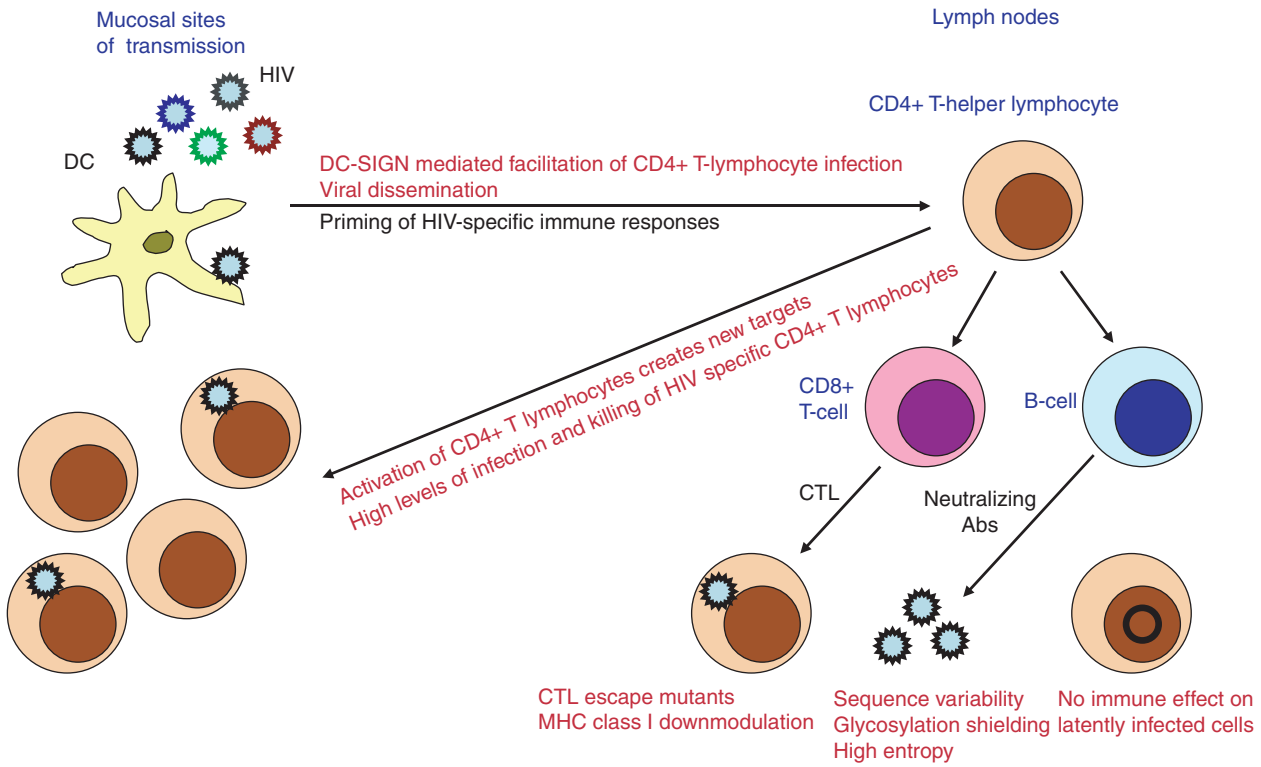

Figure 3 HIV transmission and generation of HIV-specific immune responses. HIV entry at mucosal sites is followed by capture by DCs that subsequently migrate to lymph nodes to present HIV antigens to CD4+ T-helper lymphocytes. In this process, DCs may also facilitate the infection of activated CD4+ T lymphocytes. CD4+ T lymphocytes help CD8+ T lymphocytes and B cells in mounting cellular and humoral anti-HIV immune responses. Legend in black indicates events of the HIV-specific immune response; legend in red indicates events leading to HIV immune evasion and dissemination.

and it is likely that their massive (and potentially irreversible) depletion may significantly affect the proper function of the mucosal barrier. This setting then allows for the emergence of numerous subclinical infections, thus inducing further microenvironment destruction and contributing to a state of chronic immune system activation (**Figure 2**). It should be noted, however, that to date the specific consequences of the early depletion of MALT-associated memory CD4+ T lymphocytes remain unknown, and it is still unclear why the opportunistic infections that are typical of full-blown AIDS do not appear until peripheral blood CD4+ T lymphocyte counts decline. Particularly puzzling is the observation that a rapid, severe, and persistent depletion of mucosal CD4+ T lymphocytes also occurs during nonpathogenic SIV infection of natural hosts such as SMs and AGMs (**Table 2**). However, in the context of the typically low levels of systemic and mucosal immune activation found in these species, no signs of mucosal immune dysfunction are observed, further emphasizing the potential protective role of an attenuated immune response during retroviral infection. Alternatively, it is possible that the early and rapid depletion of mucosal CD4+ T lymphocytes observed in pathogenic HIV/SIV infections simply reflects the systemic virus dissemination that is necessary to establish a chronically productive infection.

Generation of HIV-Specific Immune Responses and the Acute-to-Chronic Phase Transition

As mentioned above, the determinants of the relatively abrupt cessation of the early phase of HIV infection and the onset of the long chronic phase that occur at 2–3 weeks post infection are still poorly understood. However, several investigators have put forward the hypothesis that HIV-specific CTL responses as well as humoral responses directed against the virus envelope protein (i.e., neutralizing antibodies) play a central role in reducing the level of virus replication from its peak to set-point level. The evidence in favor of a significant role of CD8+ CTL-mediated responses reducing HIV replication include: (1) the temporal association between decline of viremia and emergence of cellular immune responses during primary HIV/SIV infection; (2) the increase in virus replication after experimental depletion of CD8+ T lymphocytes during pathogenic SIV infection of rhesus macaques; and (3) the observation that CTL escape mutations present in viruses transmitted between individuals with different HLA haplotypes are rapidly replaced by wild-type sequences. While CD8+ CTL-mediated responses play a significant role early on in protecting from unchecked HIV-1 replication and disease progression, their impact is ultimately limited by the extreme genetic variability of HIV that favors the emergence, during both acute and chronic infection, of viral escape mutants (**Figure 3**). The fact that HIV preferentially infects and kills HIV-specific memory CD4+ T lymphocytes (that are more likely to be activated, **Figure 3**) over memory T lymphocytes specific for other pathogens further complicates the situation, and results in a functional deficit in the anti-HIV response as compared to that directed against other pathogens. What must now be elucidated is whether preexisting, AIDS vaccine-induced HIV-specific CTLs will be more effective in controlling virus replication than those generated during natural infection. HIV-specific autologous neutralizing antibodies also exert potent and continuous selective pressure on the viral quasispecies. Unfortunately, HIV is able to escape antibody-mediated neutralization as efficiently as it does CTL control. A series of recent studies have clarified some of the mechanisms of HIV evasion from the humoral immune response (**Figure 3**). First, the envelope glycoprotein (Env) is highly variable, particularly in specific regions that form the surface of the virus. Second, the outer surface of gp120 is covered with a highly dynamic carbohydrate shield, in which glycans shift through point mutations to mask adjacent and distant epitopes. Third, conserved structural domains of Env are either sterically hindered or only transiently exposed. Fourth, receptor binding of Env is characterized by a high level of intrinsic entropy that makes it a moving target for antibody neutralization. The failure of both HIV-specific CTLs and neutralizing antibodies to completely suppress HIV replication during the transition between acute-to-chronic infection likely sets the stage for the following pathogenic events that are characterized by continuous, generalized immune activation in the face of chronic virus replication (**Figure 2**).

The Chronic Phase of Infection

Chronic HIV infection is a process lasting for several years that is characterized by a very slow decline of CD4+ T lymphocytes in peripheral blood, a small fraction of infected CD4+ T lymphocytes, and increased death rates of both CD4+ and CD8+ T lymphocytes. This last finding is related to the state of chronic, generalized immune activation that is now recognized as a major driving force behind CD4+ T lymphocyte depletion and a strong predictor of disease progression. The causes of the HIV-associated generalized immune activation are complex, and involve activation of T lymphocytes by specific antigens (e.g., HIV and a plethora of opportunistic pathogens), as well as bystander activation of T lymphocytes due to the presence of high levels of lymphotropic cytokines and other as yet poorly defined factors. But how does this increased immune activation induce CD4+ T lymphocyte depletion? First, CD4+ T lymphocyte activation provides new targets for HIV

replication (that occurs preferentially in activated CD4+ T lymphocytes, **Figure 3**), thus creating an environment conducive to further virus-mediated damage to the immune system. Second, the increased T-lymphocyte turnover driven by this chronic immune activation (and, to some extent, by the increased compensatory homeostatic proliferation of T lymphocytes) results in chronic consumption of the pools of naïve and resting-memory cells, with a resultant relative expansion of short-lived effector CD4+ T lymphocytes. Third, the chronic activation and proliferation of T lymphocyte results in perturbations of cell-cycle control and an increased propensity to undergo activation-induced apoptosis. It is also possible that the HIV-associated immune activation is, at least in part, responsible for the changes in the lymph node architecture and thymic function that likely limit the proper reconstitution of the CD4+ T lymphocyte pool. It is hypothesized that depletion is unique to CD4+ T lymphocytes (and involves CD8+ T lymphocytes only in the very late stages of HIV disease) not only because these cells are targeted by HIV, but also because they are more sensitive to the deleterious effects of immune activation and/or are less efficiently regenerated.

Evidently, the assertion that chronic T-lymphocyte activation is a key pathogenic mechanism during HIV infection is in an apparent conflict with data suggesting that cellular immune responses to HIV/SIV infections may limit primary infection and/or disease progression. While T-lymphocyte responses to HIV likely play a protective role early on, T-lymphocyte immunity virtually always fails to control HIV infection due to the emergence of viral escape mutants. Once HIV-specific cellular immune responses are unable to control the virus, other mechanisms may determine the net effect that this ongoing T-lymphocyte activation has on the course of disease.

Is it possible that there is a direct connection between the early damage that HIV causes to the MALT-based pool of memory CD4+ T lymphocytes and the generation of the HIV-associated generalized immune activation? It is known that MALT-associated memory CD4+ T lymphocytes are an integral component of the mucosal immunological barrier that protects the host from both invading pathogens as well as commensal enteric bacteria that may also be recognized as pathogens if they cross the intestinal epithelium. It is likely that a massive depletion of these cells may affect the proper function of this mucosal barrier and thus may open the door to a series of subclinical infections (i.e., micro-invasion of the intestinal mucosa) that will, in turn, induce further micro-environment destruction and contribute to the generation of a state of chronic immune system activation (**Figure 2**). While this model delineates an interesting mechanistic link between direct and indirect (i.e., virus vs. immune activation-mediated) mechanisms of HIV-associated CD4+ T-lymphocyte depletion, the specific consequences of the early depletion of MALT-associated memory CD4+ T lymphocytes are in fact unknown, and it remains unclear why the opportunistic infections that are typical of full-blown AIDS do not manifest until peripheral blood CD4+ T-lymphocyte counts decline.

Implications for HIV Therapy and Vaccine Development

As described above, AIDS pathogenesis likely recognizes two distinct phases, a brief acute phase dominated by the direct killing of large numbers of memory CD4+ T lymphocytes followed by a long chronic phase characterized by a slow attrition of the CD4+ T lymphocyte pool that is related mainly to the prevailing level of immune activation (**Figure 2**). However, many questions remain to be answered. First, a precise quantification of the relative contribution of the direct and indirect mechanisms of AIDS pathogenesis is still lacking. Second, we do not have a clear explanation as to why HIV appears to be so uniquely powerful in inducing a chronic state of immune activation (as opposed to other chronic viral infections), and why the HIV-induced immune activation is so disruptive of the immune system homeostasis. The fact that generalized immune activation follows HIV infection of humans, which is a very recent disease, but does not follow infections that date back many thousands or even millions of years (such as HCV infection of humans or SIV infection of natural hosts), would suggest that attenuation of the immune response to a chronically replicating virus is the result of an advantageous evolutionary adaptation of the host immune system. Unfortunately, the mechanisms underlying the ability of natural hosts for SIV infection to avoid the chronic immune activation seen in HIV-infected humans are still poorly understood.

This biphasic model of AIDS pathogenesis provides a few important implications for HIV therapy and vaccine design. In terms of therapy, an important observation is that a complete recovery of the mucosal CD4+ T-lymphocyte system is unlikely with the currently available antiretroviral drugs even in the presence of prolonged viral suppression. As such, additional immune-based interventions, in particular using CD4+ T-lymphocyte tropic cytokines (e.g., IL-2, IL-7) as well as factors promoting the CD4+ T-lymphocyte repopulation of the MALT, may be useful to improve the immune system recovery from the severe and persistent damages inflicted during the early phase of the infection. In addition, given the well-recognized pathogenic role of the generalized immune activation during the chronic infection, it is conceivable that, in many HIV-infected patients, immune-based interventions aimed at reducing immune activation, preserving proper cell-cycle control, and preventing excessive levels of bystander cell death may restore the overall CD4+ T-lymphocyte homeostasis.

Among these potentially interesting new interventions are those that interfere directly with the signaling pathways involved in establishing the generalized immune activation or cell-cycle dysregulation (i.e., toll-like receptors, cytokine receptors, nuclear factor kappa B (NF-κB), cell cycle-dependent kinases) and those that improve the regeneration and/or the differentiation of T lymphocytes (i.e., cytokines and growth factors). Finally, a clearer understanding of the reason(s) why SIV infection is nonpathogenic in natural hosts (and, in particular, how virus replication can proceed in the absence of immune system damage and chronic immune activation) will likely also reveal further immune-based therapies to delay progression of disease.

Advances in the understanding of the early events of HIV transmission, with special emphasis on the immunogenic vulnerabilities of Env and the correlates of immune protection at the mucosal level, may lead to the development of vaccine and microbicide strategies that can limit the acute HIV-induced damage. In terms of vaccine development, the main implication of the accumulated pathogenesis research is that there may be only a short window of opportunity to control this rapidly disseminating virus that produces such extensive damage to the host immune system. This premise is especially disheartening for CTL-based vaccines that, in order to be effective, will have to induce a persistently high level of mucosa-associated, long-lived, HIV-specific memory CD8+ T lymphocytes that can rapidly proliferate and differentiate into effectors in the event of viral infection. Recent findings are more encouraging for a vaccine that aims to induce a high titer of broadly neutralizing antibodies, particularly if one considers that structural bottlenecks seem to be required for the virus to be efficiently transmitted to a new host in certain settings. In addition, it should be noted that even a vaccine that is only partially effective in containing the early viral dissemination (and resultant immune system damage) may end up having a significant impact on shaping the course of disease.

In summary, there have been many advances in the field of HIV immunopathogenesis over the past 24 years, but there is much that remains to be elucidated, particularly at the mechanistic level. It is critical that, with the help of new and highly sophisticated tools of analyses, we endeavor to more fully understand the dynamic interaction between HIV and the host immune system in order to eradicate this disease.

Human Respiratory Syncytial Virus

P L Collins, National Institute of Allergy and Infectious Diseases, Bethesda, MD, USA

Published by Elsevier Ltd.

Glossary

Fractalkine The sole known CX3C cytokine. It is present as a membrane-bound form that is upregulated by inflammation and promotes adhesion of monocytes and lymphocytes and as a secreted form that promotes chemotaxis of monocytes and lymphyocytes.

Furin A subtilisin-like cellular endoprotease present in the exocytic pathway with the consensus cleavage sequence Arg-X-Arg/Lys-Arg↓.

Glycosaminoglycan Long, unbranched, highly negatively charged polysaccharides that consist of repeating disaccharide subunits and are located on the cell surface or in the extracellular matrix.

Humanized antibody Substitution, by recombinant DNA techniques, of the antigen binding sequences of a nonhuman antibody molecule into the backbone of a human antibody molecule.
Mucin A family of large, heavily glycosylated, secreted or transmembrane proteins that form a protective barrier on the respiratory, gastrointestinal, and reproductive tracts.
Polylactosaminoglycan Carbohydrate of unknown function formed in the Golgi apparatus by the addition of a variable number of repeating units of lactosamine (galactose-β-1,4-N-acetylglucosamine-β-1,3) to an N-linked core oligosaccharide.
Rhinorrhea Runny nose.
Ribavirin A nucleoside analog (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide) that has antiviral activity against a number of RNA viruses.
Syncytium A multinucleated cell, formed in the case of human respiratory syncytial virus by fusion of the plasma membrane of an infected cell with those of its neighbors.
Tachykinin A family of biologically active peptides (prototype, substance P) that can be potent vasodilators and can induce smooth muscle contraction directly or indirectly.

History

Human respiratory syncytial virus (HRSV) was first isolated in 1956 from a laboratory chimpanzee with upper respiratory tract disease. Shortly thereafter, an apparently identical virus was recovered from two children ill with pneumonia or croup and was identified as a human virus. HRSV quickly became recognized as the leading viral agent of pediatric respiratory tract disease worldwide. It has also gained recognition as a significant cause of morbidity and mortality in the elderly and severely immunocompromised individuals. Its inefficient growth in cell culture and propensity to easily lose infectivity due to physical instability impede research. HRSV lacks an approved vaccine or clinically effective antiviral therapy, although, as described below, passive immunoprophylaxis is available for infants at high risk for serious HRSV disease.

Classification

HRSV is a member of family *Paramyxoviridae* of order *Mononegavirales*, the nonsegmented negative-strand RNA viruses. *Paramyxoviridae* has two subfamilies: (1) subfamily *Paramyxovirinae* contains five genera whose members include Sendai virus, the human parainfluenza viruses (HPIVs), and mumps and measles viruses among others; and (2) subfamily *Pneumovirinae* contains genus *Metapneumovirus*, which includes avian and human metapneumoviruses, and genus *Pneumovirus*, which includes HRSV, bovine respiratory syncytial virus (BRSV), ovine respiratory syncytial virus (RSV), and pneumonia virus of mice (PVM). **Figure 1**(**a**) compares gene maps of the two genera of *Pneumovirinae* with those of a representative genus (*Respirovirus*) of *Paramyxovirinae*. **Figure 1**(**b**) illustrates the relatedness among members of the two genera of *Pneumovirinae* based on the nucleotide sequence of the N gene. HRSV is most closely related to BRSV. One might speculate that HRSV originally emerged in the past from infection of humans with BRSV-like virus.

Virion Structure and Viral Proteins

HRSV virions consist of spherical particles of 80–350 nm in diameter and filamentous particles that are 60–200 nm in diameter and up to 10 μm in length (**Figure 2**). Filaments appear to be the predominant form produced in cell culture. The virion contains a helical nucleocapsid (diameter 12–15 nm compared to 18 nm for *Paramyxovirinae*) packaged in a lipoprotein envelope acquired from the host cell plasma membrane during budding. The outer surface of the envelope contains a fringe of surface projections or spikes of 11–12 nm. HRSV lacks a hemagglutinin or neuraminidase.

HRSV encodes 11 proteins. Four are associated with the nucleocapsid: the major nucleocapsid protein N (56 kDa), the nucleocapsid phosphoprotein P (33 kDa), the transcription processivity factor M2-1 (22 kDa), and the large L protein (250 kDa). The N protein binds tightly along the entire length of genomic RNA as well as its positive-sense replicative intermediate that is called the antigenome. L is the major polymerase subunit containing the catalytic domains. P is thought to associate with free N and L to maintain them in soluble form for association with the nucleocapsid and probably also participates as a cofactor in RNA synthesis. N, P, and L are the viral proteins that are necessary and sufficient to direct RNA replication. They also direct transcription, but this is poorly processive unless the M2-1 protein is also present.

There are three transmembrane viral glycoproteins that are expressed on the surface of infected cells and are packaged in the virion: the large G glycoprotein (90 kDa), the fusion F glycoprotein (70 kDa), and the small hydrophobic SH protein (7.5–60 kDa, depending on the amount of added carbohydrate). These assemble separately into homo-oligomers that constitute the surface spikes: F assembles into trimers, G assembles into trimers or tetramers, and SH has been detected as a pentamer.

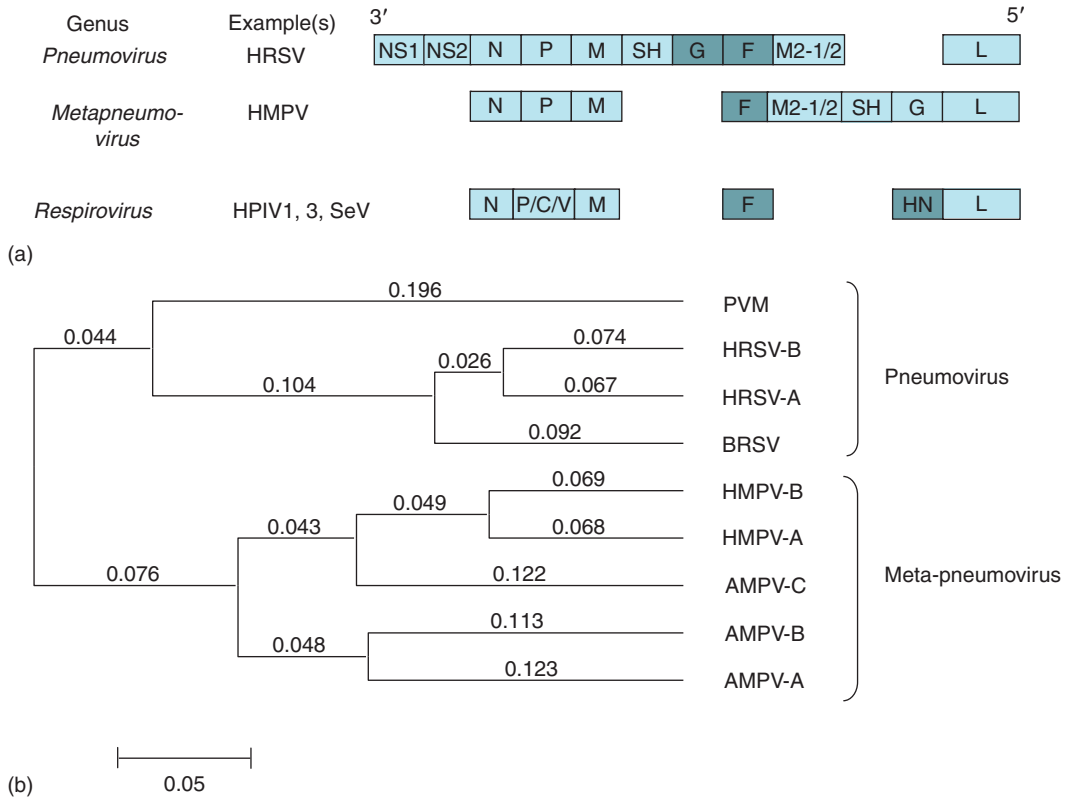

Figure 1 Comparison of human respiratory syncytial virus (HRSV) with other selected members of family *Paramyxoviridae*. (a) Alignment of the gene maps of HRSV, human metapneumovirus (HMPV), human parainfluenza virus (HPIV) types 1 and 3, and Sendai virus (SeV). (b) Relationships among the members of the two genera of subfamily *Pneumovirinae* based on the nucleotide sequence of the N gene. The scale bar represents approximately 5% nucleotide difference between pairs.

The G glycoprotein mediates viral attachment. It is a type II glycoprotein: there is a signal/anchor sequence near the N-terminus, with the C-terminal two-thirds of the molecule oriented extracellularly. G is heavily glycosylated, with several N-linked carbohydrate side chains and an estimated 24–25 O-linked side chains. The unglycosylated protein has an M_r of 32 500 compared to 90 000 for the mature protein. Most of the ectodomain is thought to have an extended, heavily glycosylated, mucin-like structure. In the middle of the ectodomain there is a predicted disulfide-linked tight turn (cystine noose) in the secondary structure. The cystine noose is overlapped on its N-terminal end by a 13-amino-acid conserved sequence of unknown significance and on its C-terminal end by a C–X3–C motif that it is embedded in a region of limited sequence relatedness with the CX3C chemokine fractalkine. A synthetic peptide containing this sequence has fractalkine-like chemotactic activity *in vitro*. The role of this apparent chemokine mimicry in the biology of HRSV is unclear. The tight turn, the conserved domain, and the fractalkine domain can be deleted from recombinant HRSV without significantly reducing its replication efficiency in cell culture or in the respiratory tract of mice. Thus, the region of G that is necessary for attachment has not been identified.

The F glycoprotein mediates cell-surface membrane fusion, which is responsible for delivering the viral nucleocapsid to the cytoplasm. In addition, F expressed at the cell surface mediates fusion of infected cells with their neighbors, resulting in the formation of syncytia. F is a type I glycoprotein, with an N-terminal cleaved signal anchor and a C-proximal membrane anchor. It has four or five N-linked carbohydrate side chains. F is synthesized as a precursor, F_0, which is cleaved intracellularly at two sites (amino acids 109/110 and 136/137) by a furin-like cellular protease. This yields the following fragments, in N- to C-terminal order: F_2 (109 amino acids), p27 (27 amino acids), and F_1 (438 amino acids). F_2 and F_1 remain linked by a disulfide bond and represent the active form of F. In BRSV, the p27 fragment has tachykinin activity and may play a role in promoting inflammation, but p27 of HRSV does not resemble a tachykinin.

The function of the SH glycoprotein is not known. Molecular modeling suggests that it might be an ion-channel-forming protein, although the significance of this to HRSV biology is unclear. SH is anchored in the

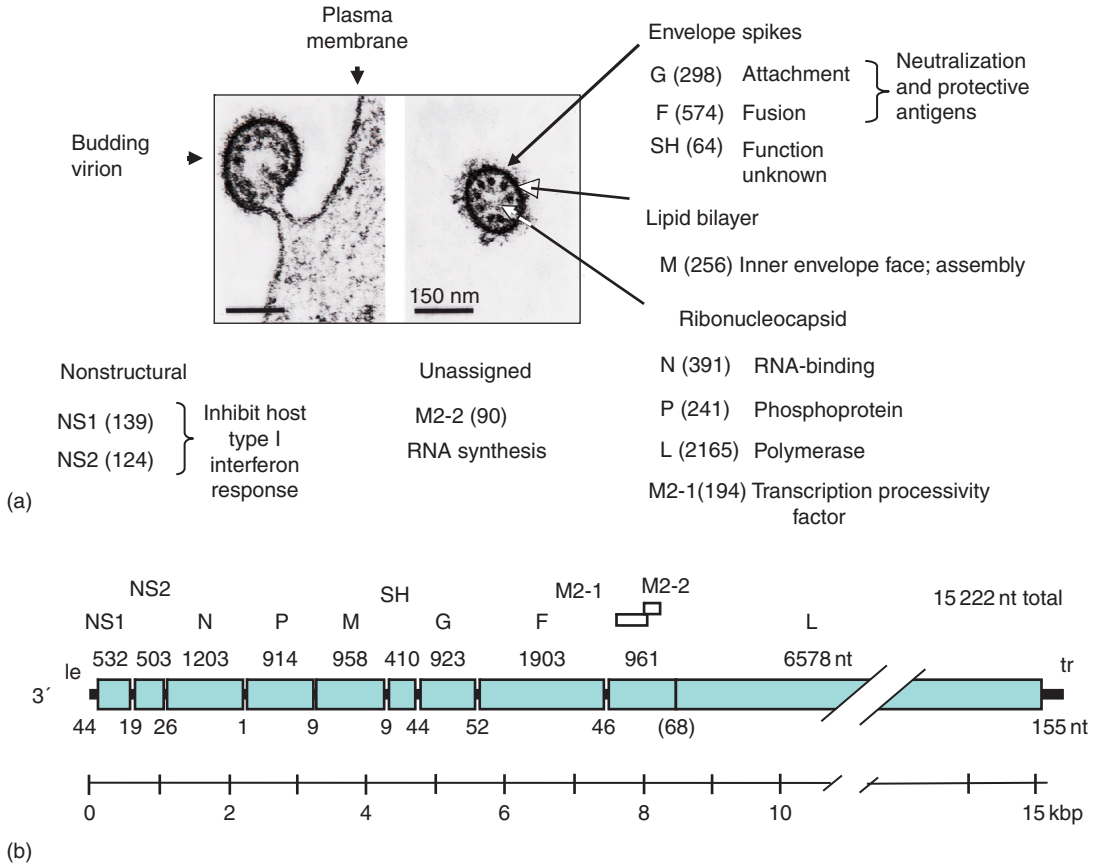

Figure 2 HRSV virion, proteins, and genome. (a) The electron photomicrographs illustrate an RSV virion budding from the plasma membrane of an infected cell (left) and a free virion (right). The viral proteins are indicated, with the amino acid length of the unmodified protein in parentheses. (b) The RNA genome is illustrated 3′ to 5′. Each large rectangle indicates a gene that is transcribed into a separate mRNA, with the gene nucleotide length shown above. The overlapping open reading frames of the M2 gene are indicated. The nucleotide lengths of the extragenic leader (le), intergenic, and trailer (tr) regions are shown underneath. The overlap between the M2 and L genes is indicated by its nucleotide length in parentheses. Nucleotide and amino acid lengths are for strain A2.

membrane by a centrally located signal/anchor sequence, with the N-terminus oriented intracellularly and the C-terminus extracellularly. A portion of SH present intracellularly and in virions is unglycosylated (M_r 7500), a portion has a single N-linked side chain (M_r 13 000–15 000), and a portion has the further modification of polylactosaminoglycan added to the N-linked sugar (M_r 21 000–60 000 or more). This multiplicity of forms is conserved in *Pneumovirinae* but its significance is unknown.

Remarkably, the G and SH genes can be deleted individually or in combination from viable HRSV. Deletion of SH does not reduce the efficiency of replication in cell culture and has only a modest attenuating effect on replication in mice, chimpanzees, or humans (the last observation is based on trials of experimental live vaccines). Deletion of G was attenuating in HEp-2 cells but not Vero cells, and was highly attenuating in mice and humans. Since SH and G are dispensable, at least in cell culture, it is thought that F can function as an alternative attachment protein in that setting.

The nonglycosylated M protein is thought to be located on the inner surface of the envelope and to have a central role in organizing the envelope and directing packaging of the nucleocapsid.

The M2-2 protein is expressed at a low level and its status as structural or nonstructural is unknown. Recombinant HRSV from which the M2-2 coding sequence was deleted replicates more slowly than wild-type HRSV in cell culture and is attenuated *in vivo*. This deletion virus exhibits an increase in transcription and a decrease in RNA replication, suggesting that M2-2 normally is involved in downregulating transcription and upregulating RNA replication.

NS1 and NS2 are small proteins and do not appear to be packaged significantly in the virion. Both proteins inhibit the host interferon response. NS1, and to a lesser extent NS2, inhibit the induction of interferon α/β by blocking activation of interferon regulatory factor 3. In addition, NS2, and to a lesser extent NS1, inhibit interferon α/β-induced signaling through the Janus

kinases/ signal transducers and activators of transcription (JAK/STAT) pathway, thus inhibiting the amplification of the interferon response, the upregulation of interferon-stimulated genes, and the development of the antiviral state. This appears to involve enhanced degradation of STAT2. Deletion of NS1 and NS2 individually or in combination yields viable viruses that replicate almost as efficiently as wild-type HRSV in cells that do not make interferon, but which are attenuated in interferon-competent cultured cells and *in vivo*.

Genome Organization, Transcription, and Replication

The HRSV genome is a single negative-sense strand of RNA that ranges in length from 15 191 to 15 226 nt for the strains that have been sequenced to date (**Figure 2**(**b**)). Its organization, expression, and replication follow the general pattern of *Mononegavirales*. The genome is neither capped nor polyadenylated. It is tightly encapsidated with N protein both in the virion and intracellularly. Based on the prototype A2 strain, the genomic RNA has a 44 nt 3′-extragenic leader at the 3′ end. This is followed in order by the NS1, NS2, N, P, M, SH, G, F, M2, and L genes. The L gene is followed by a 155 nt extragenic trailer region that comprises the 5′ end. The first nine genes are separated by intergenic regions of 1–52 nt. The last gene, L, initiates within the downstream nontranslated region of the M2 gene, and thus these two genes overlap by 68 nt.

In transcription, the viral polymerase initiates at a single promoter at the 3′ end of the genome and copies the genes by a sequential stop–start mechanism that yields subgenomic mRNAs. The upstream and downstream boundaries of each gene contain transcription signals: the upstream end consists of a conserved 10 nt gene-start motif that directs transcriptional initiation, and the downstream end consists of a moderately conserved 12–13 nt gene-end motif that directs termination and polyadenylation. The intergenic regions appear to lack any conserved motifs and seem to be nonspecific spacers. Between genes, the majority of polymerase remains template-bound and scans for the next gene. However, some polymerase dissociates from the template during transcription, yielding a polar gradient such that upstream genes are expressed more efficiently than downstream ones.

The HRSV mRNAs contain a virally synthesized 5′ cap [$m^7G(5')ppp(5')Gp$] and a 3′ polyadenylate tail. The latter is produced by reinterative copying by the viral polymerase on a tract of 4–7 U residues at the downstream end of each gene-end signal. Each mRNA encodes a single major viral protein except for the M2 mRNA, which contains two open reading frames (ORFs) that overlap by approximately 32 nt and encode two distinct proteins, M2-1 and M2-2 (**Figure 2**(**b**)). Expression of the downstream M2-2 ORF appears to be coupled to translation of the upstream M2-1 ORF and presumably involves a ribosomal stop–restart mechanism.

In RNA replication, the viral polymerase initiates in the same promoter region and ignores the gene-start and gene-end signals to make a full-length positive-sense copy called the antigenome. The antigenome is neither capped nor polyadenylated. It is tightly encapsidated with N protein and serves as the template for the synthesis of progeny genomes.

The first 11 nt at the 3′ end of the viral genome are essential for both transcription and RNA replication. The two processes involve overlapping sets of residues. For replication, nucleotides 16–32 are required in addition for encapsidation and the synthesis of complete antigenome. For transcription, nucleotides 36–43 are required in addition for full activity. The first 24 nt at the 3′ end of the antigenome have 81% sequence identity with the 3′ end of the genome, indicative of a conserved promoter element.

Viral Infection in Cell Culture and Experimental Animals

HRSV can infect and produce virus, with varying degrees of efficiency, in a surprisingly wide array of cell lines from various tissues and hosts. Replication is most efficient in epithelial cells, in particular the human HEp-2 line. HRSV that has been propagated *in vitro* generally retains its virulence.

Efficient infection by HRSV of established cell lines *in vitro* involves binding to cellular glycosaminoglycans, in particular heparan sulfate and chondroitin sulfate. Both G and F can mediate this binding. It is not known whether this represents attachment in total or whether it is an initial interaction that is followed by a second, higher-affinity step that remains to be identified. It is also not known how closely this mirrors the attachment process *in vivo*.

All events in HRSV infection occur in the cytoplasm. Viral mRNAs and proteins can be detected intracellularly by 4–6 h post infection. The accumulation of mRNAs has been reported to plateau by 14–18 h. This apparent shut-off of transcription might be due to accumulation of the M2-2 regulatory factor, since it does not appear to occur when the M2-2 coding sequence has been deleted. Apart from this, there is no apparent temporal regulation of gene expression. The release of progeny virus begins by 10–12 h, reaches a peak after 24 h, and continues until the cells deteriorate by 30–48 h. Although most of the infected cells in the culture are killed, persistent infections *in vitro* can readily be established.

In an *in vitro* model of human airway epithelium, HRSV infection was strictly limited to ciliated cells of the apical surface. Remarkably, HRSV infection caused

little gross cytopathic effect despite ongoing infection over several weeks. In particular, infection did not result in the formation of syncytia. The expression of the F protein was polarized to the apical surface, which might have prevented contact with neighboring cells and might explain the lack of syncytia. Thus, HRSV is not inherently a highly cytopathic virus in the absence of syncytia formation, and much of the damage to infected cells that occurs *in vivo* might be a consequence of immune attack rather than direct viral effects. HRSV infection causes a modest reduction in cellular DNA, RNA, and protein synthesis. Apoptosis does not occur until late in infection. The virus buds at the plasma membrane. In polarized cells, this occurs at the apical surface.

HRSV does not replicate to high titer *in vitro*. Most of the virus remains cell associated and is released by freeze–thawing or sonication. HRSV can rapidly lose infectivity during unfrozen storage or freeze–thawing. Stability can be improved by adjusting the harvested culture supernatants to pH 7.5 and 0.1 M magnesium sulfate, or by including 15% w/v sucrose. The yield of virus is relatively low: 10 PFU per cell is typical. Most of the infectious particles produced *in vitro* were trapped by a 0.45 μm filter, suggesting that the infectious unit is in the form of large filaments or aggregates. The instability and size heterogeneity of the virus produced *in vitro* makes purification and concentration difficult.

The most permissive hosts for HRSV are the human and the chimpanzee, and these are the only hosts in which respiratory tract disease can reliably be observed. HRSV can also replicate in the respiratory tract of several species of monkey as well as in hamsters, guinea pigs, infant ferrets, cotton rats, and mice. However, infection in these animals is only semipermissive, particularly in the case of rodents. In the BALB/c mouse, the most commonly used experimental model, intranasal infection with 10^6 PFU yields only 10^6 PFU in lungs harvested at the peak of virus replication 4 days post infection.

Genetics

Like RNA viruses in general, HRSV has a high misincorporation rate (approximately one substitution in 10^4 nt), providing the potential for diversity. RNA recombination involving exchange between viruses appears to be exceedingly rare. Defective interfering particles presumably occur but have not been described molecularly.

Negative-sense RNA is not directly infectious alone. However, as for *Mononegavirales* in general, complete infectious recombinant virus can be produced entirely from cloned cDNAs (reverse genetics). This involves transfecting cells with plasmids that express a complete antigenomic RNA and the proteins of the nucleocapsid, which in the case of HRSV are the N, P, M2-1, and L proteins. These components assemble (inefficiently) into a nucleocapsid that initiates a productive infection. This method can be used to introduce desired changes into infectious virus via the cDNA intermediate.

Another system that has been very useful for basic studies involves helper-dependent mini-replicons. These are short, internally truncated versions of genomic or antigenomic RNA in which the viral genes have been replaced by one or more reporter genes under the control of HRSV transcription signals. When complemented by the appropriate mix of plasmid-encoded HRSV proteins, a mini-replicon can be encapsidated, transcribed, replicated, and packaged into virus-like particles. The small size and simplicity of a mini-replicon makes it ideal for detailed structure–function studies.

Antigens and Antigenic Subgroups

The F and G proteins are the only known HRSV neutralization antigens. They have markedly different antigenic properties. Many of the available F-specific monoclonal antibodies (MAb's) efficiently neutralize HRSV *in vitro*, whereas most of those for G neutralize weakly or not at all. However, polyclonal antibodies specific to G neutralize infectivity efficiently. The high content of O-linked carbohydrate in the G protein may be a factor in its unusual antigenic properties, and indeed the sugars have been shown to be important, directly or indirectly, in the binding of many, but not all, MAb's. The sugar side chains might mask the viral polypeptide. In addition, microheterogeneity might exist in the placement and composition of the side chains, which might alter or mask epitopes. In seropositive humans, most of the HRSV proteins have been shown to stimulate HRSV-specific memory CD8+ T lymphocytes.

HRSV has a single serotype. However, isolates can be segregated into two antigenic subgroups A and B. These exhibit a fourfold difference in cross-neutralization *in vitro* by postinfection sera. Epitopes in F tend to be conserved whereas those for G are not, such that antigenic relatedness between the two subgroups is greater than 50% for the F protein compared to only 5% or less for G. At the amino acid level, F is 89% identical between subgroups while G is the most divergent of the proteins and is only 53% identical, with most of the diversity occurring in the ectodomain. Other proteins range from 76% (SH) to 96% identical (N). Thus, the two antigenic subgroups have substantial differences throughout the genome and represent two divergent lines of evolution, as opposed to differing at only a few antigenic sites.

In a 2 year window following infection, there was a 64% reduction in the incidence of infection by the same subgroup versus a 16% reduction against the heterologous subgroup. In epidemics, typically, there is an alternating

pattern with a 1–2 year interval with regard to the predominant subgroup. These observations indicate that antigenic dimorphism contributes to the ability of HRSV to reinfect, although its effect is modest rather than absolute.

Viral isolates obtained over successive years or decades exhibit some evidence of progressive amino acid changes and some changes in reactivity detectable with MAb's. However, all isolates retained a high level of antigenic relatedness and thus HRSV did not exhibit significant antigenic drift during this time frame.

Epidemiology and Clinical Factors

HRSV is the most important cause of serious viral respiratory tract disease in the pediatric population worldwide. In many areas it outranks all other microbial pathogens as a cause of bronchiolitis and pneumonia in infants less than 1 year of age. HRSV is conservatively estimated to cause 64 million infections and 160 000 deaths annually in the pediatric population. In the United States, HRSV is estimated to account for 73 400–126 300 hospitalizations annually for bronchiolitis and pneumonia in children of under 1 year of age, and is responsible for 90–1900 pediatric deaths annually. Hospitalization rates in developed countries are approximately one in 100–200 infections.

In a 13 year study of infants and children in the United States, HRSV was detected in 43%, 25%, 11%, and 10% of those hospitalized for bronchiolitis, pneumonia, bronchitis, and croup, respectively, and in aggregate accounted for 23% of pediatric hospitalizations for respiratory tract disease as a conservative estimate. Middle ear infection is a common complication. As another complication, approximately 40–50% of infants hospitalized with HRSV bronchiolitis have subsequent episodes of wheezing during childhood. HRSV infection also can exacerbate asthma.

Infection and reinfection with HRSV are frequent during the first years of life. Sixty to seventy percent of infants and children are infected by HRSV during the first year of life. The peak of serious disease is approximately 1–2 months of age (**Figure 3**). By age 2, 90% of children have been infected once with HRSV and 50% have been infected twice. The greatest incidence of serious disease occurs between 6 weeks and 6 months of age. Maternal antibodies account for the relative sparing of newborns. The major risk factors for serious HRSV disease in the pediatric population include chronic lung disease, congenital heart disease, prematurity, and young age (<6 months). While underlying disease is an important risk factor, the majority of infants hospitalized for HRSV disease were previously healthy.

Reinfection of older children and adults is common. For example, hospital staff members on pediatric wards

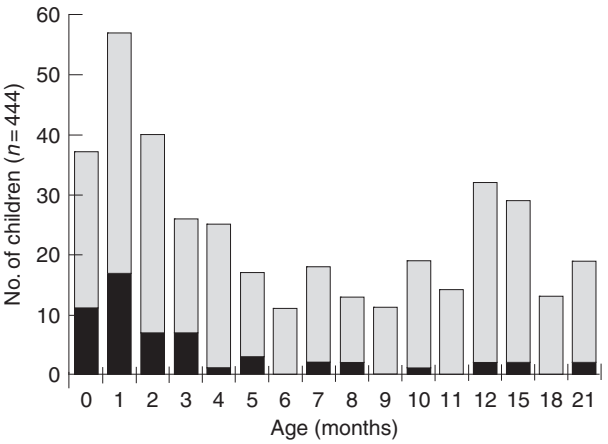

Figure 3 Age at the time of hospitalization for RSV disease at the Johns Hopkins Hospital during 1993–96. The filled bars indicate more severe disease. Adapted from Karron RA, Singleton RJ, Bulkow L, *et al*. (1999). Severe respiratory syncytial virus disease in Alaska native children. *Journal of Infectious Diseases* 180: 41–49.

have an infection rate of 25–50% during HRSV epidemics. Healthy individuals usually suffer only a common cold syndrome. However, HRSV is also an important cause of morbidity and mortality in the elderly, with an impact that is estimated to approach that of nonpandemic influenza virus. HRSV has been estimated to cause 17 000 deaths annually in the elderly in the United States. HRSV infection is also associated with a high mortality rate in children and adults with immunodeficiency or immunosuppression, particularly hematopoietic cell transplant recipients.

HRSV is highly contagious and is readily spread in day-care settings, to family members, in nursing homes, and in the hospital. Spread involves close contact and inoculation of conjunctival or mucosal surfaces by large droplets or by contaminated hands or objects. In experimental infections, HRSV had an incubation period of 4–5 days. Virus typically is shed for 7–12 days coincident with clinical disease, although sometimes shedding is longer and can continue after recovery.

Most primary infections are symptomatic, with upper respiratory tract disease and sometimes a fever. Twenty-five to forty percent of primary infections progress to the lower respiratory tract with the primary manifestations of serious disease being bronchiolitis or pneumonia. There is profuse rhinorrhea, coughing, intermittent fever, expiratory wheezes, and, frequently, middle-ear disease. Seriously ill infants have increased coughing and wheezing, rapid respiration, and hypoxemia, requiring the administration of humidified oxygen.

HRSV causes yearly epidemics that are centered in the winter months in temperate climates (**Figure 4**) or in the rainy season in the tropics, although there can also be local variations to this pattern.

The most definitive diagnosis is by virus isolation in cell culture. Rapid diagnosis can be made by (1) detection of viral antigen using an antigen-capture enzyme-linked immunosorbent assay (ELISA) or by an immunofluorescence analysis of exfoliated cells with HRSV-specific antibody or (2) detection of nucleic acid by reverse transcriptase polymerase chain reaction (RT-PCR). The sensitivity of detection can be over 90%.

Pathogenesis and Immunity

HRSV replicates primarily in the epithelial cells that line the lumen of the respiratory tract. It can also infect macrophages and dendritic cells and modify their functioning. Immunohistochemistry of airway tissues from infected individuals suggests a patchy distribution of infection, with only superficial cells expressing viral antigen. There is destruction of the epithelium and an influx of mononuclear cells, lymphocytes, plasma cells, and macrophages. Tissues become edematous and the secretion of mucus is excessive. Mucus, inflammatory cells, and debris from dead infected cells accumulate in the airways and can cause obstruction, which is a particular problem in infants due to the small diameter of their airways. With pneumonia, the alveolar spaces may fill with fluid and the interalveolar walls may thicken due to mononuclear cell infiltration.

HRSV is an acute infection that typically is completely cleared by host immunity, although sometimes shedding can persist for weeks. Studies in experimental animals and in the clinic indicate that virus-neutralizing secretory IgA antibodies, virus-neutralizing serum antibodies, and cytotoxic CD8+ T lymphocytes participate in resolving infection. These same effectors also confer protection against reinfection. Protection conferred by cytotoxic T lymphocytes appears to diminish within several weeks or months and thus is more important in the short term. Virus-neutralizing secretory IgA antibodies are particularly effective in restricting infection; this response is short-lived following primary infection but can increase in duration following reinfection. Virus-neutralizing serum antibodies provide long-lasting protection. However, they gain access to the respiratory lumen by the inefficient process of transudation, and thus protection is not efficient, particularly in the upper respiratory tract.

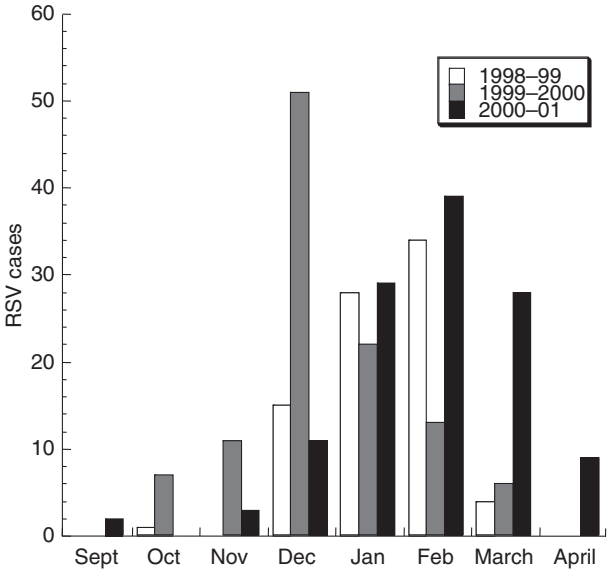

Figure 4 Variation in the timing of the RSV epidemic during three successive years at the Johns Hopkins Hospital. Unpublished data kindly provided by Karron RA, Johns Hopkins School of Hygiene and Public Health and School of Medicine.

Perhaps the most important determinant of HRSV pathogenesis is its ability to infect young infants early in life despite the presence of maternal serum antibodies (**Figure 3**). Why HRSV seems more able than most other respiratory pathogens to evade maternal antibodies and infect very early in life is not understood. The fact that the virus can infect in early infancy when disease is less easily supported and airways are small and more easily obstructed probably accounts for much of its impact.

The immune response during the first months of life is reduced due to immunologic immaturity as well as the immunosuppressive effects of maternal antibodies on humoral responses. This probably contributes to difficulty in controlling the virus and facilitates reinfection early in life. The Th2-biased nature of immune responses in early infancy has also been speculated to contribute to HRSV disease and reduced immune responses. In addition, the tropism of HRSV to the superficial epithelium might reduce its exposure to immune effectors and might also provide reduced immune stimulation.

There is some evidence that HRSV might have suppressive effects on cell-mediated immunity, although the significance and magnitude of these effects are unclear. The cystine noose of the G protein has been shown to inhibit innate immune responses in human monocytes. The inefficiency of virus-neutralizing serum antibodies in controlling HRSV presumably is also a factor in its ability to reinfect throughout life.

Treatment and Immunoprophylaxis

Treatment of severe disease is largely supportive, including mechanical ventilation in the most severe cases. Ribavirin has potent antiviral activity in cell culture and experimental animals, but it has not been clearly beneficial clinically and is not routinely used in most hospitals. Anti-inflammatory therapies have not been beneficial to date

but are still being investigated. Animal studies suggest a benefit of combining antiviral and anti-inflammatory therapies. Bronchodilators are commonly used but have, at most, modest benefits.

Passive immunoprophylaxis is available for infants who are at high risk for serious HRSV disease. This involves monthly intramuscular injections during the HRSV season of an HRSV-neutralizing MAb called palivizumab (Synagis), developed by MedImmune, Inc. This is a humanized version of a mouse MAb specific to the F protein.

A vaccine is not available. A major obstacle to developing a pediatric vaccine is that immunization ideally should start during the first weeks of life. As already noted, immune responses during the first few months of life are reduced due to immunologic immaturity and the immunosuppressive effects of maternal antibodies.

A vaccine consisting of formalin-inactivated, concentrated HRSV (FI-RSV) was evaluated in the 1960s. FI-RSV was found to be poorly protective and, unexpectedly, primed for immune-mediated enhanced HRSV disease that occurred on subsequent natural infection. In subsequent studies, FI-RSV was shown to induce antibodies that bound efficiently to viral antigen but did not efficiently neutralize infectivity. Antigen–antibody complexes might contribute to enhanced disease. In addition, compared to natural infection, FI-RSV caused a disproportionate stimulation of the Th2 subset of CD4+ T lymphocytes, whose role in enhanced disease was confirmed by depletion studies in experimental animals. Disease enhancement appears to be specific to killed or protein subunit HRSV vaccines and might occur because these nonreplicating vaccines do not efficiently stimulate natural killer cells and CD8+ T lymphocytes, which in turn play an important role in regulating the T-helper-cell response via secreted interferon γ. Disease enhancement appears to be an issue only for immunization early in life, and thus protein subunit vaccines appear to be safe in HRSV-experienced individuals.

Because of the phenomenon of vaccine-related disease enhancement, pediatric vaccine development is focused on the development of live-attenuated HRSV strains for intranasal administration. A number of candidate live vaccines developed by reverse genetics are presently in clinical trials. There is also a need for an HRSV vaccine for the elderly. Subunit vaccines are presently being developed for that age group.

Human Respiratory Viruses

J E Crowe Jr., Vanderbilt University Medical Center, Nashville, TN, USA

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Bronchiolitis A disease condition characterized by trapping of air in the lungs with difficulty expiring (i.e., wheezing), caused by inflammation or infection of the bronchioles, the smallest and highest-resistance airways.
Croup A disease condition characterized by a difficulty in inspiration, associated with a barky cough, caused by inflammation or infection of the larynx, trachea, and bronchi.
Lower respiratory tract The anatomical region below the vocal cords, including the trachea, bronchi, bronchioles, and lung.
Pneumonia Infection of the alveolar space of the lungs.

Introduction

Respiratory virus infections of humans are the most common and frequent infections of man. Hundreds of different viruses can be considered respiratory viruses. Viruses that enter through the respiratory tract include viruses that replicate and cause disease that is restricted to the respiratory epithelium, and other viruses that enter through the mucosa but also spread by viremia causing systemic disease. An example of the latter is measles virus. SARS coronavirus is another. In general, viruses that do not cause viremia are capable of reinfecting the same host multiple times throughout life. In contrast, infections with systemic viruses induce lifelong immunity. Probably, the high rate of reinfection of mucosally restricted viruses reflects the difficulty and metabolic cost of maintaining a high level of immunity at the vast surface area of the mucosa. Virus-specific IgA levels are maintained at high levels generally only for several weeks or months after infection.

The Human Respiratory Tract

The anatomy and the cell types of the respiratory tract dictate to a large degree the type of disease observed during respiratory virus infection. The demarcation between the upper and lower respiratory tracts is the vocal cords. The structures of the upper respiratory tract, which are all interconnected, include the nasopharynx, the larynx, the Eustachian tube and middle ear space, and the sinuses. Significant collections of lymphoid tissue reside in the upper respiratory tract, the tonsils and the adenoids. The lower respiratory tract structures include the trachea, bronchi, bronchioles, alveoli, and lung tissue. The cell types that line the respiratory tract are complex, and exhibit different susceptibilities to virus infection. The predominant cell types are ciliated and nonciliated epithelial cells, goblet cells, and Clara cells. Smooth muscle cells are prominent features of the airways down to the level of the bronchioles, and the lung possesses type I and II pneumocytes.

Disease Syndromes

The disease syndromes that are associated with respiratory viruses generally follow the anatomy of the respiratory tract. Different viruses appear to have tropisms for different cells or regions of the respiratory tract; therefore, there are particular associations of viruses with clinical syndromes. The clinical diagnoses for infections with disease manifestations in the respiratory tract are rhinitis and the common cold, sinusitis, otitis media, conjunctivitis, pharyngitis, laryngitis, tracheitis, acute bronchitis, bronchiolitis, pneumonia, and exacerbations of reactive airway disease or asthma. Clinical syndromes with more systemic illness due to respiratory viruses include the influenza syndrome, measles, severe acute respiratory syndrome (SARS), and hantavirus pulmonary syndrome (HPS).

Viruses That Cause Respiratory Illness in Immunocompetent Humans

The principal causes of acute viral respiratory infections in children became apparent through large epidemiologic studies conducted soon after cell culture techniques became available. The landmark studies of association of viruses with clinical syndromes were performed in the 1960s and 1970s. Recent studies have increased our understanding of the causes of viral respiratory infection in infants, especially because of the advent of molecular tests such as the polymerase chain reaction (PCR), which is more sensitive than cell culture. Respiratory syncytial virus (RSV), parainfluenza viruses (PIVs), adenoviruses, and influenza viruses were identified initially as the most common causes of serious lower respiratory tract disease in infants and children. More recently, human metapneumovirus (hMPV) was identified as a major cause of serious illness. In the last 10 years, a number of additional viruses have been associated with respiratory illness, as discussed

below. However, still, infectious agents are not identified in 30–50% of clinical illnesses in large surveillance studies, even using sensitive diagnostic techniques such as viral culture on multiple cell lines, antigen detection assays, and RT-PCR based methods. It is not known if these illnesses are due to identified pathogens that are simply not detected due to low titers of virus in patient samples or if there are novel agents that are yet to be identified.

Immunocompromised Hosts

Reactivation of latent viruses, such as the herpesviruses HSV and CMV, and adenoviruses occurs in immunocompromised humans, particularly subjects with late-stage HIV infection, those with organ transplantation, and patients with leukopenia and neutropenia caused by chemotherapy. CMV is the most frequently recovered virus from diagnostic procedures such as bronchoalveolar lavage in immunosuppressed patients with pneumonia. These patients also suffer more frequent and more severe disease including mortality with common respiratory viruses, including RSV, hMPV, PIV, influenza viruses, rhinoviruses, and adenoviruses. Nosocomial transmission including large unit outbreaks is not uncommon, and can result in high frequency of transmission.

Specific Viral Causes of Respiratory Disease

Picornaviridae

A wide variety of picornaviruses cause respiratory disease, including rhinoviruses, the enteroviruses A to D including coxsackieviruses A/B, echoviruses, non-polio enteroviruses, and parechoviruses 1–3. Enterovirus infections occur most commonly in the summer months in temperate areas, which differs from the season of many of the other most common respiratory viruses such as paramyxoviruses and influenza virus. Rhinovirus infections occur year-round.

Rhinoviruses

Rhinovirus is a genus of the family *Picornaviridae* of viruses. Rhinoviruses are the most common viral infective agents in humans, and a causative agent of the common cold. There are over 105 serologic virus types that cause cold symptoms, and rhinoviruses are responsible for approximately half of all cases of the common cold. Rhinoviruses have single-stranded positive-sense RNA genomes. The viral particles are icosahedral in structure, and they are nonenveloped. Rhinovirus-induced common colds may be complicated in children by otitis media and in adults by sinusitis. Most adults, in fact, have radiographic evidence of sinusitis during the common cold, which resolves without therapy. Therefore the primary disease is probably best termed rhinosinusitis. Rhinovirus infection is associated with exacerbations of reactive airway disease in children and asthma in adults. It is not clear whether rhinovirus is restricted to the upper respiratory tract and induces inflammatory responses that affect the lower respiratory tract indirectly, or whether the viruses spread to the lower respiratory tract. In the past, it was thought that these viruses did not often replicate or cause disease in the lower respiratory tract. However, recent studies discern strong epidemiological associations of RVs with wheezing and asthma exacerbations, including episodes severe enough to require hospitalization. Likely, rhinoviruses can infect the lower airways to some degree, inducing a local inflammatory response. Another possibility is that significant local infection of the upper respiratory tract might induce regional elaboration of mediators that causes lower airways disease. Association of rhinovirus infection with lower respiratory tract illness is difficult to study because cell diagnosis by cell culture is not sensitive. RT-PCR diagnostic tests are difficult to interpret because they are often positive for prolonged periods of time and even asymptomatic individuals may have a positive test. Comprehensive serologies to confirm infection are difficult because of the large number of serotypes. Nevertheless, most experts believe rhinoviruses are a common cause of lower respiratory tract illness.

Coxsackieviruses

These viruses cause oral lesions and often are associated in children with a disease syndrome termed 'hand-foot-and-mouth disease'. The pharyngitis associated with this infection often is marked by the very characteristic findings of herpangina, a clinical syndrome of ulcers or small vesicles on the palate and often involving the tonsillar fossa associated with the symptoms of fever, difficulty swallowing, and throat pain. Outbreaks commonly occur in young children, in the summer.

Enteroviruses

Non-polio enteroviruses are common and distributed worldwide. Although infection often is asymptomatic, these viruses cause outbreaks of clinical respiratory disease, sometimes with fatal consequences. Studies have associated particular types with clinical syndromes, as enterovirus 68 with wheezing and enterovirus 71 with pneumonia.

Echoviruses

The term 'echo' in the name of the virus is an acronym for enteric cytopathic human orphan, although this may be an archaic notion since most echoviruses are associated with human diseases, most commonly in children. There are at least 33 echovirus serotypes. Echoviruses can be isolated from many children with upper respiratory tract

infections during the summer months. Echovirus 11 has been associated with laryngotracheitis or croup. Epidemiology studies also have associated echoviruses with epidemic pleurodynia, an acute illness characterized by sharp chest pain and fever.

Parechoviruses

These viruses have been assigned a new genus of the family *Picornaviridae* because of distinctive laboratory-based molecular properties. The most common member of the genus *Parechovirus*, human parechovirus 1 (formerly echovirus 22) is a frequent human pathogen. The genus also includes the closely related virus, human parechovirus 2 (formerly echovirus 23). Human parechoviruses usually cause mild respiratory or gastrointestinal illness. Most infections occur in young children. There is a high seroprevalence for parechoviruses 1 and 2 in adults, and a few clear descriptions of neonatal cases of severe disease.

Paramyxoviridae

Respiratory syncytial virus

RSV is a single-stranded negative-sense nonsegmented RNA genome virus of the family *Paramyxoviridae*, genus *Pneumovirus*. It is one of the most infectious viruses of humans and infects infants at a very young age, often in the first weeks or months of life. It is the most common viral cause of severe lower respiratory tract illness in children and one of the most important causes of hospitalization in infants and children throughout the world. There is one serotype, but circulating viruses exhibit an antigenic dimorphism such that there are two antigenic subgroups designated A and B. Reciprocal cross-neutralization studies using human sera showed that the antigenic groups are about 25% related. Reinfection is common and can be caused by viruses of the same subgroup. Yearly, epidemics of disease often peak between January and March in temperate regions. RSV infection causes mild upper respiratory tract infection in most infants and young children, but results in hospitalization in 0.5–1% of infants. Most children have been infected by the age of 2 years. There is an association of RSV infection early in life and subsequent asthma, although a causal relationship is controversial. Most hospitalized infants are otherwise healthy, but some groups are considered high risk for severe disease such as premature infants especially those with chronic lung disease and infants born with congenital heart disease. Immunocompromised patients of any age are at risk of severe disease.

Human parainfluenza viruses

These viruses constitute a group of four distinct serotypes (types 1–4) of single-stranded RNA viruses belonging to the family *Paramyxoviridae*. When considered as a group, they are the second most common cause of lower respiratory tract infection in young children. PIV3 is the most common cause of severe disease. Repeated infection throughout life is common. First infections are more commonly associated with lower respiratory tract disease, especially croup, while subsequent infections typically are limited to the upper respiratory tract. PIVs are detected using cell culture with hemadsorption or immunofluorescent microscopy, and RT-PCR.

Human metapneumovirus

In 2001, investigators in the Netherlands described a new human respiratory virus, hMPV. Evidence of near universal seroconversion was found in the general population by 5 years of age, suggesting ubiquitous infection in early childhood. This virus, a member of the genus *Pneumovirus* with RSV, differs from RSV in that it lacks the NS1 and NS2 nonstructural genes that counteract host interferons and it possesses a slightly different gene order. Studies of the role of hMPV in pediatric lower respiratory tracts infection (LRI) in otherwise healthy children in the United States, using a prospectively collected 25-year database and sample archive representing about 2000 children, revealed that nearly 12% of LRI in children was associated with a positive hMPV test. This and similar studies suggested that the virus is one of the major respiratory pathogens of early childhood. The clinical features of hMPV LRI were similar to those of other paramyxoviruses, most often resulting in cough, coryza, and a syndrome of bronchiolitis or croup. Interestingly, hMPV seemed to be clinically intermediate between RSV and PIV in that it tended to cause bronchiolitis with similar frequency to RSV but more frequently than PIV, while causing croup less often than the latter. Studies in subjects with conditions predisposing to increased risk of respiratory illness suggest that hMPV plays a significant role in exacerbations of asthma in children and adults, LRI in immunocompromised subjects, and in the frail and elderly.

Measles virus

Measles virus, a paramyxovirus of the genus *Morbillivirus* causes infection with systemic disease, also known as rubeola. The virus is spread both by direct contact/fomite transmission and by aerosol transmission, and therefore is one of the most highly contagious infections of man. The classical symptoms of measles include 3 or more days of fever that is often quite high and a clinical constellation of symptoms termed 'the three Cs': cough, coryza, and conjunctivitis. A characteristic disseminated maculopapular rash appears soon after onset of fever. Transient mucosal lesions in the mouth of a characteristic appearance (Koplik's spots) are considered diagnostic when identified by an experienced clinician. The virus causes a number

of systemic effects and can be complicated by severe pneumonia, especially when primary infection occurs in an unvaccinated adult or immunocompromised person of any age. Mortality in developing countries is high, especially when infection occurs in the setting of malnutrition.

Hendra and Nipah viruses

These emerging pathogens that are grouped in their own new genus *Henipaviruses* may not be respiratory pathogens in a conventional sense, but they are paramyxoviruses that probably infect humans by the respiratory route. Nipah virus is a newly recognized zoonotic virus, named after the location in Malaysia where it was first identified in 1999. It has caused disease in humans with contact with infectious animals. Hendra virus (formerly called equine morbillivirus) is another closely related zoonotic paramyxovirus that was first isolated in Australia in 1994. The viruses have caused only a few localized outbreaks, but their wide host range and ability to cause high mortality raise concerns for the future. The natural host of these viruses is thought to be a certain species of fruit bats present in Australia and the Pacific. Pigs may be an intermediate host for transmission to humans in Nipah infection, and horses in the case of Hendra. Although the mode of transmission from animals to humans is not defined, it is likely that inoculation of infected materials onto the respiratory tract plays a role. The clinical presentation usually appears to be an influenza-like syndrome, progressing to encephalitis, may include respiratory illness, and causes death in about half of identified cases.

Orthomyxoviridae

Influenza viruses

Influenza is a single-stranded segmented negative-sense RNA genome virus of the family *Orthomyxoviridae*. There are three types of influenza viruses: influenza virus A, influenza virus B, and influenza virus C. Influenza A and C infect multiple species, while influenza B infects humans almost exclusively. The type A viruses are the most virulent human pathogens among the three influenza types, and cause the most severe disease. The influenza A virus can be subdivided into different subtypes based on the antibody response to these viruses. The subtypes that have been confirmed in humans in seasonal influenza, ordered by the number of known human pandemic deaths, are: H1N1 which caused the 1918 pandemic, and H2N2 which caused the 1957 pandemic of avian influenza that originated in China, H3N2 which caused the pandemic of 1968. Currently, H3N2, H1N1, and B viruses cause annual seasonal epidemics. In addition, H5N1 virus infection of humans occurred during an epizootic of H5N1 influenza in Hong Kong's poultry population in 1997. The disease affected animals of many species and exhibited a high rate of mortality in humans. The virus is spreading throughout Asia, carried by wild birds. Human-to-human transmission does not occur efficiently at this time; however, there is widespread current concern about the potential for an H5N1 pandemic if the virus acquired transmissibility among humans. The H7N7 avian virus also has unusual zoonotic potential. In 2003 this virus caused an outbreak in humans in the Netherlands associated with an outbreak in commercial poultry on several farms. One death occurred and 89 people were confirmed to have H7N7 influenza virus infection. H1N2 virus appears to endemic in pigs and humans. H9N2, H7N2, H7N3, and H10N7 human infections have been reported. Influenza B virus is almost exclusively a human pathogen, and is less common than influenza A. It mutates less rapidly than influenza A, and there is only one influenza B subtype. In humans, common symptoms of influenza infection and syndrome are fever, sore throat, myalgias, headache, cough, and fatigue. In more serious cases, influenza causes pneumonia, which can be fatal, particularly in young children and the elderly. Influenza pneumonia has an unusually high rate of complication by bacterial superinfection with staphylococcal and streptococcal bacterial pneumonia occurring in as many as 10% of cases in some clinical series.

Adenoviridae

Viruses of the family *Adenoviridae* infect both humans and animals. Adenoviruses were first isolated in human lymphoid tissues from surgically removed adenoids, hence the name of the virus. In fact, some serotypes establish persistent asymptomatic infections in tonsil and adenoid tissues, and virus shedding can occur for months or years. These double-stranded DNA viruses are less than 100 nm in size, and have nonenveloped icosahedral morphology. The large dsDNA genome is linear and nonsegmented. There are six major human adenovirus species (designated A through F) that can be placed into 51 immunologically distinct serotypes. Human respiratory tract infections are mainly caused by the B and C species. Adenovirus infections can occur throughout the year. Sporadic outbreaks occur with many of the serotypes, while others appear to be endemic in particular locations. Respiratory illnesses include mild disease such as the common cold and lower respiratory tract illness, including croup, bronchiolitis, and pneumonia. Conjunctivitis is associated with infection by species B and D. There is a particular constellation of symptoms called 'pharyngoconjunctival fever' which is very frequently associated with acute adenovirus infection. In contrast, gastroenteritis has been associated most frequently with the serotype 40 and 41 virus of species F. Immunocompromised subjects are highly susceptible to severe disease during infection with respiratory adenoviruses. The syndrome of acute

respiratory disease (ARD), especially common during stressful or crowded living conditions, was first recognized among military recruits during World War II and continues to be a problem for the military following suspension of vaccination. ARD is most often associated with adenovirus types 4 and 7.

Coronaviridae

Members of the genus *Coronavirus* also contribute to respiratory illness including severe disease. There are dozens of coronaviruses that affect animals. Until recently, only two representative strains of human coronaviruses were known to cause disease, human coronavirus 229E (HCoV-229E) and HCoV-OC43. A recent outbreak of SARS-associated coronavirus (SARS-CoV) showed that animal coronaviruses have the potential to cross species to humans with devastating effects. There has been one major epidemic to date, between November 2002 and July 2003, with over 8000 cases of the disease, and mortality rates approaching 10%. SARS-CoV causes a systemic illness with a respiratory route of entry. SARS is a unique form of viral pneumonia. In contrast to most other viral pneumonias, upper respiratory symptoms are usually absent in SARS, although cough and dyspnea occur in most patients. Typically, patients present with a nonspecific illness manifesting fever, myalgia, malaise, and chills or rigors; watery diarrhea may occur as well. Recently, investigators reported the identification of a fourth human coronavirus, HCoV-NL63, a new group 1 coronavirus. Evidence is emerging that HCoV-NL63 is a common respiratory pathogen of humans, causing both upper and lower respiratory tract illness. Human coronavirus (HCoV) HKU1 was first described in January 2005 following detection in a patient with pneumonia. Several cases of respiratory illness have been associated with the virus, but the infrequent identification suggests to date that this putative group 2 coronavirus causes a low incidence of illness.

Herpesviridae

Several herpes viruses cause upper respiratory infections, especially infection of the oral cavity. Herpes simplex pharyngitis is associated with characteristic clinical findings, such as acute ulcerative stomatitis and ulcerative pharyngitis. Herpes simplex virus 1 (HSV-1) and herpes simplex virus 2 (HSV-2), also called human herpesvirus 1 (HHV-1) and human herpesvirus 2 (HHV-2), respectively, cause oral lesions, although over 90% of oral infections are caused by HSV-1. Primary oral disease can be severe, especially in young children, who sometimes are admitted for rehydration therapy due to poor oral intake. A significant proportion of individuals suffer recurrences of symptomatic disease consisting of vesicles on the lips. Epstein–Barr virus (EBV) mononucleosis syndrome is often marked by acute or subacute exudative pharyngitis; in some cases, the swelling of the tonsils in EBV pharyngitis is so severe that airway occlusion appears imminent. Most of the viruses of the family *Herpesviridae* can cause severe disease in immunocompromised patients (especially hematopoietic stem cell transplant patients), including cytomegalovirus (CMV), EBV, varicella-zoster virus, herpesvirus 6, herpesvirus 7, and herpesvirus 8.

Parvoviridae

Human bocavirus

A new virus was identified recently in respiratory samples from children with lower respiratory tract disease in Sweden. Sequence analysis of the viral genome revealed that the virus is highly related to canine minute virus and bovine parvovirus and is a member of the genus *Bocavirus*, subfamily *Parvovirinae*, family *Parvoviridae*. This virus was tentatively named human bocavirus (HBoV). HBoV has been identified as the sole agent in a limited number of respiratory samples from children hospitalized with respiratory tract disease. It remains to be seen whether the virus is causative of or merely associated with disease in these preliminary studies.

Bunyaviridae

Hantavirus

Over 400 cases of HPS have been reported in the United States. The disease was first recognized during an outbreak in 1993. About a third of recognized cases end in death. The Four Corners area outbreak is well known; however, cases now have been reported in 30 states. Patients with HPS usually present with a febrile illness beginning with symptoms of a flu-like illness. Physical examination is not specific, often only with findings of fever, and increased heart and respiratory rates. In addition to the respiratory symptoms, abdominal pain and fever are common. Diagnosis is often delayed until a severe illness occurs requiring mechanical ventilation.

Reoviridae

Rotavirus

Rotaviruses are dsRNA enteric viruses that are the most common cause of severe viral infectious gastroenteritis in children. Clinical series suggest that some children with gastroenteritis suffer upper respiratory symptoms during the prodrome of disease manifestation, and virus can be recovered from respiratory secretions. Some reports suggest

that rotavirus infection is associated with lower respiratory tract illness, although this association is unclear.

Reovirus

These dsRNA viruses (named using an acronym for respiratory enteric orphan virus) are not clearly associated with respiratory disease, but seroconversion rate is high in the first few years of life, and they probably cause minor or subclinical illness.

Retroviridae

Human immunodeficiency virus

Pharyngitis occurs with primary HIV infection and may be associated with mucosal erosions and lymphadenopathy.

Papovaviridae

Polyomaviruses

Polyomaviruses are small dsDNA genome nonenveloped icosahedral viruses that may be oncogenic. There are two polyomaviruses known to infect humans, JC and BK viruses. Eighty percent or more of adult US subjects are seropositive for these viruses. JC virus can infect the respiratory system, kidneys, or brain. BK virus infection causes a mild respiratory infection or pneumonia and can involve the kidneys of immunosuppressed transplant patients.

Co-Infections

Given the overlap in the winter season of these viruses in temperate areas, it is not surprising that co-infections with two or more viruses occur. In general, when careful studies using cell culture techniques were used for virus isolation, more than one virus was isolated from respiratory secretions of otherwise healthy subjects with acute respiratory illness in about 5–10% of cases in adults and 10–15% in children. There is little evidence that more severe disease occurs during co-infections, although there is insufficient evidence on this point to be definitive. The incidence of two molecular diagnostic tests being positive (generally RT-PCR, for these RNA viruses) is expected to be higher than that of culture, because molecular tests can remain positive for an extended period of time after virus shedding has ended.

Transmission

Respiratory viruses generally have two main modes of transmission, large particle aerosols of respiratory droplets transmitted directly from person-to-person by coughing or sneezing, or by fomites. Fomite transmission occurs indirectly when infected respiratory droplets are deposited on hands or on inanimate objects and surfaces with subsequent transfer of secretions to a susceptible subject's nose or conjunctiva. Most respiratory viruses, unlike measles virus or varicella zoster virus, do not spread by small particle aerosols across rooms or down halls. Therefore, contact and droplet precautions are sufficient to prevent transmission in most settings; handwashing is critical in healthcare settings during the winter season.

Antiviral Drugs for Respiratory Viruses

Ribavirin is a nucleoside antimetabolite pro-drug that is activated by kinases in the cell, resulting in a 5′ triphosphate nucleotide form that inhibits RNA replication. The drug was licensed in an aerosol form in the US in 1986 for treatment of children with severe RSV lower respiratory tract infection. The efficacy of aerosolized ribavirin therapy remains uncertain despite a number of clinical trials. Most centers use it infrequently, if ever, in otherwise healthy infants with severe RSV disease. Intravenous ribavirin has been used for adenovirus, hantavirus, measles virus, PIV, and influenza virus infections, although a good risk/benefit profile has not been established clearly for any of these uses.

A humanized mouse monoclonal antibody directed to the F protein of RSV, 'palivizumab', is licensed for prevention of RSV hospitalization in high-risk infants. It is efficacious in half or more of high-risk subjects. A more potent second-generation antibody is being studied in clinical trials. Experimental treatment of both immunocompetent and immunocompromised RSV-infected subjects has been reported but the efficacy of this approach is not established.

There are four licensed drugs in the US for treatment or prophylaxis of influenza. 'Amantadine' and 'rimantadine' are two of the drugs that interfere with the ion channel activity caused by the viral M2 protein of influenza A viruses, which is needed for viral particle uncoating following endocytosis. The other two drugs, 'oseltamivir' and 'zanamivir', are neuraminidase inhibitors that act on both influenza A and B viruses by serving as transition state analogs of the viral neuraminidase that is needed to release newly budded virion progeny from the surface of infected cells. The cell surface normally is coated heavily with the viral receptor sialic acid. Resistance to the ion channel inhibitors arises rapidly during prophylaxis or treatment, and in 2006 resistance levels became so common in circulating viruses that the CDC no longer recommends use of these drugs.

'Interferon-α' has been shown to protect against rhinovirus infections when used intranasally. This biological drug causes some side effects, such as nasal bleeding, and resistance to the drug developed during experimental use, so the molecule is no longer being developed for this

purpose. 'Pleconaril' has been tested for treatment of rhinovirus infection, as it is an oral drug with good bioavailability for treating infections caused by picornaviruses. This drug acts by binding to a hydrophobic pocket in the VP1 protein and stabilizing the protein capsid, preventing release of viral RNA into the cell. The drug reduced mucus secretions and other symptoms and is being further examined.

'Acyclovir' and related compounds are guanine analog antiviral drugs used in treatment of herpes virus infections. HSV stomatitis in immunocompromised patients is treated with 'famciclovir', or 'valacyclovir', and immunocompetent subjects with severe oral disease compromising oral intake are sometimes treated. These compounds have also been used prophylactically to prevent recurrences of outbreaks, with mixed results. Intravenous acyclovir is effective in HSV or varicella zoster virus pneumonia in immunocompromised subjects. 'Ganciclovir' with human immunoglobulin may reduce the mortality associated with CMV pneumonia in hematopoietic stem cell transplant recipients and has been used as monotherapy in other patient groups.

'Cidofivir' is a nucleotide analog with activity against a large number of viruses, including adenoviruses. Intravenous cidofovir has been effective in the management of severe adenoviral infection in immunocompromised patients but may cause serious nephrotoxicity.

Vaccines

There are licensed vaccines for influenza viruses. In the US, both a trivalent (H3N2, H1N1, and B) inactivated intramuscular vaccine and a live attenuated trivalent vaccine for intranasal administration is available. The efficacy of these vaccines is good when the vaccine strains chosen are highly related antigenically to the epidemic strain. Antigenic drift caused by point mutations in the HA and NA molecules leads to antigenic divergence, requiring new vaccines to be made each year. The influenza genome is segmented, which allows reassortment of two viruses to occur during co-infection, which sometimes leads to a major antigenic shift resulting in a pandemic. Pandemics occur every 20–30 years on average. There is current concern about the potential for an H5N1 pandemic, and experimental vaccines are being tested for this virus. To date, H5N1 vaccines have been poorly immunogenic compared to comparable seasonal influenza vaccines. Vaccines were developed for adenovirus serotypes 4 and 7, and these were approved for preventing epidemic respiratory illness among military recruits. Essentially, these were unmodified viruses given by the enteric route in capsules, instead of the respiratory route, which is the natural route of infection leading to disease. Inoculation by the altered route resulted in an immunizing asymptomatic infection. All US military recruits were vaccinated against adenovirus from 1971 to 1999 with near complete prevention of the disease in this population, but the sole manufacturer of the vaccine halted production in 1996 and supplies ran out 3 years later. Since 1999, adenovirus infection has reemerged as a significant problem in the military with approximately 10% of all recruits suffering illness due to adenovirus infection during basic training; some deaths have occurred. Live attenuated vaccine candidates are under development and being tested in phase I and II clinical trials for RSV and the PIVs. Mutant strains with reduced pathogenicity were isolated in the laboratory, tested, and sequenced. Now, vaccine candidates are being optimized by combining mutations from separate biologically derived viruses into single strains using recombinant techniques for generating RNA viruses from cDNA copies, a process called reverse genetics. Subunit vaccines have been developed for RSV, but there are safety concerns about their use in young infants because formalin inactivated vaccine induced a more severe disease response to infection in the 1960s. There are no vaccines against rhinoviruses as there is little or no cross-protection between serotypes, and it is not feasible to develop a vaccine for over 100 serotypes. Efforts to develop coronavirus vaccines are in the preclinical stage.

Summary

Viruses are the leading causes of acute lower respiratory tract infection in infancy. RSV is the most common pathogen, with hMPV, PIV-3, influenza viruses, and rhinoviruses accounting for the majority of the remainder of acute viral respiratory infections. Humans generally do not develop lifelong immunity to reinfection with these viruses; rather, specific immunity protects against severe and lower respiratory tract disease.

Human T-Cell Leukemia Viruses: General Features

M Yoshida, University of Tokyo, Chiba, Japan

© 2008 Elsevier Ltd. All rights reserved.

Glossary

pX region HTLV sequence between the env and 3′ LTR, encoding Tax, Rex and other small regulatory proteins.
Rex Trans-modulator of viral RNA splicing and transport.
Tax Pleiotropic regulator activating viral and cellular replication interacting with cellular transcription factors, tumor suppressor proteins, and cell cycle checkpoints.

Introduction

Human T-cell leukemia virus 1 (HTLV-1) is the first established tumorigenic retrovirus of humans; exogenous to humans this virus is classified as the species *Human T-cell leukemia virus*, in *Deltaretroviridae*, within the family *Retroviridae*. HTLV-1 infection is associated with leukemia and neural disease, adult T-cell leukemia (ATL) and HTLV-1-associated myelopathy/tropical spastic parapasis (HAM/TSP), respectively. The genomic structure of the virus with genes for nonstructural proteins established a distinct viral genus that includes *Bovine leukemia virus*. HTLV-1 has no oncogene, but nevertheless transforms T cells rather efficiently and is identified as the etiologic agent of ATL. HTLV-1 has unique regulatory proteins, Tax and Rex, and Tax has been identified as a critical molecule not only in regulation of viral replication but also in induction of ATL.

History and Classification

After long and enormous efforts to identify a retrovirus in human tumors, HTLV was described in T-cell lines as a convincing human retrovirus. The first report of the virus (HTLV) was from a patient with Mycosis (MF) in the US, and another (adult T-cell leukemia virus (ATLV)) was from a patient with ATL in Japan. Subsequently, the MF case was characterized as ATL and the two isolates were established to be the same following a comparison of their genomes.

A prototypical retroviral genome contains the *gag*, *pol*, and *env* genes encoding the virion proteins including core proteins, reverse transcriptase, and surface glycoprotein, respectively. Acute leukemia viruses generally have an oncogene acquired from cellular genes that substitutes a part of the *gag*, *pol*, and *env* sequences. In contrast to these genomes, HTLV has additional genes in an extra pX region between *env* and the 3′ LTR (LTR – long terminal repeat). This unique genomic structure classified HTLV as a member of a distinct genus of the *Retroviridae*, which includes HTLV-1, and-2, bovine leukemia virus (BLV), and simian T-cell leukemia viruses (STLV-1, -2, and -3). HTLV-2 was isolated from a patient with hairy T-cell leukemia and its genome similarity to the type 1 is about 60%.

STLVs have been isolated from various species of Old World nonhuman primates, including the Japanese macaque, African green monkey, pig-tailed macaque, gorilla, and chimpanzee. Their genomes share 90–95% homology.

BLV infects and replicates in B cells of cows and sheep and induces B-cell lymphoma.

Geographic Distribution

Geographic Clustering

HTLV-1 carriers are defined by virus-specific antibodies. Nationwide surveys in Japan revealed the following: almost all ATL and HAM/TSP patients are infected with HTLV-1, 5–15% of adults in southwestern Japan are infected with HTLV-1 but this percentage is less in other areas of Japan. Worldwide, virus carriers are localized in the Caribbean islands and South America, Central Africa, and Papua New Guinea and the Solomon Islands. The prevalence of asymptomatic, seropositive adults varies significantly from district to district and even from village to village within these endemic areas. The unique clustering of virus infection in such remote areas is considered to reflect its mode of transmission and familial close contact such as sexual relations and breastfeeding. The presence of ATL and HAM/TSP is overlapping and clustered with HTLV-1 infection. Although some patients with ATL and healthy HTLV-1-infected carriers are found in nonendemic areas, they have frequently moved from an endemic area.

HTLV-2 is endemic in South America and is also detected in populations infected with HIV. STLVs are distributed in Old World monkeys in various areas, but not in New World monkeys. Although viruses were isolated from most species of Old World monkeys, some colonies are found to be virus-free even in the same geographic area.

Age-Dependent Infection

The frequency of HTLV-1 carriers increases with age after 20, reaching a maximum between 40 and 60 years of age. The prevalence is slightly (1.6 times) higher in females than in males, which is attributed to sexual transmission.

Familial aggregation

Familial aggregation of the HTLV-1 infection is apparent. If a mother is HTLV-1 positive, her children are frequently positive. This aggregation is due to viral transmission from husband to wife and mother to her children.

Host Range and Transmission

Receptor, Infection, and Transformation

The receptor for HTLV-1 infection is a glucose transporter, Glut-1, which is ubiquitously expressed on most cell types. Glut-1 is required for viral binding and infection, but it alone is not sufficient to understand preferential infection of CD4+ T cells *in vivo*. Cell-free viral particles of HTLV-1 released from established cell lines show extremely low infectivity *in vitro*, and co-cultivation with virus-producing cells is generally used to establish infection. A variety of cell types are infected including human T and B lymphocytes, fibroblasts, and epithelial cells, as well as cells from monkeys, rats, rabbits, and hamsters, but curiously not cells from mice. These cells infected by co-cultivation contain multiple integrated proviral copies of complete and defective genomes. Only T cells of the CD4+ phenotype are immortalized upon infection *in vitro*.

Despite the broad cell type host range *in vitro*, the cells infected *in vivo* are T cells. HTLV-1 infects both T cells with CD4+ and CD8+ phenotypes, although preferentially those of the CD4+ phenotype, but ATL cells are exclusively CD4+ T cells. Inoculation of infected cells can establish infection in rats, rabbits, and mice providing animal models for studies of the virus.

Natural Transmission

HTLV-1 is transmitted through (1) nursing of infants by infected mothers, (2) sexual contact, and (3) blood transfusion.

Mother to child. About 30% of the children born to seropositive mothers were seropositive. Infected T cells in breast milk are a source of transmissible virus. This mode of transmission was initially suggested by epidemiological studies and then direct evidence was obtained through cessation of breastfeeding by seropositive mothers that drastically reduced the seropositive rates in their children.

Sexual transmission. Wives with seropositive husbands are usually seropositive. Conversely, the husbands of seropositive wives show the same frequency of seropositivity as those in the region under study, indicating transmission occurs from husband to wife but not vice versa. Infected T cells in semen are thought to mediate transmission. This pathway may explain the higher (1.6 times) prevalence in females than in males, and is in sharp contrast to HIV infection. Infection in adulthood is not thought to be linked to subsequent ATL.

Blood transfusion. Transfusion of fresh and total blood transmits HTLV-1 into 60–70% of the recipients. The transfer of infected cells is critical for transmission. This mode of transmission does not lead to ATL, but does to HAM/TSP.

Zoonotic infections with retroviruses endemic in most Old World primates are described in people living in central African forests who have had contact with blood and body fluids of wild nonhuman primates. Such interspecies infection may explain the unique similarities between HTLVs and STLVs.

Genetics and Replication

Genome

The virion is spherical, enveloped with a membrane similar to that of the host cell and contains RNA genomes, core proteins, and reverse transcriptase, and envelope

glycoproteins on the surface (**Figure 1**). The RNA genome is copied into a 'proviral' DNA upon infection and analysis of the retroviral genome is generally performed with the integrated proviral genome.

The integrated HTLV-1 proviral genome is 9032 bp long and its organization is LTR-*gag*-*pol*-*env*-pX-LTR. The pX sequence contains multiple overlapping genes encoding for the regulatory factors for the viral replication, but none of them has any homology to cellular genes. The major regulatory factors are $p40^{tax}$ and $p27^{rex}$. Alternative splicing of the pX sequence also expresses various proteins such as p12(I), p10(I), p11(V).

Antisense viral transcripts from the pX region code for HBZ proteins (HTLV-1 bZIP with a leucine zipper motif), which represent additional regulatory proteins, and also function at the RNA level.

Replication with Feedback Regulation

Reverse transcription and integration

Upon infection, the viral RNA genome is reverse-transcribed into complementary DNA (cDNA) by viral reverse transcriptase in the virion and further copied into double-stranded DNA, defined as 'proviral DNA'. The proviral DNA is integrated into the host cell DNA establishing the viral infection.

Transcription and splicing

RNA transcription from the 5′ LTR to 3′ LTR generates the viral genomic RNA, and this step represents a potential regulatory stage of the viral replication cycle. HTLV genomic RNA serves as an mRNA for Gag and Pol proteins, but has to be spliced to express other viral proteins: into a 4.2 kbp (singly spliced) env mRNA for Env expression, and into a 2.1 kbp (doubly spliced) mRNA for the regulatory proteins, Tax and Rex (**Figure 1**). Various alternative splicing events also take place to express alternative proteins.

Genomic transcription depends on cellular factors that respond to 21 bp enhancers in the HTLV LTR, but initial transcriptional activity is weak. The low levels of viral transcripts are fully spliced into Tax/Rex mRNA. The Tax thus produced *trans*-activates transcription further enhancing viral transcription to produce more Tax/Rex mRNA. This *trans*-activation is mediated by Tax binding to a transcriptional factor, cAMP-responsive element binding protein (CREB) that responds to the 21 bp enhancers in the

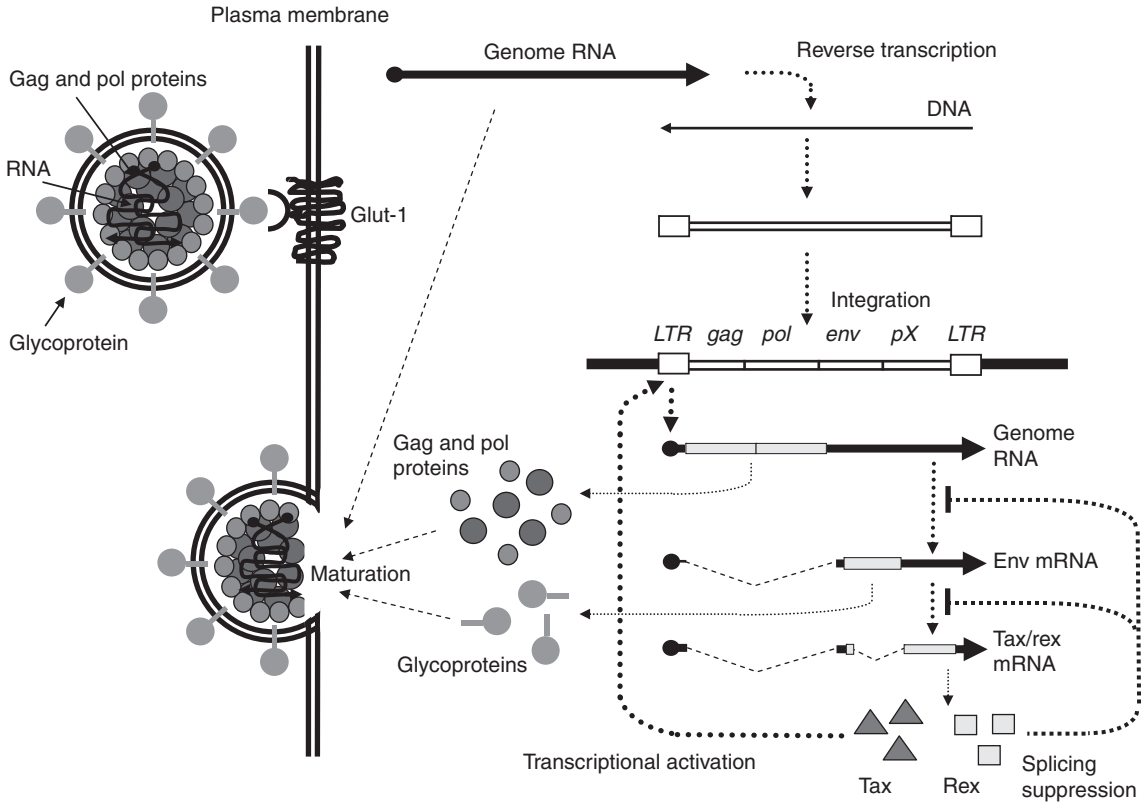

Figure 1 Replication cycle of HTLV. HTLV-1 binds to glucose transporter (Glut-1) and the genomic RNA is transcribed into complementary DNA by reverse transcriptase. The circularized proviral DNA is finally integrated into host chromosomal DNA establishing infection. The integrated provirus is transcribed into genomic RNA and expression of the viral proteins is regulated by Tax and Rex at transcriptional and splicing level making the expression transient. Genomic RNA and virion proteins mature at specific sites under plasma membrane and bud as the matured particles.

LTR. To express the virion proteins, Gag, Pol, and Env, the accumulated Rex protein specifically suppresses splicing of the viral RNA, and thus upregulates expression of unspliced genomic RNA and singly spliced *env* mRNA. In return, this Rex regulation reduces the level of spliced Tax/Rex mRNA, resulting in a lower level of Tax and ultimately reducing viral transcription. The combination of Tax and Rex functions exerts a feedback control on viral expression, making viral expression transient and resulting in the escape of infected cells from host immune surveillance. This feedback mechanism is unique to HTLV among oncogenic retroviruses and explains why HTLV is so repressed in expression and replication.

HTLV replication has also been reported to be regulated by small proteins such as p12(I), p10(I), p11(V), that are expressed by alternative splicing of the pX sequence. The regulatory mechanisms are not well understood but seem to be important for *in vivo* viral replication.

Maturation and budding

Genomic and *env* RNAs are efficiently accumulated by Rex and thus virion proteins, Gag, Pol, and Env, are transiently expressed. These virion proteins and genomic RNA come together and assemble at specific sites under the plasma membrane, finally budding by being enveloped with cellular membrane. The molecular mechanisms of these processes are not well characterized.

Variability and Evolution

The retroviral genome is rather labile in general since the reverse transcription process has no proofreading mechanism. In sharp contrast to HIV for example, however, the HTLV genome is highly stable and conserved among isolates from Japan, the Caribbean, and Africa. The viral isolates from Papua New Guinea may vary somewhat more but are still 90–95% homologous. This stable property is a reflection of an HTLV survival strategy that replicates the viral genome through infected cell replication rather than virus replication.

It has been suggested that HTLV and STLV are transmitted across species. Each of the isolates from various monkeys (STLV-1, -2, and -3) and humans (HTLV-1 and -2) are highly homologous and their variability is sometimes higher within the species than among species. Such unusual genomic conservation under different conditions is also well explained by a viral survival strategy through proliferation of infected cells.

Pathogenicity

Adult T-Cell Leukemia

Clinical features

Symptoms of ATL are variable and frequently complicated by skin lesions, enlargement of lymph node, liver and/or spleen, and infiltration of leukemic cells into various organs. Patients usually have antibodies to HTLV-1 proteins, show an increased level of serum lactate dehydrogenase (LDH), and most suffer from hypercalcemia.

The onset of ATL is observed in individuals between 20 and 70 years of age, the highest frequency being observed in people in their 40s and 50s. The male/female ratio of ATL incidence is 1.4/1.

Smoldering, chronic, acute forms of ATL and a lymphoma type have been recognized. Patients with smoldering ATL have a few or several percent of morphologically abnormal T cells in their peripheral blood, but do not show signs of severe illness for a long period. Patients with chronic ATL have rather high levels of HTLV-1-infected leukemic cells, but can maintain stable phenotypes for a certain period of time. Acute ATL is aggressive and resistant to any treatment; consequently, most patients die within one-half year of its onset.

Leukemic cells are exclusively CD4+ T cells with usually a highly lobulated nucleus. Leukemic cells generally have one complete integrated copy of an HTLV-1 provirus in their genome. Less frequently two copies are found, sometimes with defective forms. The site of integration is clonal in a given ATL patient, but different among patients. Leukemic cells carry aberrant chromosomes, frequently with multiple abnormalities, and express a high level of IL-2Ralpha, PTHrP, IL-1alpha, but no common abnormality has been described.

Etiology of ATL

An etiologic linkage of HTLV-1 with ATL is apparent from the observations: (1) ATL and HTLV-1 show identical geographic distribution, (2) almost all ATL patients are infected with HTLV-1, (3) leukemic cells are all infected with HTLV-1 but a vast majority of normal T cells are not, (4) leukemic cells are clonally integrated with an HTLV-1 provirus indicating their origin from a single infected cell, and (5) infection by HTLV-1 can immortalize T cells *in vitro* and the phenotypes of immortalized T cells are similar to those of leukemic cells.

There are approximately 1 million carriers of HTLV-1 in Japan. About 2–5% of all carriers of HTLV-1 are thought to develop ATL during their lifetime. While the vast majority of cases of ATL are associated with HTLV-1 infection, a form of ATL 'unrelated to HTLV-1 infection' has been described. The etiologic factor of these cases has not been identified.

Molecular mechanism of leukemogenesis

ATL cells have clonally integrated HTLV-1 proviruses; however, no common site for integration was observed among ATL patients. In this respect, HTLV-1 differs from animal chronic leukemia viruses, wherein integration was commonly adjacent to a proto-oncogene for its activation. Thus, the Tax protein has been focused on as a critical transforming protein.

Tax protein

Tax is able to transform fibroblasts and immortalize CD4+ T cells *in vitro*, and can induce tumors in transgenic mice. Tax exerts pleiotropic effects including (1) transcriptional activation of specific genes, (2) transcriptional repression of some other specific genes, (3) functional inactivation of tumor suppressor proteins, and (4) attenuation of cell-cycle checkpoints (**Table 1**). Cooperation of these pleiotropic functions is thought to contribute to ATL induction.

Transcriptional activation. Tax activates HTLV-1 genome transcription, which in turn is regulated by an enhancer binding protein, cyclic AMP-responsive element binding (CREB) protein. CREB has to be phosphorylated for active transcription, while Tax binds to CREB and activates it without a phosphorylation signal leading to a constitutively active protein. Similarly, Tax binds to other enhancer binding proteins such as nuclear factor kappa B (NF-κB) and serum responsive factor (SRF) and activates many specific cellular genes including IL-2Ralpha, IL-6, c-fos, and Bcl-x. NF-κB is alternatively activated by Tax through activation of IκB kinase (IKK) which disrupts inactive IκB–NF-κB complexes. The genes finally activated are linked to enhancement of cell proliferation or suppression of apoptosis.

Transcriptional repression. Tax also binds to transcription factors, CBP and P300, which interact with various enhancer binding proteins. The binding of Tax to CBP or p300 interferes with their interaction with the corresponding enhancer binding protein unless Tax is able to bind to enhancer binding protein, and consequently inhibits formation of a transcriptional initiation complex. The targets include p53-dependent transcription, DNA polymerase beta, p18ink4, Bax, and many others. The genes eventually repressed are linked to downregulation of p53-dependent stress responses, DNA repair and apoptosis.

Functional inactivation of tumor suppressor proteins. Tax directly binds to or modifies some tumor suppressor proteins and inactivates their negative regulation of the cell cycle. RB, APC, and p53 are targets. (a) Tax binds to and inactivates p16ink4 and p15ink4, which normally inhibit CDK4 and maintain an active RB pathway; consequently, Tax activates CDK4 which results in inactivation of RB and promotes cells to move from G1 arrest into S phase. Tax is also reported to bind directly to CDK4 to activate kinase activity. (b) Tax also binds to another tumor suppressor protein, hDlg, through its PDZ domain and inactivates its growth-retarding signal through APC and β-catenin. An abnormality in this pathway has been shown to play a critical role in colorectal tumors. (c) Tax inactivates p53 through phosphorylation and complex formation of p53–p300. Inactivation of the p53 pathway implies suppression of DNA repair resulting in the frequent fixation of mutations.

Attenuation of cell-cycle checkpoints. Check and review mechanisms for genomic processes before entering the next phase of the cell cycle is important to avoid genetic fixation of mutations. Tax interacts with hMad-1 and Chek-1 and attenuates the S- and G2-checkpoint functions. Tax also binds to Ran and Ran-binding protein and induces centrosome fragmentation and aneuploidy. These properties would explain a higher mutation rate in Tax-positive cells and may be the basis for why ATL cells have highly frequent choromosomal abnormalities.

Collectively, it has been proposed that these pleiotropic effects of Tax cooperate for abnormal cell proliferation. Significance of the Tax roles are twofold: (1) enhancing proviral replication and (2) promoting cells into leukemogenesis. Infected T cells are abnormally stimulated to proliferate through transcriptional activation/repression and inactivation of tumor suppressor proteins.

Table 1 Typical examples of pleiotropic Tax effects on cellular activities

Category/primary target	*Targeted gene or process*	*Targeted cellular activity*
Transcriptional activation		
CREB–CBP	HTLV-1 provirus	Viral replication/activation
	Unidentified	Transformation/activation
NF-κB-p300 and IKK-IκB	IL-2Ralpha, IL-6	Proliferation/activation
	Bcl-X	Apoptosis/suppression
SRF-CBP	c-Fos	Transformation/activation
Transcriptional repression		
p300–p53	p53-dependent transcription	Stress response/Suppression
	p18ink4	Proliferation/activation
CBP	DNA polymerase beta	DNA repair/suppression
	Bax	Apoptosis/suppression
Tumor suppressor protein		
p16ink4-CDK4	RB signaling	Cell cycle/promotion
p15ink4-CDK4		
hDLG-APC	APC signaling	Proliferation/activation
Kinase-p53	p53 signaling	Stress response/suppression
Checkpoint		
hMad-1	G2 checkpoint	Fidelity/suppression
Check-1	S, G2 checkpoint	Fidelity/suppression

Concomitantly, attenuation of cell-cycle checkpoints, reduction of DNA repair, and apoptosis would result in more mutations and their fixation, eventually leading to the leukemogenesis. In this respect, the pleiotropic effects of Tax may be equivalent to a multistep process for tumor formation.

Paradox in the leukemogenic mechanism

Tax plays a central role in the induction of ATL. Even its functional similarity to transforming proteins of DNA tumor viruses has been pointed out. However, it remains to be answered: (1) Why HTLV-1 transformation is selective for CD4+ T cells? and (2) Why ATL cells *in vivo* maintain tumor phenotypes in the absence of Tax? Tax/Rex mRNA is expressed only in a small percentage of tumor cells even using highly sensitive RT-PCR assays, yet tumor phenotypes are maintained in all ATL cells. The simplest answer for the latter question may be that Tax was critical for induction of tumors, but after establishment of tumors Tax is no longer required. If this is the case, what is the mechanism to maintain the tumor phenotypes?

An antisense gene, HTLV basic leucine zipper (HBZ) protein, may account for the paradox. This gene is transcribed from the pX region and codes for a DNA-binding protein with a bZIP domain. HBZ is able to moderately enhance T-cell proliferation *in vitro* and counteracts Tax *trans*-activation through dimer formation with other bZIP proteins. The antisense transcripts also operate at the RNA level. An exciting aspect of HBZ is that the antisense transcript is expressed in almost all ATL cases tested so far. It is therefore proposed to play a role after Tax *in vivo*. Tax is a potent antigenic protein; thus, its downregulation may make sense for tumor cell to escape from immune responses.

HAM/TSP and other diseases

Clinical features

HTLV-1 also induces a slowly progressive myelopathy known in tropical zones as tropical spastic paraparesis (TSP) and, in endemic areas of Japan, as HTLV-1-associated myelopathy (HAM). The unique phenotypes of HAM/TSP are chronic, symmetrical, bilateral involvement of the pyramidal tracts, at mainly the thoracic level of the spinal cord, and include progressive spastic paresis with spastic bladder and minimal sensory deficits. HTLV-1-infected T cells infiltrate into the spinal fluid and cord.

Most patients with HAM/TSP have much higher titers of HTLV-1 antibodies than those of asymptomatic carriers or ATL patients. This might be associated with particular types of human leukocyte antigens (HLAs). Despite their strong immunological responses to HTLV-1 infection, most HAM/TSP patients have larger populations of infected cells than do HTLV-1 carriers.

Etiology and other features

In endemic Japanese, all HAM/TSP patients are infected with HTLV-1. After screening for seropositive blood, the incidence of HAM/TSP has greatly decreased, clearly indicating that HTLV-1 is an etiologic agent of HAM/TSP. In contrast, TSP patients in the tropical areas are not always infected with HTLV-1, but the etiology in these cases is unknown. Indirect immunological reaction has been proposed as a pathogenic mechanism, but further studies are required.

The two HTLV-1-associated diseases, HAM/TSP and ATL, are mutually exclusive. The reason for this phenomenon is not well understood, but the route of primary viral infection may affect the pathogenic course: mucosal exposure to HTLV-1 for ATL, while primary infection of peripheral blood for HAM/TSP.

HTLV-1 infection is also proposed to be associated with some other diseases including uveitis, chronic lung disease, monoclonal gammopathy, and rheumatoid arthritis, but further systematic studies are required.

Prevention and Control of Infection

Transfusion of seropositive blood transmits HTLV-1 to two-thirds of the recipients. With the introduction of HTLV-1 screening systems in blood banks, viral transmission through transfusion has been greatly reduced. Application of these systems to populations in all endemic areas is critical to prevent HTLV-1 infection.

The major, natural route of viral transmission is from mother to child via infected T cells in breast milk. In Nagasaki City, Japan, pregnant women are tested for HTLV-1 antibodies by consent and those who are seropositive are recommended to avoid breastfeeding. A trial of this approach resulted in a drastic reduction in the incidence of seropositive children, from about 30% to just a few percent. The early success of this trial provides direct evidence for viral transmission through milk and suggests the possibility of eliminating ATL in the next few generations. Unfortunately, not all of children of seropositive mothers who did not breastfeed remained seronegative.

Future

Studies on HTLV-1 infection linked to ATL and HAM/TSP have progressed, but several very basic questions are still not answered: Why does only a small fraction of the infected population develop ATL or HAM/TSP? Why are ATL and HAM/TSP mutually exclusive? Why are only CD4+ T cells transformed into leukemic cells? What is required for ATL induction in addition to Tax? On the other hand, HTLV-1 transmission is now preventable in certain countries. However, it may not be

feasible everywhere in the world. For example, cessation of breastfeeding might result in more serious problems in children in certain environments. So, original questions should be asked: Is a vaccine possible for complete eradication of the HTLV-1? Is vaccination possible for preventing disease development after infection?

Modern technologies developed in conjunction with genome research are now becoming available and make it possible to revisit these questions utilizing new appraoches.

Introduction

In 1980, Dr. Gallo's laboratory (National Institutes of Health, USA) reported the isolation of HTLV-1, the first oncoretrovirus to be discovered in humans. HTLV-1 was present in the peripheral blood cells obtained from an Afro-American patient suffering from a lymphoproliferative disease, originally considered as a cutaneous T-cell lymphoma, with a leukemic phase. The virus was thus named human T-cell leukemia/lymphoma virus (HTLV). Later, it was recognized that this cutaneous lymphoma was in fact an adult T-cell leukemia/lymphoma (ATLL), a severe T-cell lymphoproliferation, originally described in Japan in 1977 by Takatsuki. The epidemiological characteristics of ATLL in Japan suggested a strong environmental factor, which prompted researchers to characterize the tumor cells and to search for an oncogenic virus. In 1981, a virus was isolated in Japan and termed adult T-cell leukemia/lymphoma virus (ATLV). Japanese and American scientists rapidly demonstrated that both isolates represented the same virus, and agreed to name it HTLV-1. In parallel, the causal association between ATLL and HTLV-1 was established. In 1983, the authors initiated a series of studies in the French West Indies in order to investigate the epidemiological and clinical impact of HTLV-1 in this area. This led them to demonstrate the etiological association between this virus and a chronic neuromyelopathy originally named tropical spastic paraparesis (TSP) that is endemic in the Caribbean. A similar neurological entity was then uncovered in Japan and labeled as HTLV-1-associated myelopathy. These two diseases were further shown to be identical and this myelopathy is now referred to as HAM/TSP. HTLV-1 infection has also been associated with other clinical conditions including uveitis, infective dermatitis, and myositis (**Table 1**).

HTLV-1, which is not a ubiquitous virus, is present throughout the world, with clusters of high endemicity located often nearby areas where the virus is nearly absent. These highly endemic areas are the southwestern part of the Japanese archipelago; the Caribbean area and its surrounding regions; foci in South America including Colombia, French Guyana, parts of Brazil; some areas of intertropical Africa (such as South Gabon); and of the middle East (such as the Mashad region in Iran); and isolated clusters in Melanesia. The origin of this puzzling geographical or rather ethnic repartition is not well understood but is probably linked to a founder effect in certain ethnic groups, followed by the persistence of a high viral transmission rate due to favorable local environmental and cultural situations. Interestingly, in all the highly endemic areas, and despite different socioeconomic and cultural environments, HTLV-1 seroprevalence increases gradually with age, especially among women. This might be either due to an accumulation of sexual exposures with age, or due to a cohort effect.

The worldwide infected population is estimated around 15–20 million. Two to ten percent of infected persons will develop an HTLV-1-associated disease (ATLL, HAM/TSP, uveitis, infective dermatitis, etc.) during their life (**Table 1**). Three modes of transmission have been demonstrated for HTLV-1: (1) Mother to child transmission, which is mainly linked to prolonged breastfeeding after 6 months of age. Ten to twenty-five percent of the

Table 1 Diseases associated with HTLV-I infection

Adult disease	*Association*
Adult T-cell leukemia/lymphoma	++++
Tropical spastic paraparesis/HTLV-I-associated myelopathy	++++

Adult T-cell leukemia/lymphoma (very rare)	++++
Persistent lymphadenopathy	++

The strength of association is based on epidemiological studies as well as molecular data, animal models, and intervention trials. ++++, proven association; +++, probable association; ++, likely association; +, possible association.
SIBM: sporadic inclusion body myositis.

breast-fed children born from HTLV-1 infected mothers will become persistently infected. (2) Sexual transmission, which mainly occurs from male to female, and is thought to be responsible for the increased seroprevalence with age in women. (3) Transmission with contaminated blood products (containing infected lymphocytes), which is responsible for an acquired HTLV-1 infection among 15–60% of the blood recipients.

From a molecular point of view, HTLV-1 possesses remarkable genetic stability, an unusual feature for a retrovirus. Viral amplification via clonal expansion of infected cells, rather than by reverse transcription, could explain this striking genetic stability, which can be used as a molecular tool to follow the migrations of infected populations in the recent or distant past and thus to gain new insights into the origin, evolution, and modes of dissemination of such retroviruses and their hosts. The few nucleotide substitutions observed among virus strains are indeed specific to the geographic origin of the patients rather than the pathology. Four major geographic subtypes (genotypes) have been reported. The origin of most of these geographic HTLV-1 subtypes appears to be linked to episodes of interspecies transmission between STLV-1-infected monkeys and humans, followed by variable period of evolution in the human host.

Adult T-Cell Leukemia/Lymphoma

Epidemiological Aspects

After the initial discovery and characterization of ATLL in Japan, the disease was reported in the USA and in Caribbean immigrants living in the United Kingdom. ATLL cases have now been reported in all HTLV-1 endemic areas including intertropical Africa, South and Central America, Iran, and Melanesia. Sporadic cases were also described in areas of low HTLV-1 endemicity, often in immigrant patients originating from regions where HTLV-1 is endemic. In Japan, the ATLL incidence rate shows a steep increase with age, the mean age of disease onset being 57 years old and the sex ratio (male/female) being 1.4. In Japan, the annual incidence of ATLL cases is approximately 700, while the number of HTLV-1 carriers reaches 1.2 million. This gives an estimated yearly incidence of ATLL of 0.6–1.5 for 1000 HTLV-1 carriers older than 40. Lastly, the additive life-time risk of developing ATLL was estimated to be 1–5 % among Japanese HTLV-1 carriers. Studies performed in Brazil, Gabon, and French Guyana concluded that ATLL prevalence is usually underestimated until a specific disease research is performed. This is mostly due to the severity of the disease, its rapid evolution, and to confusion between ATLL and similar diseases, such as Sézary's syndrome, Mycosis fungoides, or other T cell non-Hodgkin lymphomas. In addition, laboratory tests such as Western blot and molecular investigations are not easily available in most tropical countries.

Diagnosis Criteria and Classification

Because of the extensive diversity in the clinical presentation and evolution of the disease, Japanese clinicians and researchers have defined stringent diagnosis criteria for ATLL as well as a classification into four major subtypes (**Table 2**). These diagnostic criteria are the following: (1) Histologically and/or cytologically proven lymphoid malignancy with expression of specific T-cell surface antigens (mostly CD2+, CD3+, and CD4+). (2) Abnormal T lymphocytes (flower cells and small/mature T lymphocytes with incised or lobulated nuclei) present in the peripheral blood, except in the ATLL lymphoma type. (3) Antibodies against HTLV-1 antigens present in the patient's serum at diagnosis.

The four major subtypes, as defined by the Japanese lymphoma study group, are the smoldering, the chronic, the lymphoma, and the leukemic/acute form. Both chronic and smoldering types can progress toward the acute or lymphoma forms. This classification was proved to be useful to discriminate ATLL from other type of leukemias/lymphomas. Patients who develop the smoldering form and about 30% of those suffering of the chronic ATLL have a fairly 'good prognosis' as compared to those with a leukemic or lymphoma type whose survival median does not exceed 6–9 months (**Table 2**). Finally, criteria for determining the diagnosis of ATLL during epidemiological studies have also been proposed (**Table 3**).

Table 2 Diagnostic criteria for clinical subtype of HTLV-I associated ATLL

	Smouldering	*Chronic*	*Lymphoma*	*Acute*
Anti-HTLV-I antibody	+	+	+	+
Lymphocyte ($\times 10^3/\mu l$)	< 4	≥ 4[a]	< 4	*
Abnormal T lymphocytes	$\geq 5\%$[c]	+[b]	<1%	+[b]
Flower cells of T cell marker	#	#	No	+
LDH	$\leq$1.5N	$\leq$2N	*	*
Corrected Ca (mEq/liter)	< 5.5	<5.5	*	*
Histology-proven lymphadenopathy	No	*	+	*
Tumor lesion				
Skin and/or lung	*[c]	*	*	*

Clinical, Cytological, and Immuno-Virological Features

The predominant clinical findings of ATLL at onset are lymphadenopathy, hepatomegaly, splenomegaly, specific skin lesions, and hypercalcemia (**Table 4**). The symptoms may include abdominal pain, diarrhea, pleural effusion, ascites, and cough. White blood count ranges from normal up to a very high number of abnormal peripheral blood lymphocytes, especially in acute and chronic ATLL patients, while anemia, neutropenia, or thrombocytopenia are occasionally observed. ATLL cells differ in size and characteristics, depending on the subtype. As an example, at the typical acute/leukemic stage, most abnormal cells exhibit multilobulated nuclei and are named 'flower cells' (**Figure 1**). At the terminal stage, cells often significantly vary in size. They display a cytoplasmic basophilia and a marked nuclear lobulation. Chronic ATLL cells are generally small and of uniform shape with minor nuclear abnormalities such as indentation or convolutions. Smoldering ATLL cells are often relatively large with a bi- or trifoliate nucleus.

Most ATLL cells are mature T cells of helper/inducer phenotype (CD2+, CD3+, CD4+, CD7–, CD8–) and express activation markers (CD25+, HLA DP+, DQ+, DR+). CD4– and CD8– ATLL cells are uncommon, but a decrease of the CD3/T cell receptor expression is frequent. Changes in cell activation marker expression (CD4+CD8– to CD4+CD8+) have been observed in some patients during the course of the disease. Lymph-node histology analysis frequently demonstrates infiltration by medium and large T cells with irregular nuclei effacing the nodal architecture. This is consistent with the diagnosis of pleiomorphic large T-cell lymphoma. However, there is no specific histological pattern for ATLL.

Cytogenetic abnormalities are not specific for ATLL, but are frequently reported in acute and lymphoma patients. They include chromosome 14 translocations (14q 32, 14q 11) and 6q deletions. Trisomy 3, 7, and 21 as well as X chromosome monosomy or the loss of the Y chromosome were also reported. Mutations in the p53 encoding tumor-suppressor gene are detected in 20–30% of all patients, mostly those in advanced stages, suggesting the involvement of p53 mutation in a late phase of leukemogenesis, or as a consequence of the cellular transformation.

Detecting (by Southern blot) the clonal integration of HTLV-1 provirus(es) in the tumor cells represents the gold-standard for establishing that a patient suffers from ATLL (**Figure 2**). In most cases, only one copy of the provirus is integrated in the tumor cells. Nevertheless, two or more proviruses can infrequently be detected (5–20% of all ATLL cases). It is also worth noting that 5–20% of ATLL patients carry defective HTLV-1 proviruses. The 3′pX region is commonly conserved, while deletions occur frequently in *gag*, *pol*, and/or *env* open reading frames. Inverse-PCR, a technique that is more sensitive

Table 3 Registry criteria for definition of ATLL

Definition of ATLL	
Clinical/routine laboratory criteria	
Hypercalcemia	1 point
Skin lesions[a]	1 point
Leukemic phase[b]	1 point
Research laboratory criteria	
T-cell lymphoma or leukemia	2 points
HTLV-I antibody	2 points
TAC-positive tumor cells	1 point
HTLV-I-positive tumors[c]	2 points
ATLL classification	
Classical	≥7 points
Probable	5 or 6 points
Possible	3 or 4 points
Inconsistent with ATLL	<3 points
Exclusion criteria	
B-cell positivity, nodular or follicular lymphoma, lymphoblastic lymphoma, small lymphocytic lymphoma	

[a]Lymphomatous cells documented morphologically.
[b]More than 2% abnormal lymphocytes.
[c]Determined by PCR or Southern blot analysis of the DNA of tumoral cells and indicating a monoclonal integration of HTLV-1 provirus(es).

Table 4 Main clinical features of ATLL

	Japan[a]	*Caribbean*[b]
Age at onset	58 years (range 27–82)	47 years
Sex ratio male/female	1.4	0.6
Lymphadenopathy	60%	70%
Hepatomegaly	26%	27%
Splenomegaly	22%	31%
Specific skin lesion	39%	41%
Hypercalcemia	32%	51%

[a]Based on a series of 187 Japanese patients and
[b]from a series of 57 patients, with 46 of Carribbean origin , seen in the United Kingdom.

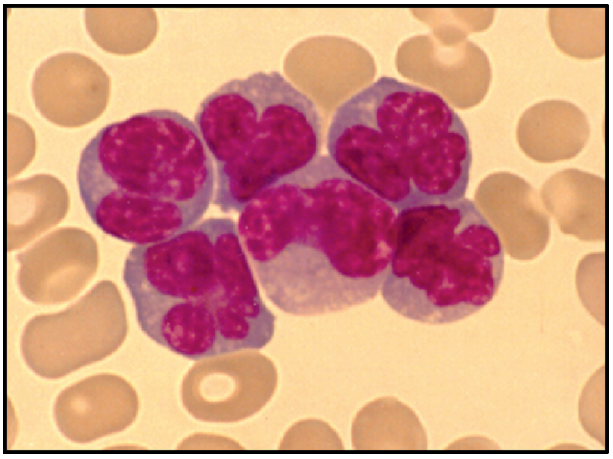

Figure 1 Peripheral blood smear from a Caribbean ATLL leukemic patient showing a cluster of atypical lymphoid cells with multilobulated nuclei (May-Grunwald-Giemsa staining).

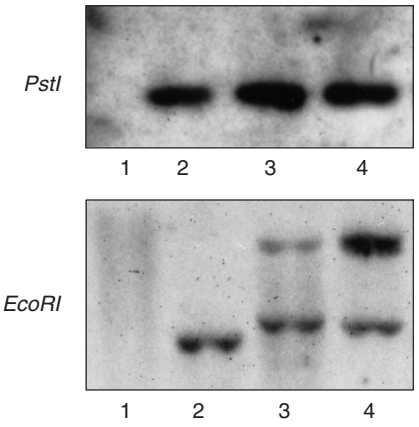

Figure 2 HTLV-1proviral integration as detected by Southern blot analysis. High molecular weight DNA was extracted from (1) negative control peripheral blood mononuclear cells and (2, 3, 4) from peripheral leukemic cells obtained from three different HTLV-1 patients diagnosed with ATLL. Because *EcoRI* restriction sites are absent from HTLV-1 provirus sequence, the observation of two bands (lane 3 and 4) demonstrates the clonal integration of two proviruses in the DNA of the leukemic cells.

than Southern blot is currently used for diagnosis of the monoclonal integration of HTLV-1 provirus(es) in the tumoral cells. Using this technique, oligoclonal or polyclonal proliferation of HTLV-1 infected T cell can also be detected in the peripheral blood lymphocytes of most HAM/TSP patients as well as in healthy HTLV-1 seropositive carriers. This also allows the precise identification of integration sites, the identification of each infected clone, and the tracing of the kinetics of the infected cells *in vivo*. The detection of persistent HTLV-1 infected monoclonal cell population could therefore be used as a method for monitoring individuals at risk for developing ATLL. Importantly, monoclonal expansion of HTLV-1 infected cells in carriers is directly associated with the onset of ATLL.

Specific Features and Complications

Hypercalcemia is very common among ATLL patients. It is detected in 20–30 % of the patients at admission and in more than 70 % of them during the entire clinical course, with or without lytic bone lesions. *In vitro*, ATLL cells induce the differentiation of hematopoietic precursor cells to osteoclasts through the expression of the RANKL (receptor activator nuclear factor kB) ligand on their surface, in cooperation with elevated M-CSF (mononuclear

phagocyte colony-stimulating factor) serum levels. This accelerates bone resorption and ultimately causes hypercalcemia. The degree of hypercalcemia might also be linked to the expression of the parathyroid hormone-related protein (PTHrP), since PTHrP also induces RANK ligand expression on osteoblasts.

Skin infiltration of a clonal population of HTLV-1 tumor cells represents a frequent ATLL clinical feature. It is present in 20–40% of all ATLL patients and in more than 50% of smoldering ATLL patients. Various cutaneous lesions have been described including papules, nodules, erythroderma, plaques, tumors, and ulcerative lesions. ATLL cells densely infiltrate both dermis and epidermis forming Pautrier's micro-abscesses. When skin lesions dominate the clinical picture, the disease is referred to as 'cutaneous ATLL' (**Figure 3**). In such cases, establishing the difference between these lesions and other cutaneous T-cell lymphomas (CTCLs) is complicated. A possible role of CCR4 (CC chemokine receptor 4) in skin invasion by ATLL cells has been suggested. Other factors such as expression of cutaneous lymphocyte antigen (CLA) by leukemic cells and inflammatory responses in injured skin that would lead to upregulation of thymus and activation-regulated chemokine (TARC) and macrophage-derived chemokine (MDC) are also likely to contribute to skin involvement of ATLL.

ATLL is also known to frequently invade the gastrointestinal tract, even though the exact incidence has not been determined yet. CCR9 is known to be involved in T-cell homing to the gastrointestinal tract. A recent study demonstrated that CCR9 is expressed by HTLV-1 T cells and ATLL cells expressing Tax and suggested that it may play a role in the gastrointestinal involvement of ATLL.

The frequency of opportunistic infections is quite high in ATLL patients, indicating that T-cell-mediated immunity is severely impaired in such patients. Infestation by *Strongyloides stercoralis* (*S.s*) is frequent among HTLV-1 seropositive carriers and *S.s* infected individuals are often infected by HTLV-1 in highly endemic areas. Numerous studies showed the presence of *S.S* in acute or lymphoma ATLL, suggesting that infection by *S.S* might play a significant role as a candidate cofactor for HTLV-1 induced leukemogenesis.

Pulmonary complications are also frequent in ATLL patients. These are either leukemic infiltrate or opportunistic infections. Central nervous system localization rarely occurs in ATLL (10%).

ATLL Pathogenesis

The development of an ATLL has been clearly associated with an early acquired HTLV-1 infection. The risk of being infected for a child born from an HTLV-1 infected mother is positively correlated with prolonged (>6 months) breastfeeding. After a limited number of replication cycles using its reverse transcriptase during primary infection, HTLV-1 replicates and increases its copy number through the proliferation of infected cells, thus using the cellular DNA polymerase which possesses a proofreading activity. Such a model could explain, in part, the very high genetic stability of HTLV-1. The clonal proliferation of the HTLV-1-infected CD4+ lymphocytes is likely to be linked to the pleiotropic effects of the viral Tax protein. *In vitro*, Tax expression induces expression of several cellular cytokines such as IL-2, IL-15, but also alters the cell-cycle control machinery, inhibits apoptosis, and promotes genetic instability. As seen above, the fact that oligo/monoclonal-infected cell populations are present in the PBMCs of HTLV-1 carriers or of HAM/TSP patients suggests that neither

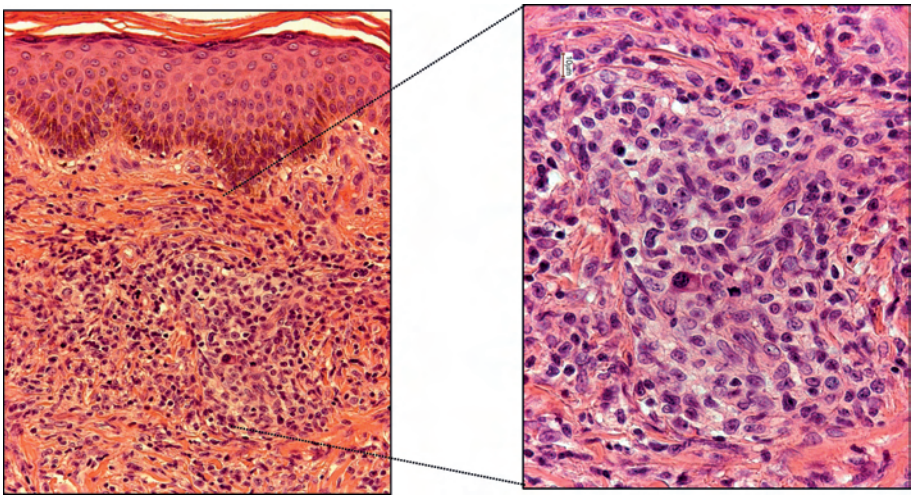

Figure 3 Histological analysis of skin invasion in an HTLV-1 patient from West Africa with a cutaneous ATLL showing an infiltration of the dermis by tumoral pleomorphic cells. These tumor cells are mature activated lymphoid T cells (CD2+, CD3+, CD4+, CD8–, and CD25+). Kindly provided by Dr. Michel Huerre, Institut Pasteur, Paris.

the monoclonal integration of the virus nor the CD4+ cell proliferation *per se* is sufficient to cause the disease. *In vivo*, the level of Tax expression is still debated. Several observations paradoxically suggested that HTLV-1 was transcriptionally silent *in vivo*, but it was shown lately that a high proportion (10%–80%) of naturally infected CD4+ peripheral blood mononuclear cells isolated from HAM/TSP patients or from HTLV-1 asymptomatic carriers are capable of expressing Tax *ex vivo*. It was also demonstrated that autologous $CD8^+$ T cells rapidly kill CD4+ cells that express Tax *in vitro* through a perforin-dependent mechanism. Altogether, these results suggest that virus-specific cytotoxic T lymphocytes (CTLs) participate in a highly efficient immune surveillance mechanism that tirelessly eradicates Tax-expressing HTLV-1-infected CD4+ T cells *in vivo*. Such CTL control of the HTLV-1-infected cell proliferation may also result in the prevention of ATLL. The role of the genetic background, especially HLA haplotypes, in such control could be crucial. A final step toward ATLL leukemogenesis consists in the accumulation of alterations in the host genome due to the pleiotropic effects of Tax (**Figure 4**).

Therapeutic Aspects of ATLL

The survival rate of ATLL patients, especially those who develop the acute leukemic or lymphoma forms, remains poor, and ATLL remains therefore one of the most severe lymphoproliferations. Treatment of ATLL patients using conventional chemotherapy (CHOP) has been and remains in most cases the standard first-line therapy. It has very limited benefit, since HTLV-1 cells are resistant to most apoptosis-inducing agents. A historical Japanese survey based on 818 ATLL cases reported a median survival time of 9 months, with a survival rate of only 27% and 10% at 2–4 years respectively. Survival is different when subtypes are considered into account, with a 4-year survival rate of 66% for the smoldering type, of 27% for the chronic type and of 5–6% for the lymphoma and acute types. Spontaneous regressions are observed in very few cases. The main prognosis factors associated with a poor response and a poor survival rate in ATLL patients are: a high LDH (lactate dehydrogenase) value, high leukemic counts (both of them reflecting a high tumor burden), hypercalcemia, and a poor clinical performance. Furthermore, the main obstacles to an efficient response to treatment are infectious complications (*pneumocystis carinii*, *cryptococcus meningitis*, disseminated herpes zoster), hypercalcemia, and liver or kidney dysfunction.

Various strategies other than CHOP have been used during clinical trials. This includes combination chemotherapy (CHOP plus methotrexate, CHOP in combination with etoposide, vindesine, ranimustine, mitoxantrone, or adriamycin), granulocyte macrophage-colony-stimulating factor (GM-CSF), supported combination chemotherapy, and other chemotherapy treatments that are highly toxic for bone marrow. Zidovudine (AZT) has been shown to inhibit HTLV-1 transmission *in vitro*. Several studies with AZT and interferon-alpha (IFN-α) have been conducted, both in the USA and in Europe (France and UK). They all demonstrated that response and survival in patients is more efficient when the drugs are used as first-line therapy. Until recently, the mechanism of action of AZT was a matter of debate. A recent study convincingly demonstrated that AZT can act as an inhibitor of the telomerase functions. More importantly, it was also shown that the p53 status

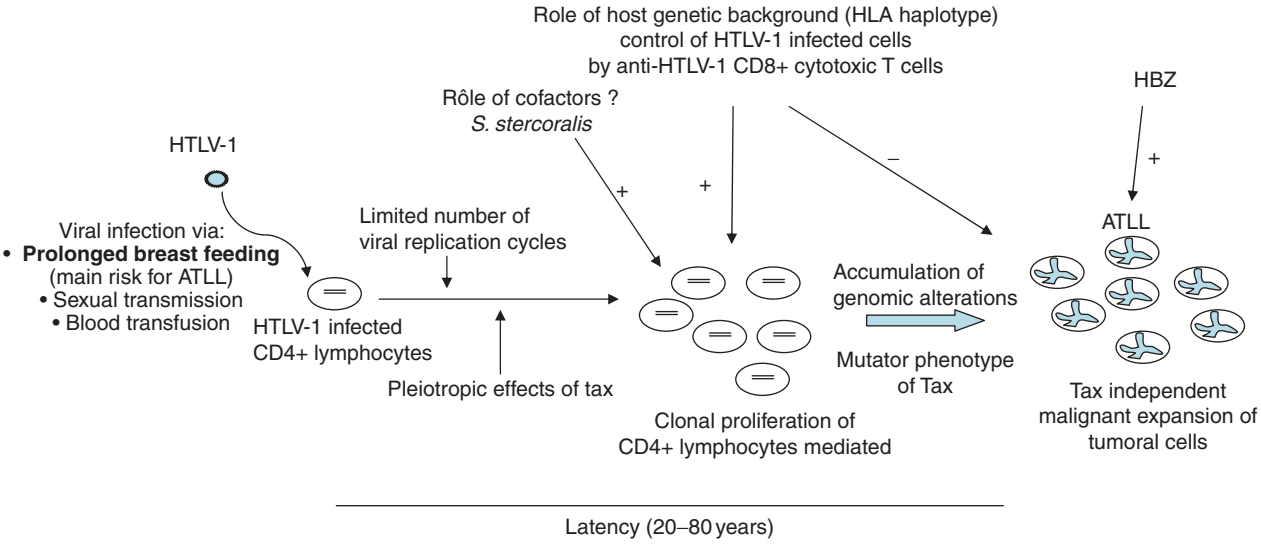

Figure 4 Pathogenesis of ATLL. Natural course from HTLV-1 primary infection by prolonged breast-feeding to the onset of the malignant proliferation of ATLL cells. HBZ: HTLV-1 bZIP factor. Adapted from Mahieux R and Gessain A (2003) HTLV-1 and associated adult T-cell leukemia/lymphoma. *Reviews in Clinical and Experimental Hematology* 7: 336–362.

(wild-type or mutated) is predictive of the response to AZT. Nuclear factor kappa B (NF-κB) inhibitor (Bay 11–7082) was found to be efficient for preventing the tumor growth in NOD-SCID (non-obese diabetic-severe combined immunodeficiency/gamma (null)) animals previously inoculated with HTLV-1 infected cells. Proteasome inhibitor PS-341 (Bortezomib) alone or combined with anti-CD25 (anti-Tac) therapy was partially successful in treating NOD/SCID animals or Tax transgenic mice. Allogenic bone marrow transplantation as well as allogenic hematopoietic stem cells transplantation have been performed on a limited number of patients. The estimated overall survival seems to compare favorably with historical data on chemotherapy, but definitive assessments are difficult to establish.

Tropical Spastic Paraparesis/HTLV-1 Associated Myelopathy

Spastic paraparesis without evidence of spinal cord compression has been described from various tropical and intertropical areas such as the Caribbean region, South and Central Africa, and India. Apart from cassava-related myelopathy and/or malnutrition in several African regions, lathyrism in India, and some infectious processes, the etiology of numerous spastic meylopathies remained elusive until 1985. The demonstration by our laboratory of the association between HTLV-1 and a form of tropical spastic paraparesis (TSP) of Unknown etiology, frequent in Martinique (French West Indies), led to the evaluation of the role of this oncoretrovirus, in this disease. Such an association was rapidly confirmed in Colombia and Jamaica. A year later, the association of HTLV-1 with a chronic spastic myelopathy of unknown etiology was documented in southern Japan, and this clinical entity was named HTLV-1 associated myelopathy (HAM). Soon after, it was recognized that HTLV-1-associated TSP and HAM were the same disease, the hybrid term HAM/TSP was adopted and WHO diagnostic criteria were established.

Hundreds of HAM/TSP patients have now been described in several HTLV-1 endemic areas, including Japan, several of the Caribbean islands (especially Jamaica, Trinidad, Martinique, Haiti), numerous countries of South and Central America (Brazil, Peru, Colombia), of Central and South Africa, as well as in Iran. Sporadic cases of HAM/TSP have also been described in Melanesia, in West African countries as well as in immigrants from high HTLV-1 endemic areas living in Europe and the USA. In Japan, the life-time risk among HTLV-1 carriers is estimated to be less than 2%, that is, lower than ATLL. HAM/TSP mainly occurs in adults, with a mean age at onset of 40–50 years, but some rare cases of HAM/TSP in children have been reported. In Japan, in contrast to ATLL, HAM/TSP is more common in women than in men at all ages, with a sex ratio (M/F) of around 1:2,3.

Diagnostic Criteria

Initially, HAM/TSP diagnostic criteria included: (1) chronic spastic paraparesis, which usually slowly progresses, with signs of bilateral pyramidal tract lesions manifested by increased knee reflexes, ankle clonus, and extensor plantar responses; (2) minor sensory signs of involvement of the posterior columns and spinothalamic tract; (3) a history of insidious onset with gait disturbance without an episode of complete remission; (4) no evidence of spinal cord compression or swelling on magnetic resonance imaging, myelography, or computed/tomographic scan; and (5) presence of specific anti-HTLV-1 antibodies in the serum and the cerebrospinal fluid (CSF).

In more than 90% of the cases, the neurological features of HAM/TSP involve: spasticity and/or hyperreflexia of the lower extremities, urinary bladder disturbance, lower extremity muscle weakness, and in around 50% of the cases, sensory disturbances with low back pain. Impotence is also frequent. Central functions and cranial nerves are usually spared. The evolution is generally chronic and progressive, and after 10 years of evolution, roughly 50% of the patients are wheel-chaired. The incubation period (between primary infection which occurs mainly in adults) to onset of the myelopathy signs ranges usually from years to decades, but HAM/TSP also developed within 3.3 years in 50% of the post-transfusion-associated cases.

Biologically, besides high level of antibodies directed against HTLV-1 antigens both in blood and CSF, ATLL-like cells can sometimes be detected on the blood smear and in the CSF. Furthermore, a high HTLV-1 proviral load is frequently observed in the peripheral blood lymphocytes from HAM/TSP patients. A mild to moderate increase of proteins may be present in the CSF. However, intrathecal production of specific antibody provides additional data to support the diagnosis of HAM/TSP and also contributes to eliminate other differential diagnoses. Multiple spotty high intensities in deep and subcortical areas on T2-weighted images are the most frequent findings in brain magnetic resonance imaging. A mild atrophy of the thoracic spinal cord can also be observed in few cases. From a pathological point of view, this neurological syndrome is characterized by a chronic inflammation with perivascular lymphocytic cuffing and mild parenchymal lymphocytic infiltrates (**Figure 5**(**a**)). The cells are mostly CD4+ in early disease and mostly CD8+ in latter disease. Pyramidal tract damage with myelin and axonal loss, mainly in the lower thoracic spinal cord are observed.

HAM/TSP can be associated with other HTLV-1-associated symptoms such as uveitis, myositis, pulmonary alveolitis, and arthritis. The coincidence of ATLL and HAM/TSP has been rarely reported.

Recently, a large group of neurologists established a proposal for a modification of the diagnostic criteria of

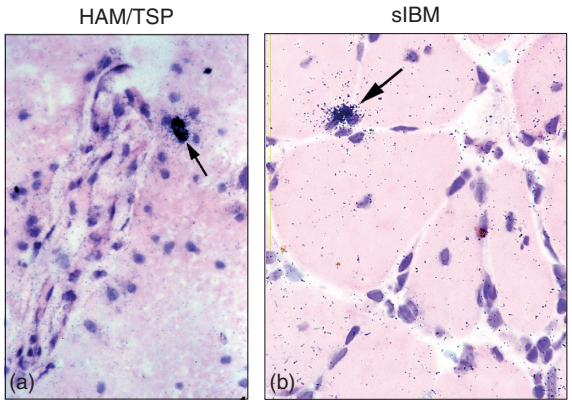

Figure 5 Detection of HTLV-1 *mRNA* expression by *in situ* hybridization with a ^{33}P *Tax* antisense riboprobe, on (a) frozen section from thoracic cord of a HAM/TSP patient, and (b) from a muscle section of a patient with an HTLV-1-associated sporadic inclusion body myositis (sIBM). Adapted from Ozden S, Seilhean D, Gessain A, Hauw J-J, and Gout O (2002) Severe demyelinating myelopathy with low human t cell lymphotropic virus type 1 expression after transfusion in an immunosuppressed patient. *Clinical Infectious Diseases* 34: 855–860 and Ozden S, Cochet M, Mikol J, *et al*. (2004) Direct evidence for a chronic CD8+-T-cell-mediated immune reaction to tax within the muscle of a human T-cell leukemia/lymphoma virus type 1-infected patient with sporadic inclusion body myositis. *Journal of Virology* 78: 10320–10327.

HAM/TSP. This was due to the fact that in some patients, especially those with early disease, HAM/TSP can be suspected but the complete WHO criteria are not met. These authors suggest that a HAM/TSP definite case corresponds to a nonremitting progressive spastic paraparesis with sufficiently impaired gait to be perceived by the patient. Sensory symptoms or signs may or may not be present. When present, they remain subtle and without a clear-cut sensory level. Urinary and anal sphincter signs or symptoms may or may not be present. Biologically, presence of HTLV-1 antibodies in serum and CSF confirmed by Western blot and/or a positive polymerase chain reaction (PCR) for HTLV-1 in blood and/or CSF should be demonstrated. Lastly, exclusion of other disorders that can resemble HAM/TSP is necessary.

HAM/TSP Pathogenesis

The pathogenesis of HAM/TSP is still poorly understood and viral and host factors as the proviral load and the immune response are considered to play a major role in disease progression. It remains unknown if the myelin and axonal loss, observed in HAM/TSP lesions, is a primary or secondary process and if it results from a direct viral effect or from an immune mediated process, as suggested by the marked lymphocytic infiltrates. Viral infection as demonstrated by *in situ* hybridization against *tax* mRNA has been clearly identified in some infiltrates by CD4+ lymphocytes by several teams, while the presence of HTLV-1 in neurons or oligodendrocytes remains controversial but unlikely.

At least three mechanisms have been proposed to explain the role of HTLV-1 in HAM/TSP development. The neurological damage is, in the first model, a direct consequence of the destruction by an antiviral attack mediated by cytotoxic T lymphocytes. These CTLs, frequent in HAM/TSP patients, both in the peripheral blood and CSF, are directed against HTLV-1 antigens, especially some immuno-dominant Tax epitopes expressed by HTLV-1-infected cells. In a second model, an autoimmune response could be due to either a chronic peripheral activation of autoreactive T cells by HTLV-1 infection, with infiltration of T lymphocytes into the CNS, or to a molecular mimicry, which could impair the immunological tolerance to the myelin antigens. A third possibility would be the bystander damage hypothesis. In this model, activated CD4+ T cells infected by HTLV-1, activated microglia, and CD8+ T cells could release into the spinal cord some myelinotoxic cytokines such as TNF-α or could directly damage the glial cells.

Therapeutic aspects of HAM/TSP

The long-term prognosis of HAM/TSP remains severe with a chronic evolution of a progressive disabling disorder without remission. Furthermore, its secondary complications may eventually lead to death, in some cases, after several years of evolution. Many small studies and cohort data have been performed using, among other drugs, corticosteroid therapy, danazol, vitamin C, interferon alpha, zidovudine, with very limited success. Recently, a randomized trial with zidovudine plus lamivudine has also been performed. Globally, a few short-term benefits have been observed, especially in early disease, but no treatment has been successful in chronic advanced disease. Failure to detect any clinical improvement is believed to be due to irreversible central nervous system damage in such patients. New controlled studies of both antiviral and anti-inflammatory agents are urgently required.

HAM/TSP is probably not the only neurological disorder associated with HTLV-1 infection. Indeed, an amyotrophic lateral sclerosis-like syndrome, as well as some peripheral neuropathies, and mild cognitive deficits have been described in some patients with HTLV-1 infection. It remains however difficult to prove a true association between such diseases and HTLV-1 infection, especially in high HTLV-1 endemic areas.

Infective Dermatitis

Infective dermatitis (ID) is a rare dermatological condition that was originally described in Jamaican children by Sweet in 1966. Subsequently, in 1990, La Grenade *et al.*

linked ID to HTLV-1 infection. A large series of patients with infective dermatitis have been described in Jamaica and more recently in Brazil. However sporadic cases of this clinical entity have also been reported in many other HTLV-1 endemic areas including Trinidad, Colombia, French West-Indies and French Guyana, Japan (where the disease seems very rare), and recently in Senegal (West Africa). In the great majority of cases, ID occurs in children from low socioeconomic backgrounds.

Infective dermatitis is a unique clinical entity characterized by a chronic and severe exudative dermatitis involving mainly the scalp, external ear and retroauricular areas, eyelid margins, paranasal skin, neck, axillae, and groin (**Figure 6**). Other symptoms include a chronic watery nasal discharge without other signs of rhinitis and/or crusting of anterior nares. A generalized fine papular rash is common in most of the severe cases. Clinically, the two differential diagnoses are atopic dermatitis and seborrheic dermatitis. In infective dermatitis, positive cultures for *Staphylococcus aureus* and/or beta-haemolytic streptococci are frequent from the anterior nares and skin samples. The evolution is typically chronic with relapse and several flares of superinfected lesions. Infective dermatitis responds well to antibiotic treatment, especially co-trimoxazole. However, relapse is very common if antibiotics are withdrawn. Infective dermatitis occurs mainly in young children (range 1–12 years), with an average age of onset of 2–6 years depending on the studies. Around 60% of the cases occur in girls. Anemia is frequent with a raised erythrocyte sedimentation rate and a hyper-immunoglobulinemia (IgD and IgE). The CD4 count, as well as the CD4/CD8 ratio, are elevated. Presence of rare ATLL-like cells is common in the peripheral blood. Pathological examination revealed an inflammatory lymphocytic infiltrate within the skin lesions. Epidemiological studies with long-term follow-up of ID patients have indicated that such disease may be associated with the later development of ATLL or of HAM/TSP. In a recent series from Brazil, neurological examination diagnosed six HAM/TSP cases among 20 children and adolescents with ID.

Figure 6 A 3-year-old boy from West Africa with infective dermatitis lesions: erosive dermatitis of the eyebrows, abscess of the scalp, and nasal discharge. Adapted from Mahe A, Meertens L, Ly F, *et al.* (2004) Human T-cell leukemia/lymphoma virus type 1-associated infective dermatitis in Africa: A report of five cases from Senegal. *British Journal of Dermatology* 150: 958–965.

Mothers of children with ID are nearly always infected by HTLV-1. Furthermore, they have breastfed their child for a long period of time (mean 20 months). Thus, nearly all ID children were infected by their mothers. This implies that reduction of HTLV-1 transmission from mother to child would be likely to prevent the occurrence of such disease as well as of ATLL. Such preventive medicine, currently performed in several areas of high HTLV-1 endemicity (Japan, West Indies), is based on HTLV-1 screening programs during pregnancy followed by adequate counseling that is adapted to the socioeconomic situation of each infected mother. The pathogenesis of ID is unknown but environmental, as well as host genetic factors are very likely involved in its occurrence.

Myositis

Myositis is an inflammatory myopathy that is represented by a heterogeneous group of muscle disorders. It is characterized by an acquired muscle weakness and inflammatory infiltrates of the muscle tissues. Depending on the clinical and histological features, myositis can be classified into dermatomyositis, polymyositis, and inclusion-body myositis. In 1989, Morgan *et al.* reported for the first time that 11 out of 13 Jamaican patients with idiopathic adult polymyositis were seropositive for HTLV-1. Later on, several epidemiological studies conducted in Jamaica, Martinique, and Japan, and based on larger series of patients, also indicated a higher prevalence of HTLV-1 antibodies in polymyositis patients as compared to that of the general population. Such data suggested a possible link between HTLV-1 and polymyositis. Lately, several sporadic cases of polymyositis, occurring in HTLV-1 infected patients of various origins, have been reported.

HTLV-1-associated polymyositis is a chronic disease that occurs mainly in adults 30–50 years of age. Patients complain mainly of musculo-skeletal symptoms including myalgia, joint and back pain, and proximal muscle weakness with muscle atrophia and falls. The four limbs can be affected. A patient's clinical pattern typically displays an elevation of muscle enzymes, especially creatine phosphokinase (CPK), and significant electromyographic abnormalities. Histological findings indicate an inflammatory myopathy with an increased variation in the fiber size and a mononuclear infiltrate located both between and within muscle cells, which appear often degenerate and necrotic. Muscle regeneration may also be present. This infiltration

is mainly due to T lymphocytes (both CD4+ and CD8+), but macrophages are also present. Expression of HTLV-1 *mRNAs* as well as of the viral proteins can be sporadically detected within the infiltrating T lymphocytes but not within muscle fibers. T-cell clones that are specifically directed against HTLV-1 Tax epitopes proliferate within the muscle lesions and may thus contribute to the pathogenesis. Patients respond poorly to corticosteroid therapy in most cases, and there is usually no sustained effect. Of note, HTLV-1 associated polymyositis is frequently associated with HAM/TSP.

A few cases of sporadic inclusion-myositis (sIBM) have also been reported in HTLV-1-infected patients. Such a disorder is a distinct form of chronic inflammatory myopathy for which a viral etiology has often been suspected. The lesions are characterized by vacuolated fibers that contain paired helical filaments similar to those of Alzheimer's diseases (**Figure 5(b)**). Immunohistochemical staining for ubiquitin may help to differentiate sIBM from polymyositis. sIBM can be associated with HAM/TSP.

Uveitis

Uveitis is an intraocular sight-threatening inflammatory disorder that can be caused by various infections, including tuberculosis, syphilis, toxoplasmosis, and cytomegalovirus. Uveitis, which does not have an infectious etiology, can occur in Bechet's diseases, Vogt–Koyanagi–Harada disease, and sarcoidosis. In roughly 40%, no cause can be identified and such disease is classified as idiopathic or unexplained uveitis. In the early 1990s, epidemiological studies demonstrated a higher prevalence of such idiopathic uveitis in HTLV-1 endemic areas from southern Japan than in areas where HTLV-1 has a lower prevalence. At the same time, some cases of uveitis were also observed in HAM/TSP patients. A large seroepidemiological study led by Mochizuki *et al.*, finally demonstrated without ambiguity that HTLV-1 infection was associated with idiopathic uveitis.

This clinico-virological entity is more frequent in females (around 60%) and the average onset age of the disease is 45 years, with few cases occurring in children. The major symptoms at initial presentation include sudden onset of occular floaters, foggy, and/or blurred vision. Unilateral disease is more common than bilateral (60% vs. 40%). The ocular signs consist mainly of iritis, vitreous opacities, and retinal vasculitis. Retinal exudates and hemorrhages are less frequent. Intermediate uveitis is more frequent than anterior or posterior lesions. Interestingly, co-morbid conditions include Graves disease and HAM/TSP. HTLV-1 uveitis responds well to topical and/or systemic corticosteroids and the intra-occular inflammation is markedly improved after steroid therapy. The visual prognosis is good in most cases. However, the inflammation tends to recur in about half of the cases. A specific opthalmological and systemic evaluation is necessary to eliminate other causes of uveitis in a given HTLV-1 infected individual. HTLV-1 antibodies are present in the aqueous humor at a level similar to that found in the plasma. HTLV-1-infected lymphocytes can be detected in the anterior chamber of the eye. Cytokines such as IL-6 and TNF-α produced by infiltrating lymphocytes are considered to play a major role in HTLV-1-associated uveitis pathogenesis. Infra-clinical uveitis can be detected through systematic examination in some HTLV-1 infected persons without any ocular symptoms.

Other Ocular Lesions Associated with HTLV-1 Infection

Kerato-conjonctivitis/sicca as well as interstitial chronic keratitis, are observed in HTLV-1 infected individuals, especially in HAM/TSP patients. The latter keratitis is also frequently associated with uveitis.

Hypovirulence

N K Van Alfen and P Kazmierczak, University of California, Davis, CA, USA

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Ascomycete A division of fungi whose members produce spores in a saclike structure called the ascus.
Canker A dead section of bark on the branches or main trunks of trees.
Hyphae Vegetative growth structures of the fungus.
Hypovirulence A reduction of virulence.

Fungal Viruses

Hypovirulence is a phenomenon that can occur in virus-infected fungi. Although fungal viruses are now known to be common and widespread within all groups of fungi, their discovery was fairly recent. It was not until the early 1960s that viruses were found in fungi, the first discovery being of viral particles that were isolated from the edible mushroom *Agaricus bisporus*. Fungal viruses became more widely known after it was discovered that strains of *Penicillium* spp., which were strong inducers of interferon, were found to be infected with a double-stranded RNA (dsRNA) virus.

Most descriptions of fungal viruses suggest that they are not normally associated with clearly defined symptoms. The lack of known infectivity cycles of fungal viruses is a major barrier to the study of these viruses since it limits the ability to demonstrate Koch's postulates. Transmission of fungal viruses is known to naturally occur only during reproduction by the formation of spores and other such structures and by cytoplasmic fusion between hyphae of different strains of the same fungus. In this respect, transmission of fungal viruses is more similar to the transmission of plasmids than it is to the transmission of other viruses, that is, the infectious agent never leaves the cytoplasmic environment. With a few exceptions, the genomic material of known fungal viruses is dsRNA, and in viruses where sequences are known, they contain a virus-associated RNA-dependent RNA polymerase (RdRp). Because fungal virus genomes are clearly viral in origin and affinity, the apparent lack of a viral-like infectivity cycle has led researchers to postulate an ancient origin for fungal viruses.

The most extensively studied fungal viruses cause symptoms that can generally be classified into three general groups of symptoms: (1) killer phenotype, (2) hypovirulence, and (3) debilitation. The killer systems consist of a helper totivirus and associated satellite dsRNAs, which encode a protein toxin that is secreted and is lethal to strains of the same fungus lacking the virus. The best studied examples of killer systems are those found in the common baker's yeast, *Saccharomyces cerevisiae*. Viruses that reduce the virulence of plant pathogenic fungi either directly, or by debilitation, are the subject of this article.

Hypovirulence

A reduction of the virulence of a plant pathogenic fungus is known as hypovirulence. Generally, anything that reduces the ability of a pathogenic fungus to grow normally

will concomitantly reduce its virulence. So, by this general definition, viruses that debilitate a pathogen cause hypovirulence. It is useful, however, to distinguish this type of debilitating hypovirulence from a symptom of virus infection that is more directly associated with reducing virulence expression and/or other developmental processes of a fungus without significant effects on fungal growth. Virus-caused hypovirulence of both types has been described in diverse groups of plant pathogenic fungi. These mycoviruses that have hypovirulence as an associated symptom may have either ssRNA or dsRNA genomes and are found in the virus families *Chrysoviridae*, *Hypoviridae*, *Narnaviridae*, *Partitiviridae*, *Reoviridae*, and *Totiviridae*.

Perturbation of Virulence/Development

Other than the viruses associated with the killer phenotype of yeast, the most extensively studied fungal virus is cryphonectria hypovirus 1 (CHV1) that infects the ascomycete *Cryphonectria parasitica*. This fungus is the causal agent of chestnut blight and is the prime example of a virus that is able to cause the hypovirulence symptom without associated debilitation. Chestnut blight was first reported in North America during the summer of 1904 in the New York City Zoological Park. It was probably imported on nursery stock of Chinese or Japanese chestnuts, *Castanea mollissima* and *Castanea crenata*, respectively. The disease rapidly spread to the American chestnut, *Castanea dentata*, growing in surrounding woodlands and forests. Within 50 years, the disease spread throughout the range of the highly susceptible native tree. Few American chestnuts now survive in their natural range because of this disease. Prior to the blight, the American chestnut was the most common tree of the Eastern deciduous forest and was found on over 200 million acres across eastern North America. This is one of the most devastating diseases of recorded history.

Chestnut blight was also accidentally introduced into Europe, but during its spread in Italy it was noticed that chestnut trees in some orchards were recovering from the disease, that is, the cankers caused by the fungus stopped spreading. When the bark was peeled back, the fungal growth was found to be confined to the uppermost layers of the bark with no penetration occurring into the living tissues of the tree. The isolates of the fungus recovered from these cankers were of low virulence in assays, so were called hypovirulent by the French plant pathologist, J. Grente. Using genetically marked virulent and hypovirulent strains of the fungus, Van Alfen and colleagues demonstrated that a cytoplasmic element found in the hypovirulent strain was responsible for the symptoms and could be transferred cytoplasmically to the virulent strain, converting it into a hypovirulent strain. This cytoplasmic element was later found to be a fungal virus that is a member of the type species of the family *Hypoviridae*. **Figure 1** shows the phenotypic differences between virulent and hypovirulent isolates of *C. parasitica* on both the chestnut tree and in culture.

C. parasitica is also host to viruses classified in several other families of viruses: these include the *Reoviridae*, *Narnaviridae*, and *Chrysoviridae*. A hypovirulent phenotype of *C. parasitica* has also been described in strains infected by the virus NB631, a mitochondrial virus classified in the family *Narnaviridae*. This virus reduces virulence and growth of the fungus somewhat, but sporulation is normal. Two reoviruses of *C. parasitica*, C18 and 9B21 have been isolated. The best characterized of the two, 9B21, reduces virulence of the fungus significantly, but sporulation and pigmentation are not significantly affected. A very

Figure 1 Phenotypic changes in *C. parasitica* caused by the hypovirus CHV1. The photograph on the right is a tree that is infected with a virulent strain of the fungus. The photograph below shows this strain in culture. In addition to producing orange/brown pigments, virulent strains produce numerous conidia in asexual fruiting bodies, both in culture and on trees. The tree on the left is infected with a fungus containing CHV1. Strains of the fungus infected with this virus typically produce superficial healing cankers that do not kill the tree. Virus-infected strains of the fungus, as shown growing in culture, are not pigmented; they remain white and produce very few asexual conidia in culture. Canker photograph courtesy of Linda Haugen, University of Georgia, http://www.forestryimages.org. Culture photograph reproduced from McCabe PM, Pfeiffer PL, and Van Alfen NK (1999) The influence of dsRNA viruses on the biology of plant pathogenic fungi. *Trends in Microbiology* 7: 377–381, with permission from Elsevier.

unusual feature of 9B21 is that purified particles of the virus are able to infect fungal protoplasts.

Hypovirulence symptoms caused by viruses have been reported in many plant pathogenic fungi. Generally these viruses remain uncharacterized and in most cases the virulence of the fungus is reduced in association with a general debilitation of the infected fungus.

Structure and Classification of CHV1

Once it was demonstrated that a cytoplasmic element caused transmissible hypovirulence of the chestnut blight fungus there was a search for a fungal virus as the potential cause. This search culminated in the report of dsRNA associated with hypovirulent strains of the fungus. Further studies of the dsRNA showed that it was associated with fungal vesicles and that no detectable capsid was associated with this dsRNA, although RdRp activity was associated with the vesicles. The dsRNA of this 12.7 kb virus was cloned, sequenced, and an infectious clone of the virus was transformed into *C. parasitica*, confirming that this virus is responsible for transmissible hypovirulence. Based on the symptoms caused by the virus it has formally been named CHV1. This virus is the type member of the family *Hypoviridae* and was the first virus family described whose members have no capsid. Comparing the genome of CHV1 with other known viruses suggested that it is most similar to plant potyviruses and other picorna-like viruses.

Further study of the nature of the RdRp associated with fungal vesicles supported the hypothesis that the genome of this virus is derived from the replicative form of an ssRNA virus that lost its capsid during evolution. The coding strand of CHV1 contains two open reading frames: ORF A encodes a polyprotein that is processed into two polypeptides, p29 and p40 and ORF B which encodes a polyprotein from which only a single 48 kDa polypeptide p48 has thus far been shown to be autocatalytically processed. The sequences contained within ORF B indicate that it also contains RNA polymerase and helicase domains. **Figure 2** shows a schematic diagram of the genomic organization and expression strategy of CHV1.

Transmission of CHV1

There is no evidence that a typical infection cycle exists in the relationship of CHV1 with its fungal host. In order for infection of new hosts to occur the virus is transmitted through cytoplasmic exchange processes of the fungus. This cytoplasmic exchange occurs during fusion of hyphae (vegetative growth structures of the fungus) that happens frequently in fungal colonies and can occur between related strains of the fungus. In fungi, this hyphal fusion is controlled by vegetative incompatibility (*vic*) genes of the fusing strains; fusions most easily occur when alleles of the *vic* genes are the same in the two fungi. In *C. parasitica*, there are six known *vic* genes that control hyphal anastomosis. The more differences that occur in the *vic* loci, the less likely that transfer of CHV1 will occur. This vegetative incompatibility reaction is a defense in *C. parasitica* and other fungi against the spread of viruses. CHV1 spreads within a population with greater success if that population has few differences in alleles at the *vic* loci. Since strains of the fungus that contain CHV1 are incapable of sexual mating, infection by the virus suppresses allelic recombination at the *vic* loci and, as a result, may increase the effectiveness of virus spread within a population over time.

Very little is known about movement of the virus within the host fungus. However, the rate of movement of dsRNA within the fungus has been measured, and is rapid. The average rate of movement of the dsRNA within a fungal colony was found to be approximately 16 mm d^{-1}. This is 3–4 times faster than the colony growth rate during the same time period. Transmission electron microscope studies on the ultrastructure of hyphal anastomosis in *C. parasitica* reported that the dsRNA containing vesicles move from hypovirulent to virulent strains within 4–6 h after anastomosis. The incompatibility reaction controlled by the *vic* genes is an imperfect defense, since virus transfer can occur despite allelic differences in *vic* genes and virus transfer has been reported between different species of *C. parasitica*. There is clearly much left to be learned about virus movement within and between fungi.

The only other means by which the virus is known to spread is through asexual spores of the fungus. Although the

Redrawn from Hillman BI and Suzuki N (2004) Viruses of the chestnut blight fungus, *Cryphonectria parasitica*. In: Maramorosch K and Shatkin AJ (eds.) *Advances in Virus Research*, vol. 63, pp. 423–472. San Diego, CA: Academic Press.

virus suppresses developmental processes of the fungus, it does not completely eliminate asexual sporulation. Many fewer asexual spores are produced by CHV1-infected strains of the fungus, but those asexual spores that are produced may contain the virus.

Hypovirulence as Developmental Perturbation

Hypovirulence caused by CHV1 is of interest not only because it provides a means of biological control for an important plant disease, but also because it offers the potential to understand critical control point(s) for development in a filamentous fungal pathogen. The perturbation of development, without fungal growth being affected, suggests that the virus interferes with development in specific ways that leave normal vegetative growth functions undisturbed. Understanding how the virus acts to perturb development in this fungus may provide insights of value on how to reduce the economic impact of filamentous fungi.

The symptoms of CHV1 infection of *C. parasitica* are a reduction of asexual sporulation, reduced pigmentation, female sterility, and hypovirulence (**Figure 1**). Careful growth measurements show little or no adverse effects of viral infection on fungal vegetative growth in culture. While there have been some claims that CHV1 reduces vegetative growth, these growth effects are likely an artifact of prolonged growth of the fungus in culture. We have found similar reduced growth rates in culture if some strains of the fungus, particularly EP713, are kept in culture too long. Such slow growth mutations are common in cultured fungi, and in our experience, are independent of virus infection. To prevent the accumulation of such growth mutations in prolonged culture, we routinely single-spore EP155 to select for a normal growth strain, and then reintroduce CHV1 by anastomosis to recreate EP713 with normal vegetative growth characteristics. Routine single-spore isolation is necessary to prevent the slower growth mutant strains from developing in culture.

Ultrastructural examination of virus-infected strains of the fungus show no significant cytopathology in CHV1-containing cells. The only differences observed between infected and uninfected cells are unique vesicles that are described as being located in association with unique Golgi in areas devoid of ribosomes and other cellular components. Recent cytological fractionation studies have isolated these small vesicles that accumulate in CHV1-infected strains and have shown that they are associated with the *trans*-Golgi network. These vesicles contain the virus and its replication-associated enzymes. **Figure 3** shows the accumulation of these vesicles in the CHV1-infected strain, EP802.

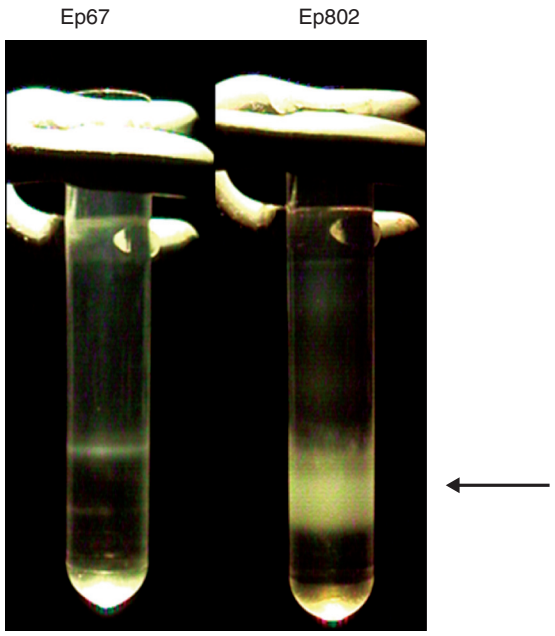

Figure 3 Subcellular fractionation on a Ficoll/^2H_2O gradient showing vesicle accumulation in CHV1-infected strain EP802 on the right and the isogenic virus free strain EP67 on the left. Gradient fractions were analyzed by Western and kex2 activity to show peak kex2 activity, AP-1μ, dsRNA, and viral helicase all cofractionate within this band. The endoprotease kex2 and the subunit for the AP-1 adaptor protein are markers for the *trans*-Golgi network.

Two general experimental approaches have been used to understand the molecular basis of how CHV1 causes symptoms in *C. parasitica*: (1) seek evidence that the virus perturbs normal fungal signal transduction pathways, and (2) identify commonalities in genes and proteins differentially expressed between normal and virus-infected strains of the fungus. A significant body of literature has been generated regarding how internal signal transduction pathways are affected in virus-infected strains, but, to date, there is no evidence of direct virus effects on signal transduction. As expected, signal transduction differs temporally and quantitatively between virus-infected and noninfected strains of the fungus. The most reasonable explanation of the published observations is that perturbation of signal transduction is the consequence of virus downregulation of development, rather than the cause. There is in fact no evidence that the symptoms are caused by direct virus perturbation of signal transduction and no testable hypothesis has emerged from these studies as to how the virus may be affecting signal transduction to cause the observed symptoms.

The approach that sought commonalities between differentially expressed proteins and genes associated with virus infection is leading to an understanding of how CHV1 may be causing symptoms. Given that the symptom of virus infection is a lack of development in infected strains,

significant differences in expression between the two strains were expected and observed. Early two-dimensional gel and differential hybridization studies identified a number of protein and gene expression differences between the infected and uninfected strains. A relatively small number of these genes/proteins that were highly expressed in uninfected but not in infected strains were characterized to seek commonalities between them.

Three of the genes highly expressed in uninfected strains, and not expressed in CHV1-infected strains, encoded sex pheromones. Two of the genes contain an 83bp ORF that encodes an identical 23-amino-acid peptide. This small peptide is similar to fungal lipopeptide sex pheromones: a C-terminal CAAX box with an asparagine residue 8–11 amino acids upstream of the box. CAAX is a prenylation signal, and farnesyl groups have been detected on the pheromones in other fungi. It was found that these peptides were expressed only in mating type 2 of uninfected strains of the fungus. Based on this similarity and loss of sexual mating upon deletion of the genes, the genes were named *mf2–1* and *mf2–2*. Deletion of *mf2–2* also resulted in a significant reduction in production of asexual fruiting bodies in culture and thus reduced numbers of asexual spores. Transcription run-on studies confirmed that these genes were transcriptionally downregulated in CHV1-infected cells.

Because *mf2–1* and *mf2–2* were so similar in structure to yeast pheromones, investigations were carried out to isolate the pheromone precursor gene of the opposite mating type. The gene isolated was shown to be similar in structure to the *S. cerevisiae* α-factor pheromone. There is a single copy of this gene expressed only by mating type 1 strains; it was named *mf1–1*. When the gene was deleted from *C. parasitica*, conidia or mycelial fragments normally used as spermatia in mating were sterile. Expression of this gene is significantly downregulated in CHV1-infected strains.

Differential protein expression studies identified two secreted proteins that are highly expressed by uninfected strains, but are downregulated in virus-infected cells. One of these is an extracellular laccase and the other an extracellular structural protein that was named cryparin. This later protein is a hydrophobin, a class of cell-surface proteins widely found in fungi and lichens. All hydrophobins are located on hyphal surfaces and confer hydrophobic properties to the surfaces, but they appear to have evolved different functions in various fungi. In *C. parasitica*, cryparin accumulates in fruiting bodies and is necessary for the eruption of the fungal fruiting bodies through the bark of the host tree. **Figure 4** shows the results of the deletion of cryparin.

The role of the laccase enzyme downregulated in CHV1-infected strains is not known. Knockout mutants did not exhibit any detectable phenotype, but did reveal the existence of multiple laccase enzymes expressed by the fungus. Laccases have been implicated in a number of

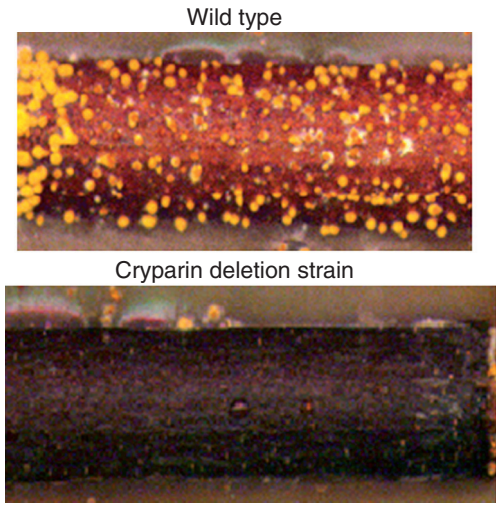

Figure 4 Stromal pustule (asexual fruiting bodies) eruption on chestnut wood. Sterile stem pieces of chestnut wood were inoculated with EP67 (upper panel) and the cryparin deletion strain (lower panel). Adapted from Kazmierczak P, Kim DH, Turina M, and Van Alfen NK (2005) A hydrophobin of the chestnut blight fungus, Cryphonectria parasitica, is required for stromal pustule eruption. *Eukaryotic Cell* 4: 931–936 with permission from American Society for Microbiology.

roles related to fungal development and virulence including degradation of lignin, formation of fruiting bodies, and pigment production.

The isolation and characterization of a number of the gene products downregulated in virus-infected cells was done to determine if there were any commonalities among them that could point to how the virus acts to cause symptoms. All of the gene products characterized are secreted into the extracellular environment and three of the proteins have sequences that suggest they are post-translationally processed by the same secretion pathway. Each protein is processed by an endoprotease after the signal peptide is cleaved, and the recognition signals suggest that they are processed by the same enzyme. **Figure 5** shows the preproproteins of Mf1–1, the fungal mating pheromone of mating type 1 strains, cryparin, and laccase. These three proteins have a signal peptide that presumably is cleaved early in the secretion process, followed by a propeptide region that terminates with a recognition sequence for processing by a kex2-like serine protease. These processing signals suggest that these three proteins are secreted via a kex2-like protein processing and secretion pathway. Kex2 processing is a post-Golgi function and the kex2 enzyme is a standard marker for *trans*-Golgi vesicles.

The processing of some secreted proteins by the kex2 pathway is highly conserved in eukaryotes. A similar pathway has been found in plants and animals and is utilized for the processing of specific proteins. It is generally not utilized for the secretion of most proteins. The specific role of this processing pathway in secretion appears to vary

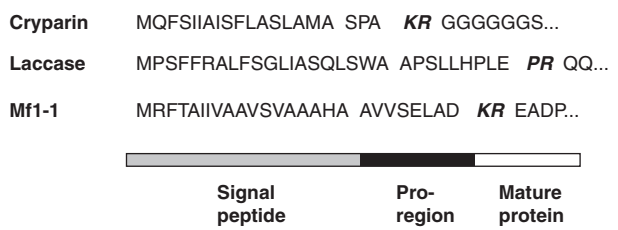

Figure 5 Amino acid N-terminal sequences derived from cloned mRNAs of three developmentally regulated host genes downregulated by CHV1. The signal peptide directs the protein to the ER for secretion and into the Golgi network for processing of the proprotein by the kex2 endoprotease at the residues lysine/arginine or proline/arginine which results in the mature form of the secreted protein.

between organisms. It was first discovered in yeast because it is involved in the processing and secretion of the viral encoded killer protein. This pathway was later found to be necessary for the secretion of the yeast alpha sex pheromone. The fact that three randomly isolated developmentally regulated host proteins, which are downregulated by the virus, are all processed by the same enzyme during secretion is an important clue in understanding how the virus perturbs development. Research has shown that not all secreted proteins of *C. parasitica* are affected by the virus; the secreted rennin-like endoprotease, endothiapepsin, for instance does not have a kex2 processing signal sequence nor it is downregulated by the virus.

The possibility that the virus directly affects secretion of some proteins, and thereby causes at least some of the symptoms associated with infection, is supported by evidence that the virus replicates using *trans*-Golgi vesicles. The vesicle fraction that contains the dsRNA genome of the virus and the viral encoded RNA polymerase and helicase co-purifies with kex2 enzymatic activity. This vesicle fraction has also been shown to contain cryparin, one of the proteins downregulated by the virus. The vesicle fraction in CHV1-infected cells that contains the virus dsRNA, viral encoded proteins, and kex2 activity are present in much greater amounts in virus-containing cells than in uninfected cells. This proliferation of vesicles in *C. parasitica* is typical of the effect of RNA viruses on their hosts, that is, the use of host membrane systems for replication by many RNA viruses cause a proliferation of these membranes within the host cells. We have estimated that in CHV1-infected cells there is at least a fivefold increase in this specific vesicle fraction when compared with noninfected cells. As previously mentioned, evidence from microscopic and cell fractionation observations suggest that CHV1 effects on membranes is specific to these *trans*-Golgi vesicles.

Recent research from our laboratory has shown that the CHV1 encoded protease p29 specifically integrates into the membranes of this *trans*-Golgi vesicle fraction. This protein is a close relative of the plant potyviral protease HC-Pro. HC-Pro is a papain-like protease that is autoprotelytic and which facilitates aphid transmission and promotes potyviral genome amplification. P29 is encoded on ORF A of CHV1 and is translated as part of the polyprotein p69 from which it is autocatalytically cleaved. Transformation of p29 into *C. parasitica* causes a loss of pigmentation, reduction in asexual sporulation, and suppression of host laccase expression, and there is evidence that it may be involved in suppression of RNA silencing by the host. Enhancement of both dsRNA accumulation and transmission of the virus through asexual spores are also functions attributed to CHV1 p29.

Recent studies show that p29 integrates into the *trans*-Golgi vesicle membranes of the host and that no other viral elements are required for this integration. While within the membrane p29 is fully susceptible to proteolytic digestion suggesting that it is primarily on the cytoplasmic side of the membrane. Deletion analysis of p29 showed that the C-terminal sequences of p29 mediate the membrane association. These transformation studies also confirmed the previous studies that showed p29 to be responsible for causing the reduced asexual sporulation and loss of pigment symptoms of virus infection. Further studies of the effect of p29 membrane integration on virus-caused host membrane proliferation and symptom production are in progress.

Based on the evidence available to date, CHV1 utilizes *trans*-Golgi vesicles of its host for replication and perhaps movement. *trans*-Golgi vesicles are critical for the final processing and secretion of proteins through the cytoplasmic membrane of the fungus, and for transport of proteins to certain cellular compartments. Studies of the viral protein p29 clearly link this protein to these vesicles and to causing some of the virus infection symptoms. The simplest hypothesis for how the virus is able to cause these and perhaps additional symptoms is that use of *trans*-Golgi vesicles for virus replication disrupts normal function of the vesicles and interferes with protein secretion or compartmentalization. The proprotein signal sequences directing kex2 endoprotease processing in a number of viral downregulated host proteins, such as the sex pheromone, cryparin, and laccase, also point to the *trans*-Golgi network as being a key to understanding the cause of virus symptom induction. The role of kex2 processing, a *trans*-Golgi vesicle function, in fungal development and its perturbation by the virus are currently under investigation.

There are precedents for RNA virus disruption of vesicle trafficking. Protein 3A of poliovirus specifically inhibits endoplasmic reticulum (ER)-to-Golgi traffic in mammalian cells, causing proteins otherwise destined for export to accumulate in ER-derived membranes. Many other viruses have been shown to have dramatic effects on the host membrane systems and a number of nonstructural virus proteins have been shown to interact with cellular factors responsible for the targeting and docking

of membranes within the various organelles and membrane systems of virus hosts. Although no vesicle membrane proteins have been isolated yet from *C. parasitica* that are involved in vesicle function, the viral protein p29 which has an extensive cytoplasmic domain upon integration into vesicle membranes is a likely candidate for interaction with any host factors that direct cellular membrane traffic. An understanding of how the virus specifically targets these *trans*-Golgi membrane vesicles, and how this targeting affects normal function of these vesicles, will likely lead to a better understanding of virus symptom production, and provide new insights into critical host developmental controls.

Glossary

Anastomosis The fusion of fungal hyphae resulting in exchange of cytoplasmic material and hypovirus transmission.

Hypovirulence Virus-mediated attenuation of fungal virulence.

Vegetative incompatibility A system controlled by at lease six genetic loci that determines the ability of two fungal strains to undergo anastomosis.

Introduction

The discovery of hypoviruses, a group of RNA viruses that reduce the virulence (hypovirulence) of the chestnut blight fungus *Cryphonecria parasitica*, has stimulated intensive research into the potential of using fungal viruses for biological control of fungal diseases. Documented examples of virus-mediated hypovirulence have been reported for fungal diseases of plants that range from trees to turfgrass and involve mycoviruses, which include representatives from the *Totiviridae*, *Chrysoviridae*, *Reoviridae*, *Narnaviridae,* and *Hypoviridae* (the hypoviruses). However, the hypoviruses remain the most thoroughly studied of the hypovirulence-associated viruses, primarily due to several significant advances in hypovirus molecular biology.

A classic example of the havoc that can result from the introduction of an exotic organism, the North American chestnut blight epidemic, first reported in 1905, caused the destruction of millions of mature chestnut trees by 1950. *Cryphonecria parasitica* was subsequently introduced into Italy during the 1930s, threatening European chestnut forests and orchards. However, for reasons still to be completely understood, the European chestnut blight

epidemic was much less severe than that witnessed in North America. One clear contribution to this reduced severity was the prevalence of *C. parasitica* strains exhibiting a reduced virulence phenotype (hypovirulence), first described by an Italian forest pathologist in the 1950s. French investigators subsequently showed that the hypovirulence phenotype was transmissible following anastomosis (fusion of hyphae) between vegetatively compatible *C. parasitica* strains, implicating a cytoplasmic genetic element as the causative agent of the phenotype. The observation that a hypovirulent strain could produce a curative effect when inoculated onto existing cankers on diseased trees stimulated a successful government-sponsored biological control program using hypovirulent *C. parasitica* strains for management of chestnut blight in French chestnut plantations. Recent studies in Switzerland also support the view that natural hypovirulent strains retard disease progression in European forest ecosystems.

In 1977, Peter Day and co-workers at the Connecticut Agricultural Experiment Station reported that hypovirulent *C. parasitica* strains harbor double-stranded (ds) RNAs, providing the first indication of the nature of cytoplasmic elements responsible for the phenotype. Subsequent surveys of dsRNAs associated with different North American and European hypovirulent strains revealed considerable variations in concentration, number, and size of dsRNA components. By the late 1980s, it was clear that a detailed molecular analysis of the dsRNAs associated with a single hypovirulent strain was required to bring some measure of order to the mounting confusion generated by such surveys. This resulted in the cloning and complete sequence determination of the prototypic hypovirus, now designated CHV1-EP713, in 1991. This milestone was followed in 1992 by the construction of an infectious full-length (12 712 bp) cDNA clone of CHV1-EP713 RNA by Choi and Nuss. This development furnished direct evidence that hypoviruses are indeed the causative agents responsible for transmissible hypovirulence and provided the means for facile manipulation of the hypovirus genome. Current interest in hypoviruses extends past biological control potential to their utility as unique experimental tools for probing fundamental processes underlying fungal pathogenesis and mycovirus–-fungal host interactions.

Taxonomy and Genetic Organization

Hypoviruses are classified within the family *Hypoviridae*, consisting of the genus *Hypovirus* and four species designated *C. parasitica* hypovirus 1–4 (CHV1–CHV4). Hypovirus taxonomy is not based on virus structure, since this group of viruses does not encode a coat protein, but on genome organization, sequence similarity and symptom expression. Hypovirus genetic information is found predominantly as dsRNA associated with membrane vesicles ranging in diameter from 50 to 80 nm. As observed for fungal viruses generally, hypoviruses exhibit no extracellular phase in their life cycle. Infections cannot be initiated by inoculation with an infected cell extract or enriched fractions. Instead, these viruses are transmitted by cytoplasmic mixing as a result of fusion (anastomosis) between vegetatively compatible strains or to a variable degree in asexual spores (conidia).

The hypovirus species designations CHV1–CHV4 were assigned in the order in which their genome sequence was completed. The primary nucleotide sequence for the coding strand of the prototypic member of the genus *Hypovirus*, CHV1-EP713, specifies two large open reading frames (ORFs) designated ORF A and ORF B (**Figure 1**). A second closely related member, CHV1-Euro7, has the same organization and shares approximately 90% identity at the nucleotide level with CHV1-EP713. The type member of the CHV2 species, CHV2-NB58, shares only about 60% nucleotide sequence identity with CHV1-EP713 and lacks a portion of ORF A that, for the CHV1 species, encodes a functional *cis*-acting cysteine protease. Sequenced members of the CHV3 and CHV4 species, CHV4-GH2 and CHV4-SR2, respectively, are several kbp shorter than the CHV1 and CHV2 species, ~9.2–9.8 kbp versus 12.5–12.7 kbp, contain a single large ORF rather than two ORFs and are both more distantly related phylogenically to species CHV1 than CHV1 is to CHV2.

Hypovirus Gene Expression Strategy

Although hypovirus genetic information is readily recovered from infected cultures as linear dsRNA, the absence of a discrete virus particle and an extracellular infection phase presents some difficulties in precisely defining the hypovirus genome. Synthetic copies of the coding strand are infectious by electroporation into fungal spheroplasts and phylogenetic analyses suggest a common ancestry with the positive strand RNA plant potyviruses. Thus, one could consider hypoviruses as having a positive strand RNA genome and the dsRNA as representing accumulated replicative form RNA. Irrespective of this complication, direct analysis of hypovirus dsRNAs, cDNA cloning studies, and *in vitro* translational analyses has provided the following view of genetic organization and expression strategies for the prototypic hypovirus CHV1-EP713 shown in **Figure 2**. One strand contains a 3′-poly A tail while the complementary strand contains a 5′-poly U tract. All of the CHV1-EP713 coding information appears to reside within two contiguous ORFs on the 12 712 nt long polyadenylated strand. ORF A encodes two polypeptides, p29 and p40, that are released from a polyprotein precursor, p69, by an autoproteolytic event between Gly-248 and Gly-249, mediated by a

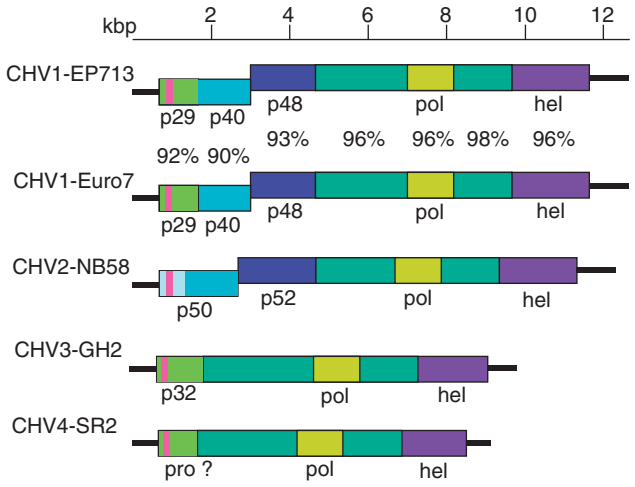

Figure 1 Genetic organization of sequenced hypovirus genomes representing the four species that comprise the genus *Hypovirus*, family *Hypoviridae*. Amino acid identity levels for coding regions of the two sequenced members of the CHV1 species, CHV1-EP713 and CHV1-Euro7, are indicated between representations of the two viral genomes. Protein coding regions homologous to CHV1-EP713 encoded p29, p40, p48, polymerase and helicase are color coded. The magenta regions represent a short conserved cysteine rich domain. Note that the genomes of CHV3-GH2 and CHV4-SR2 contain a single ORF. Modified from Dawe AL and Nuss DL (2001) Hypoviruses and chestnut blight: Exploiting viruses to understand and modulate fungal pathogenesis. *Annual Review of Genetics* 35: 1–29, with permission from Annual Reviews.

cysteine-like protease catalytic domain located within p29. ORF B has the capacity to encode a polyprotein of 3165 amino acids and contains unmistakable RNA-dependent RNA polymerase and helicase motifs. Proteolytic processing of only a portion of the ORF B polyprotein has been elucidated in the form of the autoproteolytic release of a 48 kDa protein, p48, from the N-terminus. This cleavage event occurs between Gly-418 and Ala-419 and is catalyzed by essential residues Cys-341 and His-388 within p48. The junction between ORF A and ORF B is defined by the sequence 5′-UAAUG-3′, in which the UAA portion clearly serves as the termination codon for ORF A and the AUG portion is thought to serve as the initiation codon for ORF B. While the mechanism involved in ribosome transition through the junction is not known, this unusual pentanucleotide sequence is found at the ORF A/ORF B junction for all confirmed CHV1 species. There is clearly a need for additional fine detailed mapping of the processing cascades for hypovirus-encoded polyproteins.

The genome of CHV2-NB58, type strain of species CHV2, also consists of a two ORF configuration with a UAAUG junction (**Figure 2**). However, ORF A lacks the p29 papain-like catalytic or cleavage sites and directs the translation of a 50 kDa protein product. ORF B of CHV2-NB58 does contain a p48 homolog, p52. The N-terminal portion of the single ORF of the CHV3-type strain CHV3-GH2 contains a protease, p32, with similarity to p29. A putative protease domain has been identified at the N-terminal portion of the CHV4-type strain CHV4-SR2, but protease cleavage has not been demonstrated.

In most hypovirus-infected *C. parasitica* isolates, the full-length viral dsRNA is accompanied by a constellation of shorter dsRNA species. These ancillary dsRNAs appear to be generated by internal deletion events, are replicated only in the presence of the full-length viral RNA, and are not associated with any function or phenotypic effect.

Hypovirus–Host Interactions

The phenotypic changes that are associated with hypovirus infection are not limited to hypoviurlence. Additional hypovirus-mediated phenotypic changes can include altered colony morphology, female infertility, reduced asexual sproulation (conidiation), and reduced pigmentation. The pleiotropic nature of these changes suggests that hypoviruses might perturb one or several cellular signaling pathways. Consistent with this view, alterations in G-protein, cyclic AMP-mediated-, mitogen-activated protein kinase-, and calcium/calmodulin/inositol trisphosphate-dependent-signaling pathways have been reported for hypovirus-infected fungal strains.

The construction of an ordered expressed sequence tag (EST) library representing approximately 2200 *C. parasitica* genes and development of a corresponding *C. parasitica* cDNA microarray platform has provided a view of host transcriptional responses to hypovirus infection. The modulation of transcript accumulation for approximately 13.4% of the 2200 cDNAs was shown following CHV1-EP713 infection. These transcriptional profiling studies also resulted in the identification of a

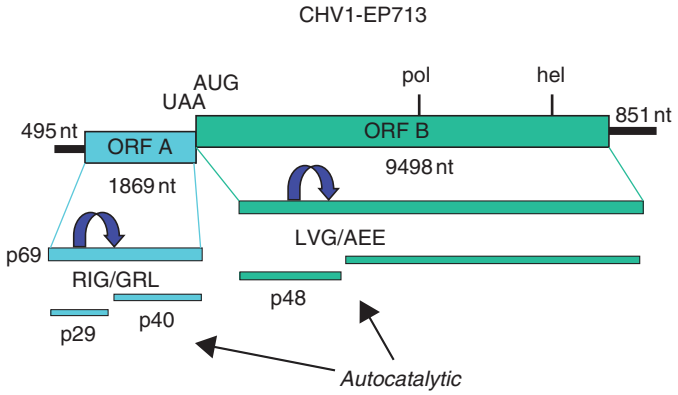

Figure 2 Expression strategy for prototypic hypovirus CHV1-EP713. The CHV1-EP713 coding strand consists of 12 712 nucleotides excluding a poly(A) tail, and contains two major coding domains designated ORF A and ORF B. Details are discussed in the text. Modified from Dawe AL and Nuss DL (2001) Hypoviruses and chestnut blight: Exploiting viruses to understand and modulate fungal pathogenesis. *Annual Review of Genetics* 35: 1–29 with permission from Annual Reviews.

subset of hypovirus responsive genes regulated through the G-protein signaling pathway and revealed a linkage between viral and mitochondrial hypovirulence.

Hypovirus-encoded symptom determinants and important replication elements have been mapped (**Figure 3**) by a combination of approaches that include (1) the construction of recombinant chimeras from hypoviruses that differ in their influence on host phenotype, (2) mutagenesis of a hypovirus infectious cDNA clone, and (3) cellular expression of viral coding domains independent of virus infection.

In analogy with plant viruses, CHV1-EP713 and CHV1-Euro7 can be viewed as severe and mild hypovirus isolates, respectively. Although these two CHV1 isolates cause quite different phenotypic changes in their fungal host, they share a high level of sequence similarity that has allowed the construction of viable chimeric viruses to begin mapping the determinants responsible for the differences in phenotypic changes.

Differences in colony morphologies were found to map to a region extending from a position just downstream of the p48 coding domain (map position 3575) to map position 9879, with clear indications of multiple discrete determinants. More specifically, the region extending from position 3575 to 5310 was able to confer a CHV1-EP713-like colony morphology when inserted into a CHV1-Euro7 genetic background. The CHV1-EP713 p48 coding region was found to be a dominant determinant contributing to suppression of asexual spore formation on the canker face.

The chimeric hypoviruses also proved to be very useful reagents when coupled with a pathway specific promoter/reporter system to map viral determinants responsible for altering G-protein/cAMP-mediated signaling. A common undesired side effect of hypovirus-mediated virulence attenuation is a significantly reduced ability of the fungal host to colonize and produce spores on the corresponding plant host. This reduces the ability of hypovirulent fungal strains to persist and spread through the ecosystem. Thus, from a practical perspective, a better understanding of the nature of viral symptom determinants and their relative effects on specific regulatory pathways and expression of gene clusters provides the means for a more rational approach for engineering hypoviruses that exhibit a desired balance between virulence attenuation and ecological fitness.

Additional insights into the functional role of viral coding regions were indirectly provided during efforts to develop hypoviruses as gene expression vectors. The nucleotide sequence corresponding to the first 24 codons of p29 was found to be required for viral replication, while the remaining 598 codons of ORF A, including all of the p40 coding region, was found to be dispensable. Substantial alterations were also tolerated in the pentanucleotide UAAUG that contains the ORF A termination codon and the overlapping putative ORF B initiation codon. For example, replication competence was maintained following either a frameshift mutation that caused a two-codon extension of ORF A or a modification that produced a single-ORF genomic organization. Further charactereization of p40 revealed a role as an accessory function in viral RNA amplication with a functional domain extending from Thr(288) to Asn(313).

Expression of the CHV1-EP713 encoded papain-like protease, p29, in the absence of virus infection was shown to cause a subset of phenotypic changes exhibited by CHV1-EP713-infected strains, for example, a white phenotype (reduction in orange pigmentation), reduced asexual sporulation and a slight reduction in the production of fungal laccase activity. By deleting all but the first 24 N-terminal codons of p29 in the context of the CHV1-EP713 infectious cDNA clone (mutant virus Δp29), it was also possible to show that the p29 protein is dispensable

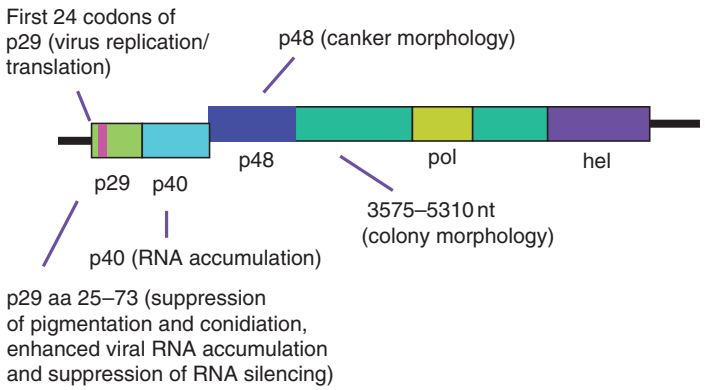

Figure 3 Emerging map of CHV1-EP713 symptom determinants and essential/dispensable replication elements as described in the text. Adapted from Dawe AL and Nuss DL (2001) Hypoviruses and chestnut blight: Exploiting viruses to understand and modulate fungal pathogenesis. *Annual Review of Genetics* 35: 1–29, with permission from Annual Reviews.

for viral replication and to demonstrate a near restoration of orange pigment production and a moderate increase in conidation levels relative to wild-type CHV1-EP713-infected fungal colonies. Deletion of p29 had no effect on virus-mediated virulence attenuation. A gain-of-function analysis involving progressive repair of the Δp29 mutant was also devised to map the p29 symptom determinant domain to a region extending from Phe-25 to Gln-73. When expressed from a chromosomally integrated cDNA copy, p29 elevated RNA accumulation and vertical transmission (through conidia) of the Δp29 mutant virus to levels observed for wild-type CHV1-EP713. Additional mutational studies indicated a linkage between p29-mediated changes in host phenotype in the absence of virus infection and p29-mediated in *trans*-enhancement of viral RNA accumulation and transmission.

The multifunctional nature of p29 was recently extended to include suppressor of RNA silencing both in the natural fungal host and in a heterologous plant system. This activity was predicted based on similarities between p29 and the well-characterized potyvirus-encoded suppressor of RNA silencing HC-Pro and has provided the first circumstantial evidence that RNA silencing in fungi may serve as an antiviral defense mechanism, a well-established function in plants.

Prospects for Biological Control

Chestnut blight cankers on American chestnut trees can be controlled by the direct application of hypovirus-infected hypovirulent *C. parasitica* strains to the canker margin, provided that the hypovirulent and resident virulent strains are vegetatively compatible. Anastomosis between the two strains results in hypovirus transmission and conversion of the canker to the hypovirulent phenotype, thereby preventing additional expansion of the canker and promoting formation of new callus tissue. However, since treated trees do not become resistant to new infections and North American *C. parasitica* populations generally exhibit a very diverse vegetative compatibility structure, this form of treatment is labor intensive and has not proved to be practical for effective control of chestnut blight in a North American forest ecosystem.

High levels of VC diversity and the severe phenotypic characteristics of the hypoviruses that have been introduced for biocontrol are thought to be two of the main contributing factors to the inability of introduced hypoviruses to spread through North America *C. parasitica* populations. In this regard, transgenic hypovirulent strains that contain a nuclear copy of the hypovirus cDNA exhibit novel hypovirus transmission properties that have been predicted to reduce these limitations. Hypovirus RNA is not transmitted to ascospores during mating. However, the hypovirus cDNA present in transgenic hypovirulent strains is inherited by a portion of the ascospore progeny, followed by the production of cDNA-derived cytoplasmically replicating viral RNA. Additionally, since the progeny represent a spectrum of vegetative compatibility groups, launching of the cytoplasmic viral RNA into these new vegetative compatibility groups is predicted to expand vegetative dissemination of hypovirus genetic information.

Three field trials with CHV1-EP713 transgenic strains have confirmed hypovirus transmission to ascospore progeny in a forest setting and also exposed the requirement for significant improvements in formulation and delivery methods. These trials also confirmed predictions that the CHV1-EP713 hypovirus performs poorly as a biological control agent because it severely reduces the ability of the fungal host to colonize, expand, and produce asexual spores on chestnut tissue. In this regard, the availability of an infectious cDNA clone for the mild hypovirus CHV1-Euro7 has provided the means to construct a transgenic hypovirulent strain that combines the properties of enhanced colonization and spore production with a novel mode of hypovirus transmission to ascospore progeny.

The infectious hypovirus cDNA clones have also been used to expand hypovirus host range to include several other pathogenic fungi that include the *Eucalyptus* canker pathogen *Cryphonectria cubensis* and the fruit tree pathogens *Phomopsis G-type* and *Valsa ceratosperma*. Hypovirus-based management of these economically important fungal diseases in controlled agricultural settings may not face the same problems of formulation and application that has been encountered for control of chestnut blight in a complex forest ecosystem.

Glossary

DNA packaging Energy-requiring process where the empty virus capsid is filled by the virus genome.
Protein-primed DNA replication Duplication of a linear DNA genome utilizing a protein covalently linked to the DNA terminus to initiate the reaction.
Triangulation number T number (T), a parameter for icosahedral capsids that describes the geometrical arrangement of the protein subunits.

Introduction

Bacterial viruses with an internal membrane all have double-stranded DNA (dsDNA) genomes. They are classified into two families, the *Tectiviridae* and the *Corticoviridae*. The former family consists of several viruses, whereas the latter has only one representative. The type species of the *Tectiviridae* is PRD1, which infects a wide variety of Gram-negative bacteria. Its host range is limited to bacteria that contain a conjugative antibiotic resistance plasmid, since it utilizes the plasmid-encoded cell surface DNA-transfer complex as a receptor. The type species of the family *Corticoviridae* is PM2.

The family *Tectiviridae* can be divided into two groups: viruses infecting Gram-negative bacteria and viruses infecting Gram-positive bacteria. The group infecting Gram-negative bacteria contains six extremely similar phages (PRD1, PR3, PR4, PR5, PR772, and L17) with a linear dsDNA genome. Their sequence similarity is between 91.9% and 99.8%, which is surprising since they have been isolated from different parts of the world. The other group infects Gram-positive bacteria (different *Bacillus* species). The length of the genomes (about 15 kbp) and the order of the genes is conserved in all the tectiviruses, but there is no sequence similarity between the two groups. The genomes of the tectiviruses encode about 35 proteins (**Table 1**).

The corticovirus PM2 was isolated in 1968 from seawater off the coast of Chile. The host is a marine bacterium, *Pseudoalteromonas espejiana*. PM2 has a negatively supercoiled circular dsDNA of about 10 kbp. It encodes about 17 proteins (**Table 2**). The combination of a membrane and a supercoiled DNA genome makes PM2 a unique virus. The entry and the DNA-packaging mechanisms are likely to differ from those of other viruses.

Virion Structure and Properties

Overall Structure

The virion of PRD1 is an icosahedrally symmetric particle approximately 65 nm in diameter (**Figure 1**). It is composed of about 70% protein, 15% lipid, and 15% DNA and has a mass of about 66 MDa. The structure of the virion has been studied extensively using electron microscopy and X-ray crystallography (**Figure 2**). X-ray crystallography results have indicated the roles of four proteins in controlling virus assembly. There are 240 hexagonally shaped trimers of the major capsid protein, P3 (**Figure 2(b)**), occupying the surface of the capsid on a pseudo $T = 25$ lattice, an arrangement that is also found in the human adenovirus capsid. In PRD1, a dimer of the linear glue protein P30 extends from one vertex to the next, cementing the P3 facets together (**Figure 2(c)**). At the vertex, pentamers of P31 interlock with P3 and the transmembrane protein P16.

The majority of the PRD1 vertices have two proteins attached to them: one is a trimer of P5 (**Figure 3(a)**) attached by the N-terminus, the other is a monomer of P2 (**Figure 3(b)**), the receptor-binding protein. Both P5 and P2 are elongated molecules (P5 is 17 nm long, P2 is 15.5 nm long). P2 is a club-shaped molecule with a pseudo β-propeller head and a long tail formed from extended β-sheet. The head is proposed to be the site of

receptor binding, lying distal to the virus. A specific vertex is used for packaging the phage DNA.

The overall size and structure of the phage Bam35 is very similar to that of PRD1. However, the exact counterparts of many of the PRD1 structural proteins have not yet been clearly identified. One of the major differences between PRD1 and Bam35 is the presence of a large transmembrane protein complex in Bam35 that modulates the curvature of the membrane under the capsid facets. Also, the host cell recognizing spike complex is likely to be different.

The corticovirus PM2 particle is icosahedral and measures 77 nm in diameter from spike to spike. The capsid is approximately 60 nm in diameter. Like the tectiviruses, it does not have a tail. The mass of the virion is $\sim 4.5 \times 10^7$ Da and it is composed of protein (72%), lipid (14%), and DNA (14%). The capsid is composed of 200 trimers of the major capsid protein arranged on a pseudo $T = 21$ lattice. Pentameric receptor-binding spikes protrude from the vertices.

Membrane and DNA

In PRD1, about half of the virion proteins are associated with the membrane (**Table 1**). The lipid headgroups are predominantly phosphatidylethanolamine (53%) and phosphatidylglycerol (43%) with 4% of cardiolipin. The membrane is well ordered, following the icosahedral outline of the capsid. Many interactions occur between the membrane and both the capsid and the underlying DNA. The average separation of the concentric layers of DNA is approximately 2.5 nm, similar to that found in other bacteriophages and animal viruses. Removal of the capsid and

spike proteins by heat or guanidinium hydrochloride treatment results in aggregation of the membrane vesicle.

In PM2, the membrane, lying underneath the capsid, follows the shape of the capsid as in PRD1, and there are many interactions mediated by additional minor proteins. The lipid composition is approximately 64% phosphatidylglycerol, 27% phosphatidylethanolamine, and 8% neutral lipids and a small amount of acyl phosphatidylglycerol. Release of the capsid and spike proteins from the virion by freeze–thawing or by chelation of calcium ions with ethylene glycol tetraacetic acid (EGTA) results in a soluble vesicle called the lipid core.

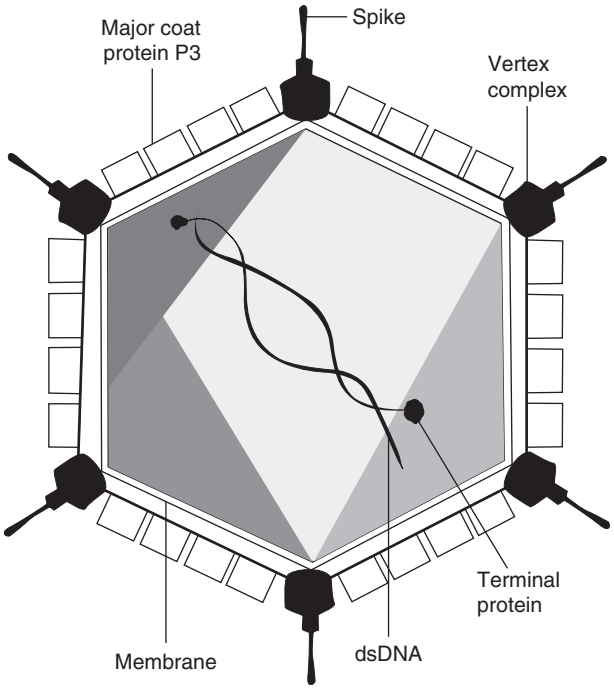

Figure 1 Schematic presentation of PRD1 virion.

Life Cycle

PRD1 is a lytic phage that exploits the transcription functions of its host. The host cell is selected by specific recognition of a plasmid-encoded receptor on the cell surface. PRD1 belongs to the class of broad-host-range, donor-specific phages, which infect cells only when an IncP-, IncN-, or IncW-type multiple-drug resistance conjugative plasmid is present. The primary function of the receptor is in bacterial conjugation. Among the hosts are several opportunistic human pathogens such as *Escherichia coli*, *Salmonella enterica*, and *Pseudomonas aeruginosa*. After adsorption, the phage genome is injected into the cell cytosol, leaving the capsid outside. After the production of the phage components, both virus- and host-encoded factors assist in particle assembly. Host cell lysis releases some 500 progeny viruses. Bam35 is a temperate phage, either growing lytically like PRD1, or existing in a dormant state within the host. In contrast to PRD1, the host range of Bam35, and its relatives GIL01 and GIL16, is limited to one species, *Bacillus thuringiensis*. AP50 infects *Bacillus anthracis*, and a defect phage replicating as a linear plasmid (pBClin15) has been described for *Bacillus cereus*. The corticovirus PM2 is lytic. Of all the dsDNA phages with an internal membrane, the life cycle of PRD1 is best understood and is described below.

Receptor Recognition

A single phage structural protein, P2, is responsible for PRD1 attachment to its host. Each of the PRD1 receptor recognition vertices is a metastable structure and possibly capable of DNA release. The injection vertex is likely to be determined by P2 binding to the receptor. The association of P2 with the receptor activates, possibly by P2 removal, the injection process. This leads to irreversible binding. Both empty and DNA-containing particles are

bound equally tightly to cells, indicating that DNA injection is not a prerequisite for this tight interaction.

DNA Entry

Isolation and analysis of PRD1 mutants have resulted in the identification of eight, phage-specific, structural proteins essential for infectivity. In addition to the spike-complex proteins (P2, P5, and P31) needed for adsorption, protein P11 starts the DNA delivery process and membrane proteins P14, P18, and P32 are involved in later stages of the DNA delivery. Mutant particles missing protein P7 (a lytic transglycosylase) are infectious but the DNA entry process is delayed.

The PRD1 membrane can undergo a structural transformation from a spherical vesicle to a tubular form. A similar process has been described for Bam35 and AP50, thus occurring in all members of the *Tectiviridae*. This tube formation might be required for DNA translocation.

Genome Replication

The genome of PRD1 is a linear double-stranded DNA molecule with proteins covalently attached to both 5′ termini and having 110 bp terminal repeats. PRD1 replicates its DNA by a protein-primed replication mechanism similarly to other viruses with linear dsDNA genomes, including adenovirus and the ϕ29-type phages. PRD1 DNA replication starts with the formation of a covalent bond between the genome terminal protein, P8, and the 5′ terminal nucleotide, dGMP, in a reaction catalyzed by the phage DNA polymerase, P1. The minimal origin of replication resides in the 20 first-terminal base pairs of both genome ends, and the fourth base from the 3′ end of the template directs, by base complementation, the linking of deoxyribonucleoside monophosphate (dNMP) to the terminal protein. The 3′ end DNA sequence is maintained by sliding back of the polymerase complex.

After initiation, elongation of the initiation complex by the same DNA polymerase takes place resulting in the formation of full-length daughter DNA molecules. Two phage-encoded single-stranded DNA binding proteins, P12 and P19, are involved in replication *in vivo*.

Particle Assembly

Approximately 15 min post infection, the major capsid protein P3 and the spike-complex proteins P2, P5, and P31 are found soluble in the host cell cytosol, whereas the phage-encoded membrane proteins (e.g., P7, P11, P14, and P18) are addressed to the host cell cytoplasmic membrane (CM). Correct folding of the soluble proteins and assembly of a number of viral membrane proteins are dependent on the host GroEL/ES chaperonins. Upon assembly, a virus-specific patch from the host CM is translocated into the forming procapsid using the membrane-bound scaffolding protein P10. In addition, two small phage-encoded proteins are implicated in the assembly process: P17 and P33.

Correct assembly results in an empty capsid enclosing a membrane rich in phage-specific proteins. The linear double-stranded DNA genome is packaged into the prohead by the packaging ATPase P9. Unlike packaging ATPases of most other icosahedral dsDNA bacteriophages, P9 is part of the mature virus structure. It resides at a single vertex that also contains proteins P6, P20, and P22. P6 is a soluble protein needed for efficient DNA packaging and the latter two are integral membrane proteins connecting the portal structure to the viral membrane.

Cell Lysis

At the end of the infection cycle, the newly synthesized progeny virions are released via host cell lysis. Two genes, *XV* and *XXXV*, are involved in this step, which means that a two-component, holin–endolysin system operates in phage PRD1. The product of gene *XV*, protein P15, is a soluble β-1,4-*N*-acetylmuramidase that degrades the

peptidoglycan of the Gram-negative cell causing host cell lysis. The PRD1 particle carries another muramidase, protein P7, which has a lytic transglycosylase activity assisting in genome entry. The presence of two lytic activities probably reflects the broad host range of PRD1.

In addition to lytic enzymes, bacteriophages quite often encode helper protein factors (holins) that facilitate the access of lytic enzymes to the susceptible bond in the cell wall and control the timing of lysis. The PRD1 holin is protein P35.

Genomes and Genomics

The length of the PRD1 genome is 14 927 bp and the guanine–cytosine (GC) content is 48.1%. It has 110 bp long inverted repeat sequences at the ends, which are 100% identical. The genomes of the other Gram-negative bacteria-infecting tectiviruses are very close to that of PRD1, varying between 14 935 and 14 954 bp. They are remarkably similar in nucleotide sequence, the overall identity being 91.9–99.8%. The Bam35 genome is 14 935 bp long with a GC content of 39.7%. The inverted repeat for Bam35 is 74 bp long. These Bam35 inverted terminal repeats (ITRs) have 81% identity. PRD1 and Bam35 do not share much sequence similarity. The discovery of the almost invariant genomes for the two *Tectiviridae* groups contrasts sharply with the situation in the tailed bacteriophages. The nucleotide identity is 100% between Bam35 and GIL01 and 83% between GIL01 and GIL16.

PRD1 genome is organized into two early and three late operons (**Figure 4**). Bam35 operons have not been mapped, but the gene order and the length of the genes are similar to those of PRD1 (**Figure 4**). Although there is no overall sequence similarity between PRD1 and Bam35 genomes, Bam35 genes for DNA polymerase, packaging ATPase, and lytic enzyme can be recognized by corresponding conserved amino acid sequence motifs in the databases. The coat protein gene can be identified by comparing the N-terminal amino acid sequence of the major virion protein to the DNA sequence. The only genes of Bam35, which seem to be in different positions in the genome compared to PRD1, are those responsible for the host cell recognition (the spike protein).

The circular PM2 genome is 10 079 bp long with a GC content of 42.2%. It contains 21 putative genes, of which 17 have so far been shown to be functional. Promoter mapping by primer extension has revealed three operons, which are expressed in a timely fashion during infection. The first early operon is highly similar to the maintenance region of the *Pseudoalteromonas* plasmid pAS28. The second early operon contains genes for DNA replication and regulation of late phage functions. The PM2 genome replicates via a rolling-circle mechanism. Protein P12 has conserved sequence motifs common to superfamily I replication initiation proteins. This superfamily consists of the A proteins of certain bacteriophages, such as ϕX174 and G4, and the initiation proteins of cyanobacterial and archaeal plasmids. The function of the late operon is activated by two phage-encoded transcription factors, P13 and P14. P14 has sequence similarity to the TFIIS-type general eukaryotic transcription factors most closely resembling those of the archaeal organisms *Thermococcus celer* and *Sulfolobus acidocaldaricus*.

The structural proteins encoded by the late genes are, similar to the corresponding proteins of tectiviruses, either membrane associated or soluble. Based on the conserved amino acid sequence motifs deduced from the nucleotide sequence, one of the structural virion proteins

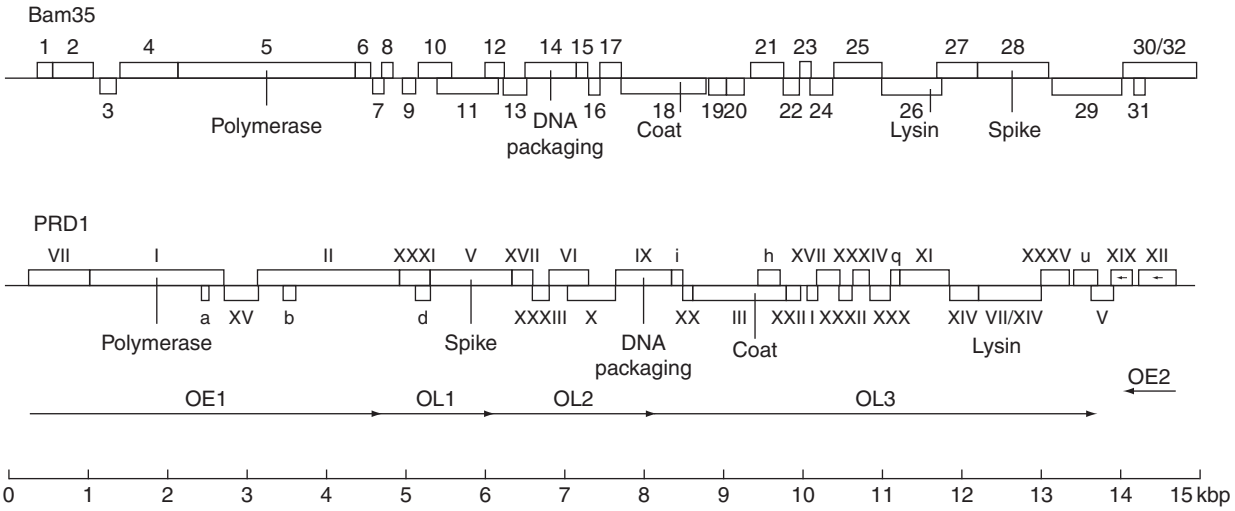

Figure 4 Alignment of the genomes of Bam35 (top) and PRD1 (middle). The two early (OE) and three late (OL) operons of PRD1 are shown at the bottom. In Bam35, the open reading frames (ORFs) are marked by Arabic numerals from left to right. PRD1 ORFs have a Roman numeral if they have been shown to encode protein, otherwise they are marked with a lowercase letter.

is a putative packaging ATPase. The packaging process of the circular supercoiled PM2 DNA is not understood at the moment.

Glossary

Carrier state A partial or complete viral genome is maintained inside the host cell as a stable episome without lysis or infection.
Genomic precursor ssRNA destined for packaging.
Genomic segment A piece of genomic dsRNA.
Packaging A process of genomic precursor acquisition.
Pac site A specific signal at 5' end of a genomic precursor which targets it for selective packaging.
Polymerase complex Viral assembly which contains the polymerase and is able to replicate and transcribe the viral genome. Usually it also contains the viral genomic dsRNA.
Procapsid Empty capsid assembly which is capable of acquiring the genomic precursors.
Reverse genetics RNA virus genome manipulation and rescue from cDNA clones.
Viral core dsRNA containing inner part of the virus which is capable of transcription.

Introduction – The *Cystoviridae* Family

Members of the family *Cystoviridae* are lipid-containing bacteriophages with segmented dsRNA genomes. The first recognized member, the bacteriophage φ6, was isolated in 1973. Several other members were discovered in the late 1990s. All known cystoviruses were isolated from the leaves of various plants and consequently infect primarily plant-pathogenic bacteria (pseudomonads). All share a similar architecture with a proteinaceous viral core hosting the three genomic segments (L, M, and S, approx. 6.5, 4, and 3 kbp in size, respectively). The core is enclosed in a lipid envelope which contains the host cell attachment proteins. The viral core contains an RNA-dependent RNA polymerase (RdRP) which plays a central role in RNA metabolism. Despite infecting prokaryotic hosts these phages exhibit structural and functional features that parallel those of the family *Reoviridae*. Because reverse genetics had been developed early on for φ6, the system has been a model for studying the assembly and replication of other dsRNA viruses.

An *in vitro* assembly of infectious nucleocapsids from purified constituents has been achieved for bacteriophages φ6 and φ8. Similarly, RNA packaging and replication have been extensively studied *in vitro*. Together with the reverse genetics system the *in vitro* methods have been instrumental in delineating the virus replication mechanisms. The host entry mechanism mimics that of viruses infecting eukaryotic cells and involves both membrane fusion and an endocytotic-like event. Structural and extensive biochemical characterization of individual proteins and subviral assemblies made the cystoviral system a paradigm for studying mechanisms of molecular machines in atomic details. The self-assembly and replication system shows promise in biotechnology and nanotechnology applications.

Classification and Host Range

Based on their sequences and host range five out of the recently discovered cystoviruses (φ7, φ9, φ10, φ11, φ14) are close relatives of φ6 while the remaining three (φ8, φ12, and φ13) are only distantly related to the φ6 group and among themselves. φ6 and the related phages attach to the host cell via a specific type IV pilus while the members of the second group utilize rough lipopolysaccharides (LPSs). This limits the host range to *Pseudomonas syringae* (*Pseudomonas pseudoalcaligenis* for certain mutants) for the former group while phages belonging to the latter can also infect rough LPS of other Gram-negative bacteria without forming plaques. Only φ8 form plaques on a heptose-less strain of *Salmonella typhimurium*. A common laboratory host of φ6 is *P. syringae* strain HB10Y. The φ8 phage is usually propagated on *P. syringae* strain LM2509.

Virion Structure and Properties

Physico-Chemical Properties

Virion molecular weight (MW, in dalton units, Da) $\sim 9.9 \times 10^7$ Da, sedimentation coefficient S_{20w} ~405S, density 1.24 g cm^{-3} (sucrose), nucleocapsid MW $\sim 4.0 \times 10^7$ Da. Composition: 70% (w/w) protein, 14% dsRNA, 16% phospholipids. RNA packaging density 350 g cm^{-3}.

Architecture of the Polymerase Complex and the Nucleocapsid

Figure 1 depicts schematically the architecture and localization of the proteins for the φ6 virion. The innermost structure is the polymerase complex (PC) which is composed of 120 copies of major structural protein P1 (MW 85 kDa), 12 copies of RdRP P2 (75 kDa), 12 hexamers of packaging motor P4 (subunit MW 35 kD), and 60 copies of assembly factor P7 (17 kDa). Structural details of the dodecahedral P1 skeleton are depicted in **Figure 2**. The $T = 1$ lattice is composed of 60 asymmetric P1 dimers as seen for other dsRNA viruses. However, the arrangement of dimers within the asymmetric unit is different from that seen in the reovirus or bluetongue virus cores. P2 monomers are attached to the inner surface of the PC

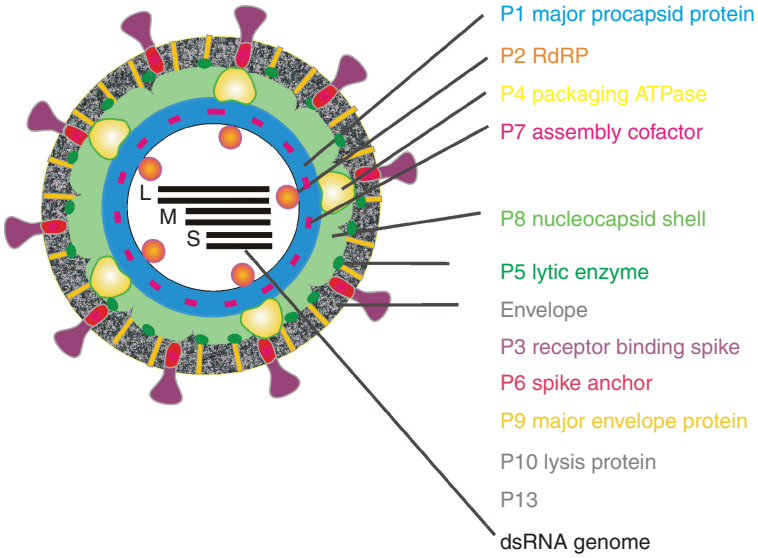

Figure 1 Schematics of φ6 virion architecture. Function of individual proteins: P1-major structural protein of PC, forms the dodecahedral skeleton of the procapsid; P2-RdRP; P3-spike protein, host cell attachment; P4-packaging ATPase, ssRNA translocation; P5-lytic enzyme (lysozyme); P6-integral membrane protein, P3 anchoring and membrane fusion; P7-assembly, packaging and replication cofactor, PC stabilization; P8-nucleocapsid coat protein; P9-membrane protein; P10-host cell lysis, perhaps holin; P11-membrane protein (most likely nonessential).

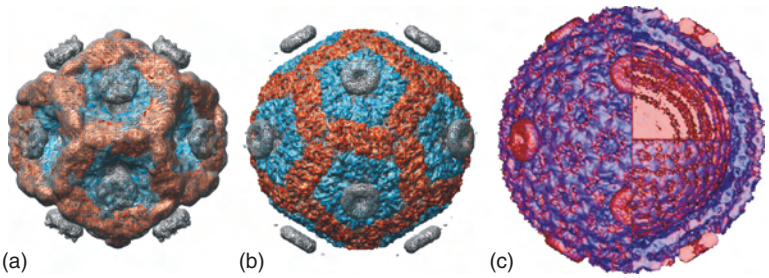

Figure 2 Structure of the polymerase complex and the nucleocapsid of φ6 as revealed by electron cryo-microscopy. (a) Modeled empty PC (void of RNA, precursor for packaging) which is also called the procapsid. (b) The $T = 1$ (triangulation number) shell of the expanded, mature, PC which contains dsRNA genome and is transcription competent. (c) The $T = 13$ P8 shell which makes the outer surface of NC together with the protruding P4 hexamers. P4 is gray, the two P1 monomers in the asymmetric dimer are colored red and blue, respectively. P8 shell is rendered purple. Reproduced from Huiskonen JT, de Haas F, Bubeck D, Bamford DH, Fuller SD, and Butcher SJ (2006) Structure of the bacteriophage φ6 nucleocapsid suggests a mechanism for sequential RNA packaging. *Structure* 14: 1039–1048, with permission from Elsevier.

shell, possibly at the fivefold vertices. P4 hexamers form turret-like protrusions on the outer surface of the fivefold vertices. Location of the P7 within the PC is not known.

PC undergoes a series of large conformational changes (expansions) during RNA packaging and genome replication. The empty dodecahedral PC (procapsid) expands into a more round, icosahedral dsRNA-filled PC, which is sometimes called the viral core. The expansion consists of motions of whole P1 subunits around hinges that run roughly parallel with the twofold edges of the dodecahedral skeleton (**Figure 2**). The expansion increases the inner volume by a factor of 2.4 and makes room for the dsRNA genome. The mature PC is subsequently enclosed in an icosahedral shell ($T = 13$) made of 200 P8 (subunit MW 16 kDa) trimers (**Figure 2**). The resulting structure is called the nucleocapsid (NC). The packaged dsRNA genome is arranged in concentric shells (layers) with average spacing 31 Å. This is larger than the 24–26 Å spacing which has been observed for other dsDNA and dsRNA viruses and reflects the lower packaging density.

The structures of P1 (PC) and P8 (NC) shells are related to the structure of dsRNA containing cores isolated from viruses belonging to the family *Reoviridae*. However, the empty packaging competent precursors have not been detected nor has a conformational change akin to the PC expansion been observed for the latter viruses.

Structure of Individual Proteins

P1

Current structural model of φ6 P1 monomer is based on high-resolution (7.5 Å) electron cryo-microscopy (**Figure 3**). The structure is composed of α-helices that are packed together to form a flat sheet. The few remaining densities have been tentatively assigned to β-sheets. The exact tracing of the polypeptide chain was not possible at this resolution; however, the two conformers in the asymmetric unit were clearly resolved.

P2

Several structures of φ6 P2 alone and in complex with various substrates were solved by X-ray diffraction. P2 is a compact, globular, monomer with α/β fold (**Figure 3**) with a domain arrangement resembling a hand (i.e., palm, fingers, and thumb domains). The fold is similar to those of other viral polymerases, for example, hepatitis C virus and HIV reverse transcriptase. RNA substrate binds in a template channel and the putative dsRNA exit site is partially occluded by the C-terminal domain in the crystal structure (**Figure 3**).

P4

The structures of φ12 P4 hexamer in apo and nucleotide-bound forms have been solved by X-ray diffraction (**Figure 3**). The hexamer has a dome-like structure with a central channel through which RNA passes during packaging. Six equivalent ATP binding sites are located between the subunits at the hexamer periphery. The subunit structure encompasses a catalytic core which is conserved among many ATPases, including Rec-A and hexameric helicases. P4 hexamer interacts with the procapsid dodecahedral framework predominantly via its C-terminal facet.

P8

The structure of the φ6 P8 trimer was derived by fragmentation of the cryo-EM density map at 7.5 Å resolution. The P8 subunit is highly α-helical. The trimer is flat (only 25 Å thick, 75 Å effective diameter) and each subunit is composed of the central, four-helix bundle core and a peripheral four helix bundle (**Figure 3**).

Membrane Envelope

Lipids are derived from the host cytoplasmic membrane but the viral envelope is enriched in phosphatidylglycerol and contains less phosphatidylethanolamine presumably due to high viral membrane curvature and charge repulsion.

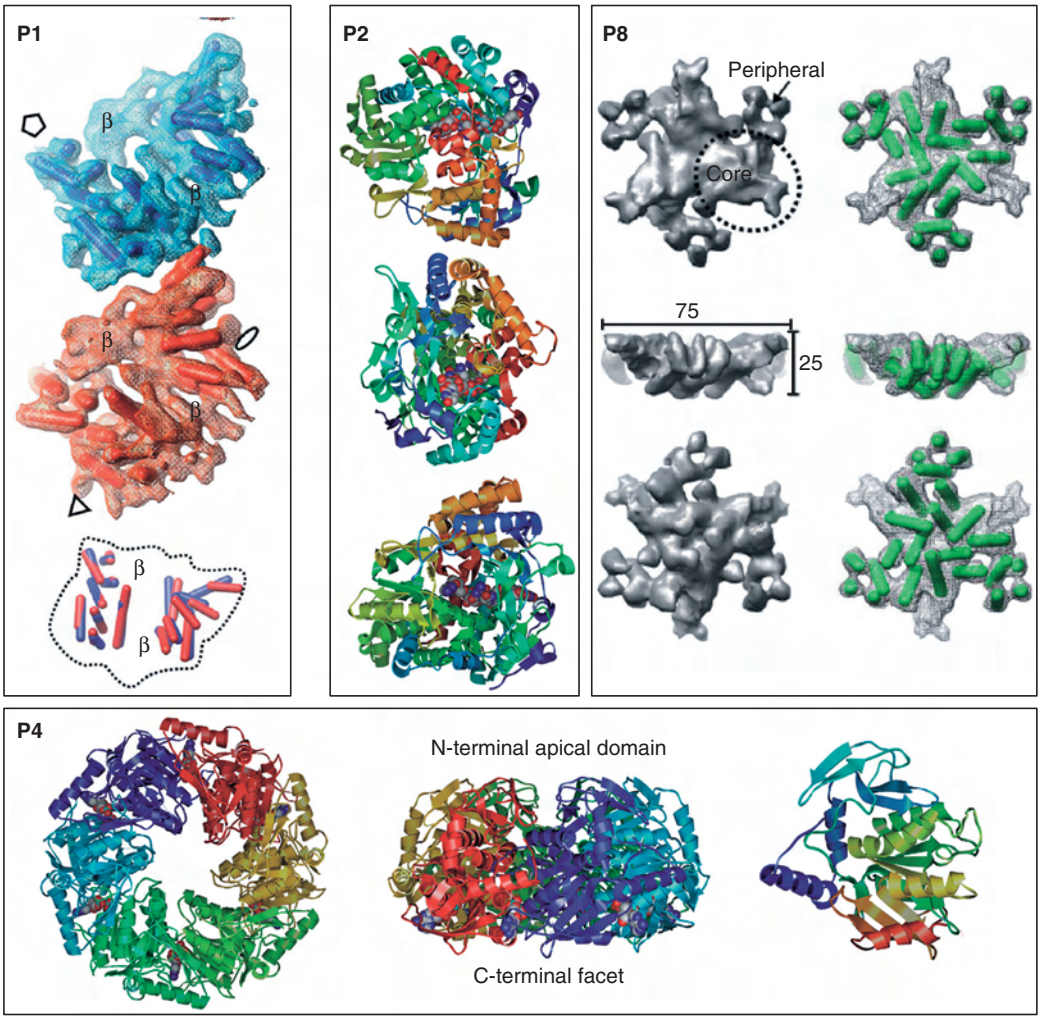

Figure 3 Structure of individual cystoviral proteins. (P1) φ6 P1 structure was derived from cryo-EM. The electron densities of the two conformers found in the asymmetric unit (see **Figure 2**) are shown in blue and red, respectively. Bottom panel shows the tentative secondary structure assignment to the electron density. Reproduced (P2) Ribbon diagram of P2 polymerase structure from phage φ6 in complex with RNA (spacefill representation). Based on PDB id 1UVI, Salgado *et al*. (2004) *Structure* 12: 307–316. Based on PDB id 1W44, Mancini EJ, Kainov DE, Grimes JM, Tuma R, Bamford DH, and Stuart DI (2004) Atomic snapshots on an RNA packaging motor reveal conformational changes linking ATP hydrolysis to RNA translocation. *Cell* 118: 743–755. Left panel: top view down the central channel, subunits in different colors. Middle: Side view. Right: One subunit colored from N-terminus (blue) to C-terminus (red). (P8) P8 structure derived from cryo-EM. Reproduced from Huiskonen JT, de Haas F, Bubeck D, Bamford DH, Fuller SD, and Butcher SJ (2006) Structure of the bacteriophage φ6 nucleocapsid suggests a mechanism for sequential RNA packaging. *Structure* 14: 1039–1048, with permission from Elsevier.

Lipids constitute about 40% of membrane mass while the remaining 60% are membrane proteins. The membrane is loosely associated with the nucleocapsid and the membrane-associated proteins lack icosahedral symmetry.

Genome Organization and Sequence Similarity

The φ6 genome (13385 bp) is organized into three segments (**Figure 4**): L (6374 bp in φ6) codes for the procapsid structural proteins, M (4063 bp in φ6) codes for the spike and membrane proteins, and S (2948 bp in φ6) codes for nucleocapsid and membrane proteins. The (coding) plus strand of each segment contains a short conserved sequence at the 5′-end. This sequence is followed by a packaging signal that is unique to each segment (*pac* site, about 200 nt). The dsRNA genome remains sequestered inside the PC throughout the viral life cycle and only the plus strands are extruded into the cytoplasm where they serve as messenger RNAs or packaging precursors.

Two genes, 12 and 14, code for the two nonstructural proteins identified thus far. While the former is essential for membrane morphogenesis, the latter is dispensable under laboratory conditions.

Genomic maps of the other cystoviruses are similar to φ6 with several exceptions. The viruses which attach directly to rough LPS (φ8, 12, 13) possess several separate genes for the receptor binding spike structure (3a, 3b, and 3c in φ12 and φ13). In addition, gene 7 is positioned after gene 1 in the φ8 L-segment and its expected place is occupied by ORF H. The functions of the nonessential ORFs F, G, and H are not known.

Identity at the amino acid sequence level is high among φ6, 7, 9, and 10, while φ8, 12, and 13 exhibit only limited sequence similarity to φ6 and among themselves. The limited similarity is restricted to the conserved motifs of the polymerase and the packaging ATPase. Sequence similarities for the structural proteins P1 and P7 are generally statistically insignificant for the latter group of phages despite conservation of the procapsid structure. However, high sequence identity detected in restricted regions (e.g., lysis proteins of φ12 and φ6, identical 3′-end of M segments in φ6 and φ13) indicate significant genetic interaction (e.g., recombination) among cystoviruses.

Replication Cycle

The virus life cycle is schematically illustrated in **Figure 5**. The steps were elucidated for φ6 but many features are likely to be similar for the other cystoviruses.

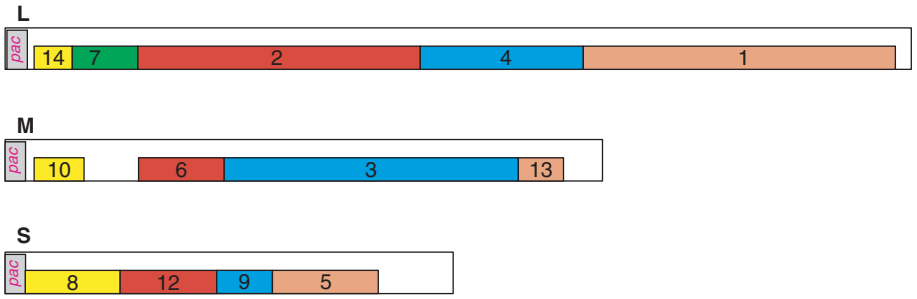

Figure 4 The phi6 genome map showing the locations of genes (gene numbers) and the packaging signal sequences (*pac*).

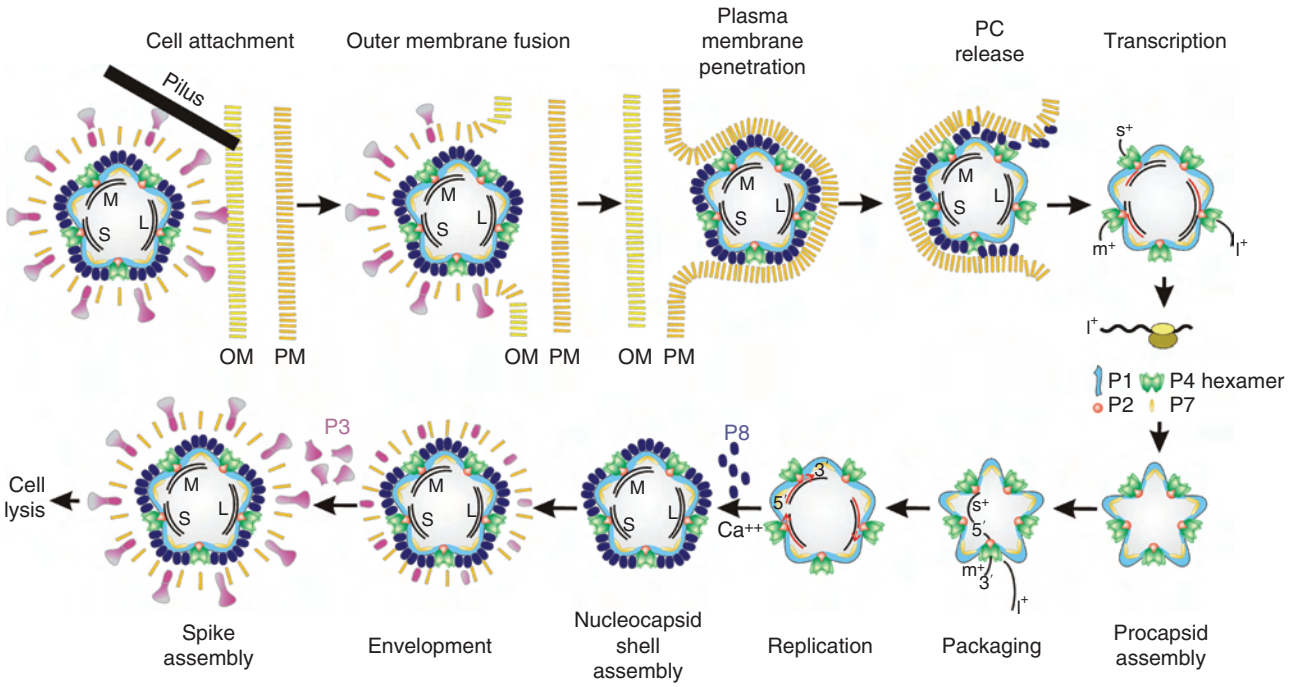

Figure 5 Life cycle diagram of φ6. See the text for details.

Host Cell Attachment and Outer Membrane Fusion

The φ6 and related phages attach to the pilus using the P3 spike protein. The pilus contracts and brings the virion into contact with the outer cell membrane (OM). The φ8, 12, 13 phages utilize a spike composed of proteins P3a, P3b, and P3c (missing in φ8) to attach directly to the rough LPS. The viral envelope then fuses with the OM using the virion fusogenic protein P6. Then the virion-associated lysozyme (P5) degrades the peptidoglycan layer to allow direct contact of the nucleocapsid with the plasma membrane (PM).

Plasma Membrane Penetration

The φ6 nucleocapsid is first enclosed in an endocytic-like vesicle which is brought into the cytoplasm. The NC coat protein P8 disassembles and disrupts the membrane vesicle in order to release the PC into the cytoplasm. The mechanism of the P8-assisted release is still elusive.

Transcription

The depolymerization of the P8 layer activates the PC to perform transcription of the dsRNA genome which produces the plus-strand copies of the three segments (s^+, m^+, l^+). These copies are made inside the PC by the P2 polymerase using a semiconservative mechanism. Several polymerase molecules may engage each segment simultaneously. The resulting RNAs are extruded via P4 hexamers into the cytoplasm where they serve as mRNA for the synthesis of phage proteins and as ssRNA precursors for packaging. Transcription of the three segments is regulated, s^+ and m^+ being produced in a several-fold excess over l^+. The regulation is due to specific interactions between the 3′-end of the minus strand and the polymerase.

PC assembly

The major structural protein P1 co-assembles with P2, P4, and P7 into empty PC (procapsid). The assembly is nucleated by a P1–P4 (P1–P2 in φ8 phage) interaction and intermediates are further stabilized by protein P7 (a 'glue' protein).

Packaging

The unique *pac* sites at the 5′-end of RNA plus strands are specifically recognized in a sequential fashion by the assembled P1 framework. This initial and selective binding brings the 5′-end to the vicinity of the packaging ATPase (P4) hexamer. The P4 ring opens and topologically encloses the RNA inside the central channel. The presence of RNA stimulates the ATPase activity. P4 translocates the ssRNA in the 5′–3′ direction into the procapsid at the expense of ATP hydrolysis. The sequential packaging order is accomplished by increasing the PC affinity for m^+ (l^+) *pac* sequence after packaging of s^+ (m^+). This switching is mediated by the expansion which is in turn driven by the increased amount of the packaged RNA (cf. the headfull packaging of dsDNA bacteriophages). The *in vivo* packaging fidelity is high. However, specific *in vitro* packaging conditions may result in acquisition of multiple s^+ segments or of m^+ segment in the absence of prior packaging of s^+. A heterologous RNA can be packaged by φ8 PCs and the sequential dependence of *in vitro* packaging is weak for this phage.

Replication and NC Maturation

During φ8 or after φ6 packaging, the polymerase performs replication (minus-strand synthesis) of ssRNA into the genomic dsRNA. P2 polymerase interacts with a specific sequence at the 3′-end of each plus strand to initiate the self-primed reaction and makes a full copy of each packaged template. This reaction doubles the amount of RNA inside the PC and yields the mature icosahedral PC. The mature PC can be coated with a layer of P8 trimers in a calcium-dependent reaction. This yields the nucleocapsid. Alternatively, PC may remain in the transcription mode and produce more plus-strand RNA. In φ8 virus the P8 protein is directly associated with the membrane and consequently the PC becomes directly enveloped. The mature φ8 PC is also infectious to host cell spheroplasts.

Membrane Acquisition and Host Cell Lysis

NC is enveloped with a lipid bilayer, which is derived from the host cell plasma membrane. It contains only the viral membrane proteins. The virion-associated lytic enzyme P5 is also incorporated at this stage. Structural protein P9 and the nonstructural protein P12 are essential and sufficient for membrane envelopment in φ6. These two proteins alone can produce lipid vesicles inside the host cell suggesting that envelopment takes place within the cytoplasm. The envelope is subsequently decorated with P3 receptor binding spike which is anchored by the integral membrane protein P6. Virions are released by host cell lysis which is assisted by phage-encoded lytic proteins P5 and P10.

Recombination

Recombination in the *Cystoviridae* is mostly heterologous requiring only about three identical nucleotides. The mechanism of recombination is template switching. The frequency of recombination is increased by truncating

the 3′-end of one of the packaged plus strands. Such truncation may be a result of cellular nuclease cleavage and yields a poor substrate for replication. Hence, recombination may serve as an effective way of correcting the nuclease damage. In addition, homologous recombination, requiring an identical sequence of about 600 nucleotides, has been demonstrated for the φ8 phage. Another mode of recombination is the exchange of whole genomic segments as also seen for other segmented genome viruses.

Genetic Tools and Applications

Reverse Genetics

A reverse genetics system allows systematic testing of the effects of engineered mutations on specific steps in the phage life cycle. Thus, it greatly facilitates delineation of the viral packaging and replication mechanisms. There are two ways to introduce a foreign gene into the dsRNA genome. (1) By constructing a recombinant ssRNA transcript containing the foreign sequences and a 5′-end *pac* site. This substrate is then packaged into procapsids, replicated and matured into NC *in vitro*. The NCs infect host cell spheroplasts to produce the engineered virus progeny. (2) A more efficient method for reverse genetics is based on electroporation of cDNA plasmids, containing the three genomic segments, into cells expressing either SP6 or T7 RNA polymerase. The foreign sequence may be introduced between the 5′-end *pac* sites and the conserved 3′-end replication sequences of each segment.

In Vitro Assembly, Packaging, and Replication System

φ6 procapsid can be efficiently produced in *Escherichia coli* by simultaneously expressing proteins P1, P2, P4, and P7 from a plasmid containing a cDNA copy of the L segment. These procapsids are capable of packaging and replicating the three genomic precursors *in vitro*. Even under optimal conditions only about 5–10% of these procapsids are successfully packaged *in vitro*. Despite the low efficiency the *in vitro* packaging system has been instrumental in delineating the sequential packaging rules and the replication specificity. Incomplete procapsids (containing proteins P1P4, P1P2P4, P1P4P7, P1P2P7) can be produced in *E. coli* and tested for packaging and polymerase activity or used for assembly of specifically labeled procapsids.

Procapsids can be assembled *in vitro* from purified proteins. The *in vitro* assembly system allowed the identification of the minimum assembly requirements and the nucleation mechanism. The *in vitro* system also allows incorporation of chemically labeled or modified subunits to facilitate biophysical and structural studies.

Carrier State

Bacteriophages φ6 and φ8 can establish a carrier state during which the viral genome (or portion of it) replicates as a stable episome inside the host cell cytoplasm. The stable episome constitutes the phage dsRNA inside polymerase complexes that assemble in the cytoplasm. Consequently, the L segment cDNA coding for the PC protein is required to establish the state. The carrier state is maintained by a selective resistance marker engineered into one of the phage genomic segments (usually M or S).

The carrier state is established by electroporating ColE1 suicide plasmids containing the cDNAs of the phage segments into a pseudomonas host that expresses T7 RNA polymerase. These plasmids cannot replicate in pseudomonads and are used to introduce the phage ssRNA into the cytoplasm.

A carrier state may be used to probe RNA packaging or to select new phage mutants. Given the high number of mutations introduced during the phage RNA replication cycle, the carrier state constitutes a good vehicle for targeted evolution of proteins or RNA with novel functions or a way to produce large quantities of siRNA.

Polymerase Applications

φ6 RdRP has the unique capacity to perform self-primed, primer-independent, replication and transcription of RNA substrates. This feature can be used, for example, to obtain complete copies of viral RNA genomes (amplification), or for primer-independent RNA sequencing. An engineered version of RdRP is commercially available.

Glossary

Procapsid A viral assembly intermediate containing a full complement of scaffolding proteins but devoid of genome.
Scaffolding protein A protein that directs the assembly of the virus, found in the procapsid assembly intermediate but not in the mature virion.
S Sedimentation constant in Svedberg units, measured by analytical ultracentrifugation.
T = 1 icosahedron A geometric shape consisting of 20 faces and 12 vertices. A T = 1 virion is composed of 60 viral coat proteins.

History

Bacteriophage øX174, the most well known virus of the family *Microviridae* (micro: Greek for small) was isolated in the 1920s by Sertic and Bulgakov. From the onset, this phage appeared very different from the other bacteriophages isolated during this extensive period of discovery. It was unusually tiny, readily passing through the smallest of ultrafilters. This biophysical characteristic defined its 'race': race X (Roman numeral ten) and the isolate was placed in a vial labeled #174, from which the phage derived its name, race X phage in test tube #174. And there it sat, relatively unperturbed, for decades. The first electron micrographs revealed small, vague isometric particles, vastly different from the tailed morphologies, which came to represent bacteriophages in general. Robert Sinsheimer unraveled the odd nature of the genome in 1959 and øX174 became the first recognized single-stranded (ss) DNA phage. While genetic maps of other phages consisted of orderly linear gene progressions, the øX174 map was most peculiar with genes located within genes. When Sanger and colleagues sequenced the genome, the first one ever sequenced, the complex arrangement of overlapping reading frames was confirmed, so beguiling that many suspected an extraterrestrial origin. As the *New York Times* reported the theory, an advanced race engineered øX174 and disseminated it into the cosmos where it would "persist until the evolution of intelligent life and finally of investigators interested in the genetics of phage." Although attempts were actually made to decipher the hypothesized hidden message, they all failed. However, rumors persist that the code has been broken, it reads, "Behold this marvelous little thing."

This small virus would continue to have a large impact on molecular biology. Arthur Kornberg and colleagues used it to elucidate the molecular mechanism of prokaryotic DNA replication. Masaki Hayashi and colleagues defined the øX174 assembly pathway and were the first to demonstrate that viral DNA packaging could be achieved *in vitro*. As the genome sequence initially defied imagination in 1978, the atomic structure of the viral procapsid, the first such structure solved, beguiled structural virologists, with its unusual external scaffolding protein lattice. And when events were at their most bizarre, the skeletons in the family *Microviridae* closet emerged, the gokushoviruses (Japanese for very small). These viruses escaped detection for decades, hiding out in their obligate intracellular parasitic bacterial hosts.

Virion Morphology and Genome Content

All members of the family *Microviridae* have ssDNA circular genomes of positive polarity and a T = 1 icosahedral capsid. The bulk of the capsid is composed of 60 copies of a major capsid protein (**Figure 1** and **Table 1**), which exhibits the common β-barrel motif found in most icosahedral virion capsid proteins. In addition to the major capsid protein, microviruses also contain 60 copies each of the major spike protein G and DNA binding protein J. The fourth structural protein, the DNA pilot protein, is buried within vertex channels running through the

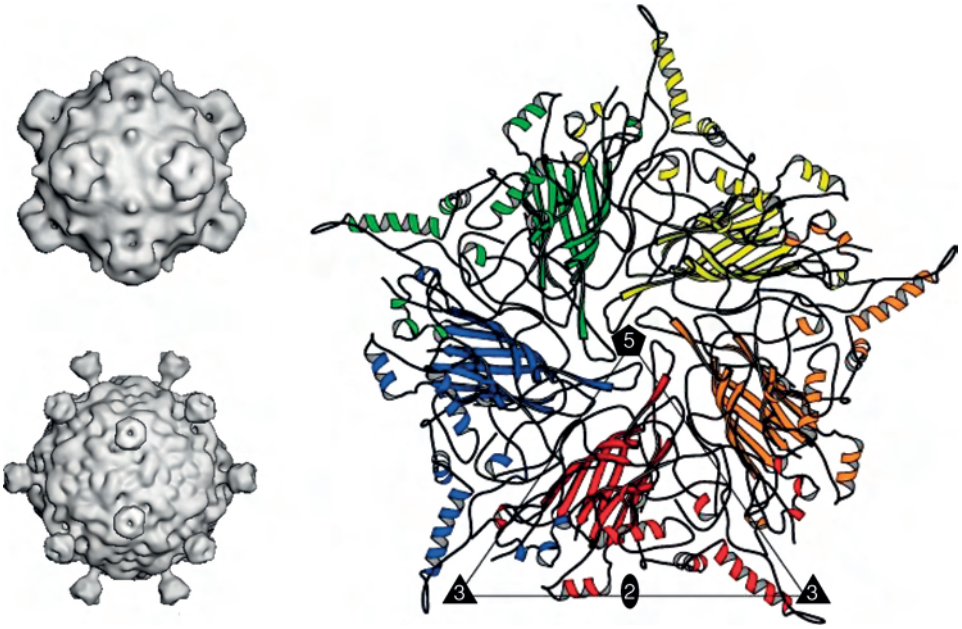

Figure 1 Virion structures. Top left, cryoelectron microscopy (cryoEM) image reconstruction of microvirus ϕX174. Bottom left, cryoEM of gokushovirus SpV4. Right, the arrangement of five ϕX174 coat proteins around a fivefold axis of symmetry. Numbers indicate axis of symmetry and the number of coat proteins that would be interacting at that axis.

Table 1 Microviridae gene products

Microvirus protein	*Gokushovirus protein*	*Function*
A	VP4	Stage II and stage III DNA replication.
A*	UD[a]	An unessential protein for viral propagation. It may play a role in the inhibition of host cell DNA replication and superinfection exclusion.
B	VP3	Internal scaffolding protein, required for procapsid morphogenesis and the assembly of early morphogenetic intermediates. Sixty copies present in the procapsid.
C	VP5?[b]	Facilitates the switch from stage II to stage III DNA replication. Required for stage III DNA synthesis.
D	NP[c]	External scaffolding protein, required for procapsid morphogenesis. 240 copies present in the procapsid.
E	UD	Host cell lysis.
F	VP1	Major coat protein. Sixty copies present in the virion and procapsid.
G	NP	Major spike protein. Sixty copies present in the virion and procapsid.
H	VP2?	DNA pilot protein needed for DNA injection, also called the minor spike protein. Twelve copies present in the procapsid and virion.
J	VP8?	DNA binding protein, needed for DNA packaging, 60 copies present in the virion.
K	UD	An unessential protein for viral propagation. It may play a role optimizing burst sizes in various hosts.

[a]UD, undetermined.
[b]indicates a hypothesized function based on bioinformatic data.
[c]NP, not present in gokushoviruses.

fivefold axes of symmetry. Particles lacking this protein extrude DNA from these locations. Protein H stoichiometry varies among the microviruses, in which there are three major clades represented by bacteriophages G4, α3, and øX174. In øX174, there are 10–12 H proteins per virion, while in bacteriophage α3 only 4–6 copies are required for viability.

Bacteriophage øX174 typifies the microvirus morphology (**Figure 1**), in which 70 Å-diameter G protein pentamers adorn the fivefold axes of symmetry, rising 30 Å from the surface of the 250 Å-diameter capsid. The gokushoviruses lack major spike proteins: hence, the fivefold axes of symmetry are not decorated. The cryoelectron microscopy image reconstruction of gokushovirus SpV4 reveals mushroom-shaped protrusions at the threefold axes of symmetry, which rise 54 Å above the surface of the 270 Å-diameter capsids (**Figure 1**). These threefold related structures appear to be composed of amino acid sequences of three interacting coat proteins. The gokushovirus VP2 is also a structural protein. Although its function has not been experimentally defined, bioinformatic approaches suggest it is analogous to the microvirus DNA pilot protein H. These proteins share a predicted N-terminal transmembrane and a central coiled-coil domain. VP8 may be analogous to the DNA binding protein J, both highly basic short peptides. However, it has not yet been detected in a gokushovirus virion. This may be due to the small size and the difficulties associated with propagating large quantities of gokushoviruses for biochemical characterization.

The genetic maps of microvirus øX174 and gokushovirus Chp2 are depicted in **Figure 2**. Gokushoviral genomes encode neither external scaffolding D nor major spike G proteins. The absence of these genes accounts for the smaller genomes. The external scaffolding protein has at least three known functions in øX174 morphogenesis. It mediates procapsid assembly, stabilizes the assembled procapsid at the two- and threefold axes of symmetry, and directs the placement of the major spike protein G pentamers into the fivefold related capsid craters. These functions are either not required or performed by different proteins in the gokushoviruses. In the gokushoviruses, procapsid assembly is most likely mediated by the internal scaffolding protein VP3, as is seen with the øX174 internal scaffolding protein B. Despite the small compact nature of microvirus genomes, two proteins A* and K with obscure or unknown functions are very strongly conserved. Three additional small ORFs are found in the H-A intercistronic region of the bacteriophage α3-like proteins. Other proteins are involved in DNA replication and lysis. These will be discussed in the context of their functions during viral replication.

Host Cell Recognition, Attachment, and Penetration

Bacteriophage øX174 attachment requires lipopolysaccharides (LPSs) containing specific terminal glucose and galactose moieties. Most microvirus research has been conducted with øX174. Six coat protein residues constitute this Ca^{2+}-dependent glucose binding site. Due to the icosahedral symmetry of the capsids, each virion has 60 glucose binding sites. Attachment is a reversible reaction. Although the molecular basis of the following irreversible penetration step remains obscure, it most likely involves the spike proteins G and H. Host range mutations map to these two proteins and to coat protein residues directly surrounding

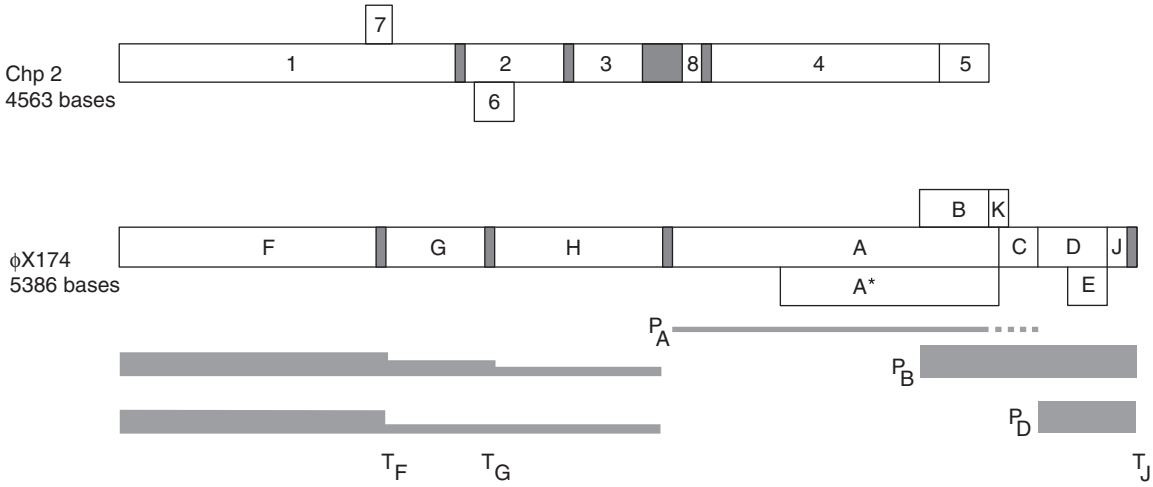

Figure 2 Genetic maps. Top, gokushovirus Chp2. Middle, microvirus øX174. Bottom, transcripts found in øX174 infected cells. The promoters and transcription terminators are indicated on the linear map of øX174. Line thickness indicates the relative abundance of the transcripts. The gene A transcript is very unstable; the terminator for this transcript is unknown. For protein functions, see **Table 1**.

the fivefold related spike complexes. Both spike proteins bind LPS of øX174 sensitive cells, but the specific details of these interactions are unknown. The location of the host range mutations argues for the existence of a second host cell penetration receptor. An analogy can be made to the large tailed bacteriophages that 'walk' along the surface of the cell, via tailspike interactions, until they find a receptor for penetration. But instead of walking, øX174 would merrily roll along.

In electron micrographs, the majority of eclipsed øX174 particles are imbedded at points of adhesion between the cell wall and inner membrane, suggesting the location of the hypothesized second receptor and indicating that the genome may be ejected directly into the cytoplasm. Penetration requires the DNA pilot protein H, which enters the cell along with the genome. Both genetic and preliminary structural data indicate that conformational changes in the capsid accompany or facilitate DNA ejection. Second-site suppressors of cold-sensitive DNA pilot proteins map to two places in the major spike protein. One set of suppressing residues lines the channel that passes through each fivefold vertex. The second set alters the interface between β-strands B and I of the G protein β-barrel, suggesting that conformational switches within this interface may mediate the channel opening.

Due to their recent discovery, the details of gokushovirus attachment and penetration have yet to be defined. The results of bioinformatic approaches combined with host range studies with the chlamydiaphages suggest that the threefold related protrusion may govern host cell specific attachment. However, there is no direct experimental evidence to support this hypothesis. Unlike microviruses, gokushoviruses appear to utilize a host cell protein, as opposed to LPS, as a receptor molecule. The exact location of the hypothesized DNA pilot protein, VP2, at the three- or fivefold axes of symmetry, is unknown as is the conduit through with the genome is ejected.

DNA Replication

The studies of øX174 DNA replication are of historical significance. Positive polarity ssDNA replication strategies are complex, occurring in three separate stages, which are described below (**Figure 3**). Kornberg and colleagues reconstituted the first two stages *in vitro* while Hayashi and colleagues reconstituted the third stage of DNA replication, which includes concurrent packaging of the single-stranded genome. Collectively, these studies established the first defined viral genome replication process on the biochemical level.

Single-stranded viral DNA is delivered into the infected cell. Stage I DNA replication involves the conversion of the ss genome into a covalently closed, double-stranded (ds), circular molecule, called replicative form one (RFI) DNA. Since purified single-stranded microvirus DNA produces progeny when transfected, host cell proteins are both necessary and sufficient for stage I replication *in vivo*. A stem–loop structure in the FG intercistronic region serves as the host cell and protein recognition site, which initiates the assembly of the primosome. After primosome assembly, the complex migrates along the ssDNA in a $5' \rightarrow 3'$ direction synthesizing the requisite RNA primers for DNA replication. Addition of the holoenzyme leads to chain elongation. The 13 host cell proteins required for this stage of synthesis are the same proteins involved in replicating the host cell chromosome.

During stage II DNA synthesis, RF1 DNA is amplified. In addition to the host cell proteins required for stage I replication, stage II replication is dependent on the viral A protein and the host cell *rep* protein, which functions as a helicase. The viral A protein binds to the origin of replication and nicks it to initiate (+) strand synthesis, which will occur via a rolling circle mechanism. After nicking, protein A forms a covalent ester bond with the DNA, forming a relaxed circular molecule called RFII. The host cell *rep* protein unwinds the helix and the host ssDNA binding protein (ssb) stabilizes the separated strands. After one round of rolling circle synthesis, protein A cuts the newly generated origin and acts as a ligase, generating a covalently closed circular molecule. Minus strand synthesis is mechanistically similar to stage I DNA synthesis.

Stage III DNA synthesis involves the concurrent synthesis and packaging of the ssDNA genome. Procapsids and viral protein C are required for this reaction along with all the proteins involved in the previous stages of replication with the exception of the ssb. Thus, a single-stranded genome is not synthesized unless there is a procapsid in which to package it. The competition between ssb and protein C for binding ssDNA most likely signals the commencement of stage III synthesis. Proteins A, C, and *rep* form a complex on the dsDNA that docks to procapsids, presumably in a groove that spans one of the twofold axes of symmetry. Procapsid binding does not occur in the absence of protein C. Mechanistically, stage III DNA synthesis is similar to the stage II (+) rolling circle synthesis. As the new (+) strand is synthesized, it is translocated into the procapsid. After one round of synthesis, protein A, which is covalently attached to the origin of replication, cuts the newly synthesized origin and acts as a ligase to generate a covalently closed circular molecule.

Gene Expression

Since microviruses contain single-stranded genomes of positive polarity, stage I DNA synthesis, which generates the negative strand, must occur before transcription.

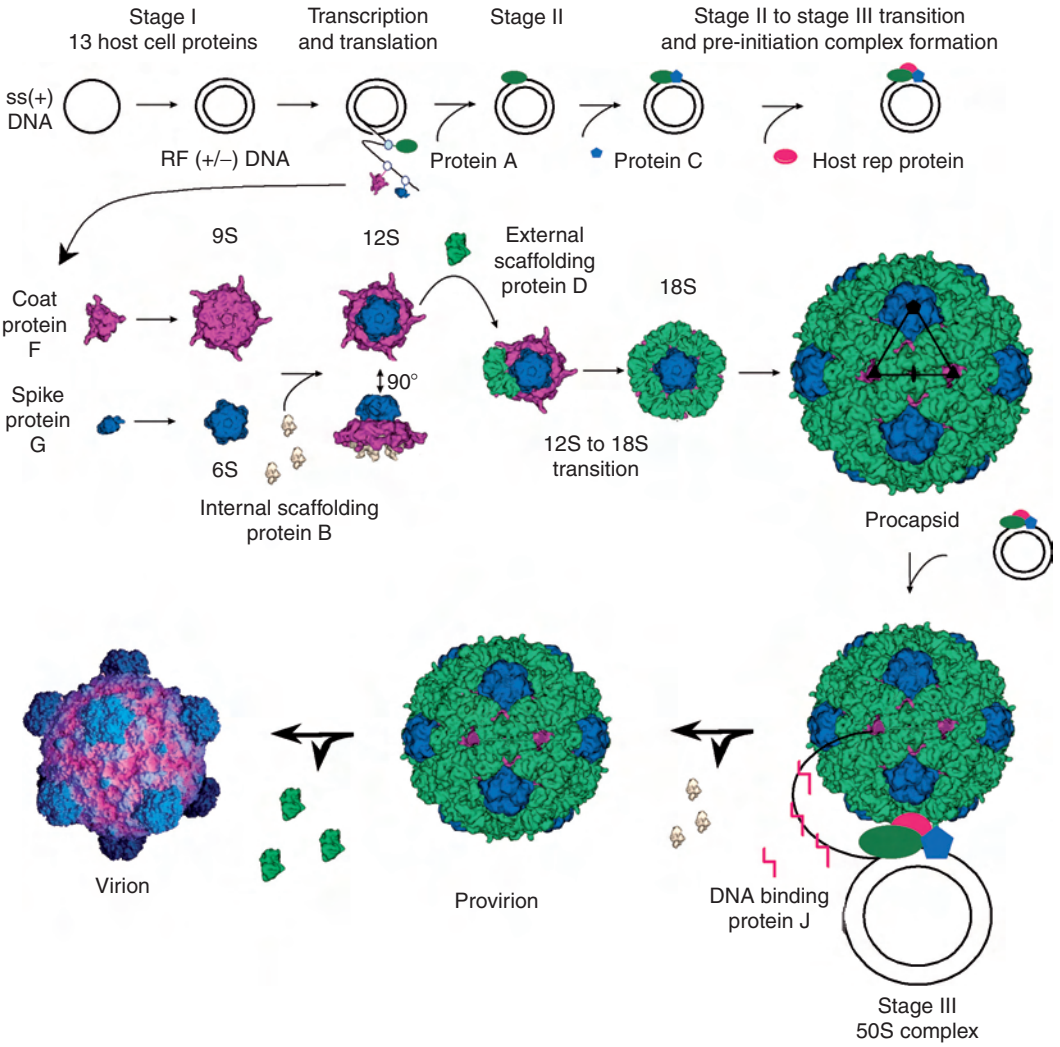

Figure 3 Morphogenesis and DNA replication of ϕX174.

Unlike large bacteriophages, gene expression in the members of the family *Microviridae* is neither temporal nor mediated by *trans*-acting mechanisms. Thus, the timing and relative production of viral proteins is entirely dependent on *cis*-acting regulation signals: promoters, transcription terminators, mRNA stability sequences, and ribosome binding sites. Promoters are found upstream of genes A, B, and D and terminators are found after genes J, F, G, and H (**Figure 2**). Since terminators are not 100% efficient, a wide variety of transcripts are produced. Yet there is a rough correlation between the abundance of a gene transcript and the amount of the encoded protein required for the viral life cycle. For example, gene D transcripts, which encode the external scaffolding protein, are the most abundant in the cell and the requirement of protein D is the greatest for progeny production. Similarly, there are more gene F, J, and G transcripts than transcripts of gene H. The relative stoichiometry of these structural proteins are 5:5:5:1, respectively. Protein expression is also affected by mRNA stability. Each mRNA species decays with a characteristic rate. Transcripts of gene A decay very rapidly, ensuring that this nonstructural protein is not overexpressed. Finally, regulation can also be achieved on the translational level. Despite gene E's location within gene D, the most abundant transcript, few E proteins, which mediate cell lysis, are translated due to an extremely ineffective ribosome binding site.

Morphogenesis

Despite extensive searches, a dependence on host molecular chaperones, such as groEL, and groES, has never been documented. Thus, chaperone independence is another factor that distinguishes the microviruses from dsDNA

bacteriophages. The first virally encoded microvirus assembly intermediates are the 9S and 6S particles, respective pentamers of the major coat F and spike G proteins (**Figure 3**). After 9S pentamer formation, five internal scaffolding proteins bind to the 9S underside, which will become the capsid's internal surface, forming the 9S* intermediate. 9S* particles then associate with spike protein pentamers to produce 12S assembly intermediates. The internal scaffolding protein also facilitates the incorporation of the DNA pilot protein H. However, the exact time protein H enters the assembly pathways remains somewhat obscure. The addition of 20 external scaffolding proteins results in the construction of the 18S particle.

The external scaffolding protein has been the focus of many research endeavors due to its inherent ability to achieve different structures. The four D subunits (D1, D2, D3, and D4) per coat protein (**Figure 4**), are arranged as two similar, but not identical, asymmetric dimers (D1D2 and D3D4). Each subunit makes a unique set of contacts with the underlying coat protein, the spike protein, and neighboring D protein subunits. Accordingly, the structure of each subunit is unique. The atomic structure of the assembly naive D protein dimer has also been determined. The subunits within that dimer, DA and DB, appear poised to achieve the four structures found in the procapsid. DA has a structure somewhat between D1 and D3, while DB has a structure midway between D2 and D4.

External scaffolding proteins are rare, only observed in parasitic satellite virus systems such as bacteriophage P4, in which the satellite virus encodes an external scaffolding protein that forces the helper's virus capsid to form a smaller capsid. Thus, microviruses are the only nonsatellite viruses known to encode an external scaffolding protein. This protein performs many of the functions typically associated with internal scaffolding proteins in one-scaffolding-protein systems, the organization of assembly precursors into a procapsid, and the stabilization of that structure. However, its function is physically and temporally dependent on the internal scaffolding protein, which can be eliminated from the pathway

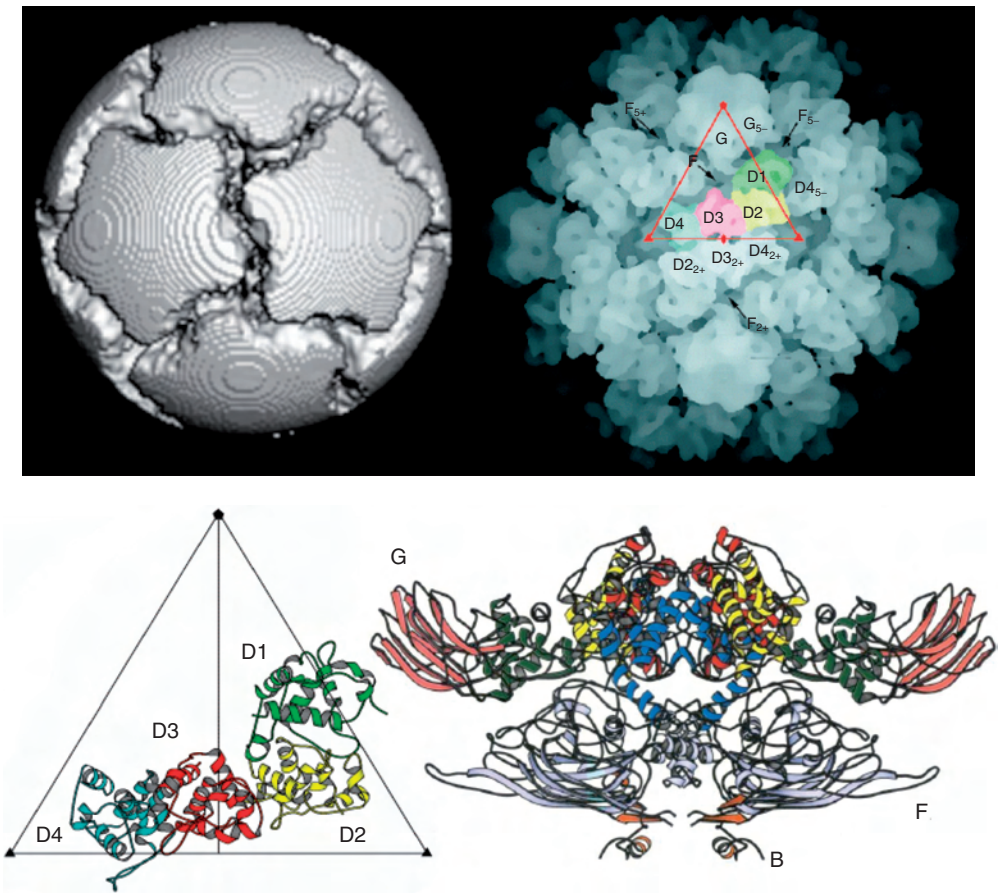

Figure 4 CryoEM and atomic renderings of the øX174 procapsid. Top left, rendering of the procapsid with the removal of the external scaffolding protein. Note that the coat protein pentamers do not contact each other. Top right, isosurface tracing of the øX174 procapsid, the four structurally unique external scaffolding proteins are depicted as D1–D4. Bottom left, the Cα backbones of the four external scaffolding protein subunits. Bottom right, cross-section of the procapsid along a twofold axis of symmetry, showing the positions of the internal B and external D scaffolding proteins relative to the coat F and spike G proteins.

(see the section titled 'Evolution and evolutionary studies' below). Procapsid morphogenesis is completed with the association of the 12 18S particles. The structure is almost exclusively held together via external scaffolding protein contacts across twofold axes of symmetry. Remarkably, there appear to be no associations between coat protein pentamers (**Figure 4**).

Gokushovirus genomes do not encode an external scaffolding protein. The details of the early assembly pathway remain to be elucidated. A gokushovirus particle containing VP3 in addition to the structural coat and DNA pilot proteins has been isolated. Unlike virions, these particles are devoid of DNA. This particle most likely represents a procapsid and indicates that VP3 functions as an internal scaffolding protein.

DNA Packaging and the DNA Binding Protein

Genome biosynthesis and packaging are concurrent processes in øX174. The pre-initiation complex, consisting of the host cell *rep*, viral A and C proteins, associates with the procapsid forming the 50S complex. As described above, the viral A protein binds the origin of replication in replicative form DNA. The results of genetic studies indicate that the pre-initiation docking site resides along a twofold axis of symmetry. The DNA binding protein J enters the procapsid during packaging and is absolutely required for genome encapsidation. Once in the procapsid, the C-terminus of the protein, which is very hydrophobic and aromatic, competes with the internal scaffolding protein for binding to a cleft in the viral coat protein. This competition results in the extrusion of the internal scaffolding protein during the packaging reaction.

Microvirus J proteins are extremely basic proteins that bind the genome via electrostatic interactions. The genome also interacts with a small cluster of basic amino acid residues in the capsid. Unlike large dsDNA bacteriophages, the øX174 genome does not exist as a dense core in the capsid. Instead, the DNA is tethered to the capsid's inner surface. In the atomic model, the protein forms an S-shaped polypeptide chain devoid of secondary structure. The C-terminus is tightly associated with the cleft located near the center of the coat protein. Each of the 60 proteins traces a path toward the fivefold axis of symmetry, crosses over to the adjacent capsid protein, and veers toward the C-terminus of the adjacent J protein. Thus, the DNA binding protein guides the incoming genome into a somewhat ordered conformation and a portion of the genome is ordered in the X-ray structure. The biophysical characterization of fully packaged particles with foreign genome-length DNA or øX174 genomes with mutant DNA binding proteins suggest that protein–DNA interactions influence the final stages of morphogenesis. Morphogenesis terminates with the provirion to virion transition: the dissociation of the external scaffolding protein and an 8.5 Å radial collapse of capsid pentamers around the genome. The tethered genome constrains the spatial orientation and secondary structure of the remaining nucleotides. Therefore, altering the tether or the base composition of the packaged nucleic acid may affect the magnitude or the integrity of the collapse. However, the role of DNA–capsid interactions in øX174 is not as dramatic as those seen in other viral systems in which abrogating genome–capsid interactions lead to severely aberrant particles.

Lysis

Unlike large double-stranded bacteriophages, microviruses do not have the genetic capacity to encode two-component endolysin and holin lysis systems. Instead, they have evolved a small protein, lysis protein E that inhibits peptidoglycan biosynthesis. Thus, lysis is dependent on host cell division, during which the cell becomes sensitive to osmotic pressure. The results of several elegant genetic studies elucidated protein E function. By selecting for lysis resistant cells, Ryland Young and colleagues first uncovered the *slyD* (*s*ensitivity to *ly*sis) gene, which encodes a peptidly-prolyl cis-transferase-isomerase, or PPIase. However, it is unlikely that the *slyD* gene product is the E protein target. Considering the function of PPIase's in protein folding and the E protein's five prolyl bonds, it seemed more likely that the E protein was a substrate for the host cell enzyme. In fact, gene E mutants, *Epos*-plates on *slyD*, can be readily isolated. The *Epos* proteins were used in a second round of selection with *slyD* cells, surviving colonies containing mutations in the *mraY* gene, which encodes tanslocase I. This enzyme catalyzes the formation of the first lipid-linked intermediate in cell wall biosynthesis and most likely the target of protein E.

Evolution and Evolutionary Studies

Due to the small genomes and the ability to interpret amino acid substitutions within the context of the virion and procapsid atomic structures, the microviruses have become one of the leading systems for molecular evolution analyses. In studies pioneered by Jim Bull, Holly Wichman, and colleagues, viruses are placed under selective conditions, and grown for numerous generations in a chemostat. At various time intervals, individual genomes are sequenced, allowing the appearance and disappearance of beneficial mutations to be monitored. Of course, the mutations obtained differ according to the selection conditions. While these studies identify beneficial changes in both structural and nonstructural proteins, many mutations are in genetic regulatory sequences, which most likely

optimize the relative level of viral proteins synthesized under the experimental conditions.

The results of an exhaustive search for new *Escherichia coli* microviruses reveal that the 47 known species can be divided into three separate clades, typified by bacteriophages øX174, G4, and α3. Although there is evidence for some horizontal gene transfer between the species, the extent is considerably lower than that observed for dsDNA viruses. The one gene that seems to be the most recent acquisition, at least in its present form, is the external scaffolding protein gene, which appears to have originated in the øX174 clade and spread to the other two.

The evolutionary relationship between the gokusho and microviruses remains somewhat obscure. There is a deep evolutionary rift between the two groups, with no known intermediate species. The rift appears to be a function of the biology of their hosts, not the hosts' evolutionary relationship. The gokushoviruses have been isolated from obligated intracellular parasitic bacteria or mollicutes. For example, the *Bdellovibrio* host for the gokushovirus øMH2K is a proteobacterium, like other microvirus hosts, but øMH2K is closely related to the phages of chlamidia. One of the primary differences between the two groups is the external scaffolding protein.

While the existence of two scaffolding proteins is unique in any system, it is particularly peculiar for the T = 1 microviruses. No other T = 1 virus requires a scaffolding protein, let alone two. An accumulation of both genetic and structural data suggests that the external scaffolding protein may be more essential for morphogenesis. The internal scaffolding protein, on the other hand, may be better viewed as en efficiency protein, facilitating several morphogenetic reactions, but not absolutely essential for any one in particular. This hypothesis has recently been tested by the isolation of a sextuple mutant strain of øX174 that no longer requires the internal scaffolding protein. Although mutations in structural and external scaffolding proteins did arise, two mutations reside in the external scaffolding gene promoters, leading to the overexpression of the mutant external scaffolding protein. These three mutations appear to have a kinetic effect on virion assembly, indicating that one function of the internal scaffolding is to lower the critical concentration of the external scaffolding protein needed to nucleate the assembly. The morphogenesis of wild-type øX174 is extremely rapid, progeny virions can be detected as quickly as 5 min postinfection, which may be critical for a small phage without the genome content to encode superinfection exclusion functions. At 5 min postinfection, most other phages are just concluding early gene expression. Rapid morphogenesis may be a consequence of having two scaffolding proteins, allowing microviruses to compete with the larger and vastly more prevalent dsDNA phages. In this evolutionary model, the external scaffolding protein is a recent acquisition. Those phages that did not acquire the gene, the gokushoviruses, persisted by finding a niche free of competition, obligate intracellular parasitic hosts like chlamidia.

Glossary

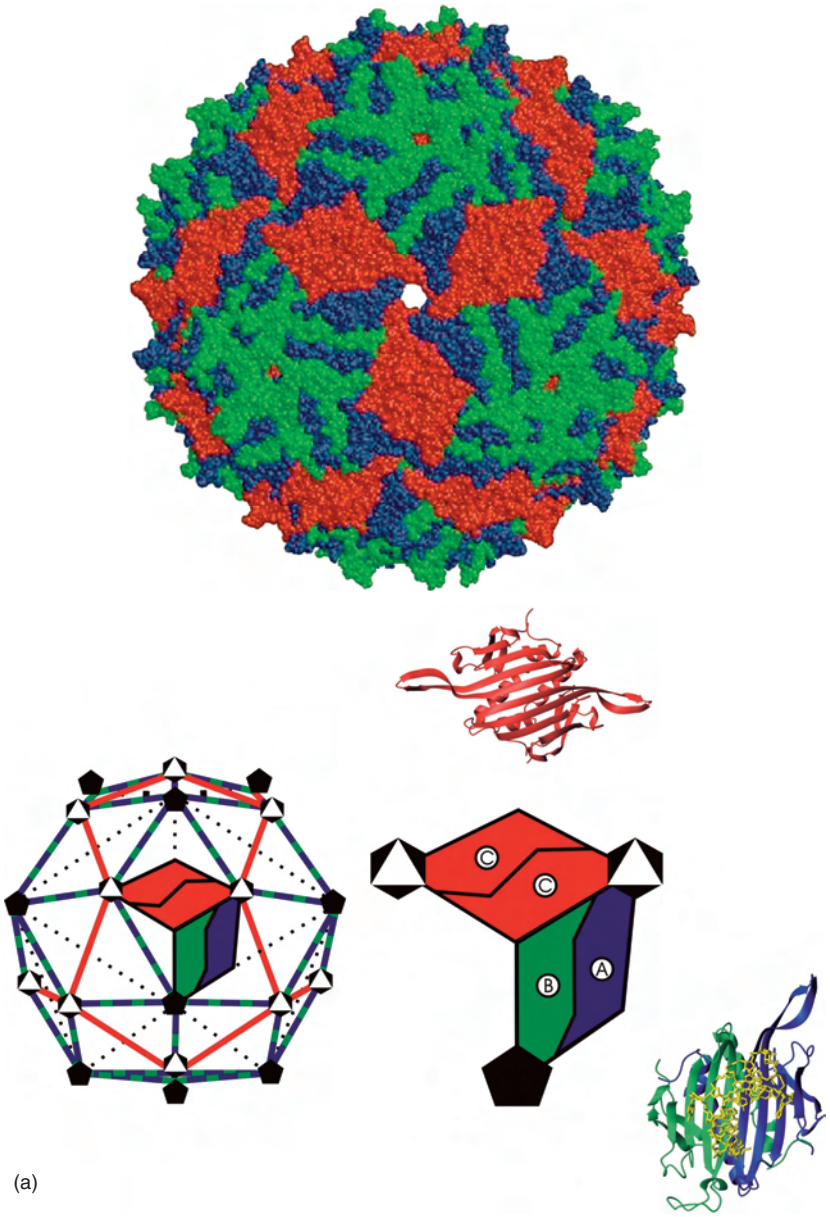
Pfu Plaque-forming unit; that is, the number of phage particles per host cell required to generate productive infections. Theoretically, this value could be 1, but in reality only very few of the phages that attach to the edge of a pilus will get access to the inside of a cell, so values in the 100s are not uncommon.
Polycistronic RNA The term cistron was coined a long time ago to mean any section of an mRNA that gets translated. The RNA phage genomes are 'polycistronic', because they encode multiple protein products.
Quasi-equivalent conformers These are different conformations of the identical polypeptide sequences that form at the differing symmetry-related positions of viral capsids.
Translational repression Refers to the process whereby a protein product interacts with an mRNA molecule, thus preventing its translation.
Triangulation number, *T* Defined mathematically as $T = (h^2 + hk + k^2)$, where h and k are any pair of positive integers, including zero. For instance, giving rise to triangulation numbers of 1 for $h,k = 1,0$, and 3 for $h,k = 1,1$. These h and k values can be determined by analysis of real capsids viruses by analyzing them in terms of networks of equilateral triangles that cover the surface of a sphere.

Background

Not all *Escherichia coli* cells are the same. Some of them produce a protein tube at the surface known as a pilus. It turns out that the information to build this structure is encoded by a separate genetic element, the F factor not carried by all cells. The RNA phages were initially identified because of their ability to infect *E. coli* carrying this factor. The pili encoded by F are used by the cells to swap DNA with other bacteria that lack the factor, resulting in a primitive form of sexual genetic transfer known as conjugation and the use of the term 'male' for bacteria that carry the F factor. Thus bacteria are able to swap useful genes, for example, for antibiotic resistance, rapidly within their populations. All processes in biology can be seen as opportunities ripe for exploitation, and the F pilus system, so useful to the bacteria in sharing useful genetic characteristics, presents an opening for a group of bacterial viruses to gain entry into F^+ cells. Tim Loeb working in Norton Zinder's laboratory at the Rockefeller University in New York was the first to realize that there might be male-specific bacterial viruses, bacteriophages. Together they isolated and began to characterize such phages from an initial sample of raw sewage. One intensively studied version known as MS2 is believed to have been named because it was male-specific factor 2, although there are unconfirmed stories that the MS also stands for metropolitan sewer.

Large numbers of similar phages were rapidly isolated worldwide after the initial discovery, and we now know that such phages are extremely common in the environment with up to 10^7 Pfu ml^{-1} in sewage. Both human and animal hosts appear to harbor *E. coli* populations able to support such phages, which are hence termed coliphage. In addition, virtually identical phages have been found that are specific to *Acinetobacter* (AP205) and other Gram-negative bacteria. In such phages, the infection process still occurs via pili but these are not the same as the sex pili of *E. coli*. For instance, phage PRR1 infects hosts via pili encoded by incompatibility type P plasmids which are widely dispersed, allowing the phage to infect a range of different bacterial cells.

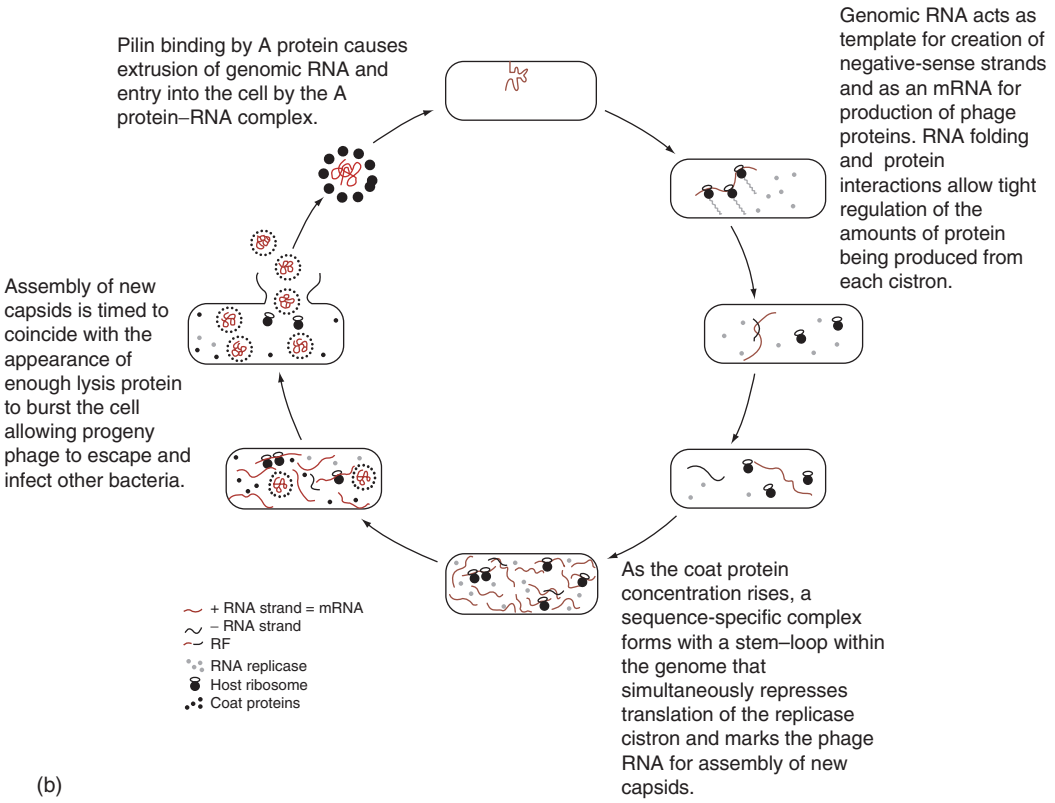
All these bacteriophages turn out to have very closely related structural and genetic features. They form spherical capsids of ~250 Å diameter that enclose a single-stranded RNA (ssRNA) genome of ~3500–4300 nt in length. The ssRNA is the positive-sense version of the genome and acts as a messenger RNA (mRNA) while in infected cells. On the basis of immunological cross-reactivity and genome organization, the phages have been classified into two genera and these have been subdivided in turn into two groups. All these phages are members of the *Leviviridae* or the *Allelolevirida*e, the latter being distinguished by having slightly longer genomes and because of the presence of read-through products from the coat protein gene. Subgroups I and II belong to the former genus and typical members are MS2 and GA, respectively, whereas group III and IV phages belong to the latter genus with typical members being Qβ and SP, respectively.



These very simple pathogens have been used since their discovery to understand many basic processes of molecular biology. They have been used to probe the structure of the bacterial pilus, to dissect the function of the protein synthesis pathway, to understand RNA replication, and to identify the initiation and termination signals on prokaryotic mRNAs. These studies led to the discovery of novel forms of genetic regulation along a polycistronic RNA, including translational repression.

Phage RNA was the first nucleic acid to be replicated in a test tube and was used as a model for the development of nucleic acid sequencing technology. Detailed insights into viral assembly processes and the molecular basis of sequence-specific RNA–protein recognition have also emerged. Research applications of these phages and their biology are still very active (see below).

Capsid Structure and Life Cycle



At the time of their discovery, the three-dimensional structures of viruses were not known but it was realized that the limited coding capacity of viral nucleic acids was likely to place a constraint on the number and size of gene products that could be dedicated to building a protective container, or capsid. This in turn implied that capsids are likely to be composed of multiple copies of one or very few 'coat' protein subunits necessarily resulting in highly symmetric structures. The two most 'efficient' designs for such structures, in terms of allowing multiple copies of the smallest protein units to enclose the maximum volume, and hence encompass the largest genome, are the helix and the icosahedron. Simple spherical virus capsids are therefore based on an icosahedral surface lattice (**Figure 1**).

A mathematically perfect icosahedron would have 60 facets in it so the stoichiometry for such viruses would be

(a)

Figure 1 Continued

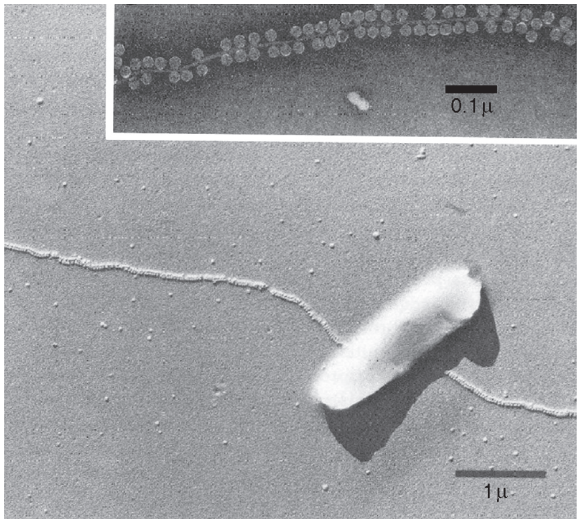


Figure 1 Capsid structure and life cycle. (a) Shows a space-filling representation of one face of the MS2 bacteriophage particle as determined using X-ray crystallography viewed along the icosahedral threefold axis. The differing quasi-equivalent protein conformers are colored red, green, and blue. There are 60 of each type accounting for the 180 coat protein copies per $T = 3$ shell. Note, the position of the A protein in the shell is not observed from the X-ray structure for technical reasons. Below is a cartoon of an icosahedron with the threefold (open triangles) and fivefold (solid pentagons) symmetry axes highlighted. The MS2 coat protein subunits form noncovalent dimers in solution and in the final capsid, and the way in which they pack around the axes is illustrated on the right both as a cartoon and as detailed three-dimensional representations of the differing quasi-equivalent conformers. Proteins are shown as ribbon diagrams representing their polypeptide backbones. The A/B dimer is shown bound to the translational repression RNA stem–loop (yellow); see also **Figure 3**. (b) Shows a schematic of the phage life cycle, including the attachment process, entry of the genomic RNA, replication, self-assembly of progeny phage particles, and subsequent lysis of the host. (c) Shows the process of infection with phage particles adhered along the length of a bacterial pilus. The magnification is ~16000× and reveals the relative sizes of the host and its virus particles. (b) Reproduced from Watson JD, Hapkins NH, Roberts JW, Steltz JA, and Winer AM (1993) *Molecular Biology of the Gene*, *Vol. I*: *General Principle*, 5th edn. New Delhi: Pearson Education, Inc., with permission. (c) Reproduced from Paranchych W (1975) Attachment, ejection and penetration stages of the RNA phage infectious process. In: Zinder ND (ed.) *RNA Phages*, p. 89. New York: Cold Spring Harbor Laboratory Press, with permission from Cold Spring Harbor Laboratory Press (NY).

60 coat proteins per shell. However, from many early studies, it was clear that viruses often had many more than 60 subunits in their capsids, although in cases where detailed biochemistry was possible it appeared that such viruses contained simple multiples of the expected value, for example, 180, 240, etc. Don Caspar and Aaron Klug offered an explanation for such protein stoichiometries via a theory they called quasi-equivalence. They argued that viral coat proteins are three-dimensional objects that are partially flexible due to the chemical properties of their constituent polypeptide backbones and amino acid side chains. It would therefore be possible to conserve inter-subunit bonding if the precise molecular interactions at any position in the capsid were flexible enough to accommodate small changes from ideality. This theory leads immediately to predictions of 'allowed' stoichiometries for capsids with subunit numbers of 180, 240, etc., derived from what is called a subtriangulation of the sphere and defined by the triangulation number, *T*. This value is allowed to vary from 1, 3, 4, etc., yielding the observed stoichiometries of 60, 180, 240, etc. subunits. The implication of this idea is that the coat proteins within the capsids with more than 60 subunits must be able to adopt slightly different conformations depending on their relative locations in the shell. These are known as quasi-equivalent conformers and this idea has subsequently been confirmed by X-ray structure determination of many viruses. The RNA phages have 180 coat protein subunits per capsid and are therefore examples of $T = 3$ shells.

As well as the major coat protein, it is known that the capsids of RNA phages contain a minor protein that is essential for infectivity known as the maturation (or A) protein. In some of the RNA phages, another minor protein is associated with the capsids due to the production of a small percentage of read-through versions of the coat protein. The function of these minor components is largely unknown. Mature infectious capsids must contain at least one copy of the maturation protein as well as the icosahedral shell composed of the major coat protein. Infection is initiated by the interaction of the A protein with the edge of a bacterial pilus, confirming that part of this protein must project on the outer surface of the virion. This interaction triggers a release of the phage RNA from inside the phage shell and proteolytic cleavage of the A protein into two major fragments. The RNA and the A protein domains then enter the cell leaving the remainder of the capsid, that is, the major coat protein, on the outside. This implies that at least one fragment of the A protein must form a tight interaction with the phage RNA. Indeed, careful measurement of the kinetics of uptake of both phage RNA and the two fragments of the A protein suggest that they enter the cell as a single complex. Two RNA-binding sites for the A protein along the genome, one toward the 5′ end and the other close to the 3′ end, have been identified. It is tempting to speculate that pilin attachment leads to conformational change in the A protein, that is made irreversible by the proteolytic cleavage, and this in turn results in expulsion of the phage genomic RNA from its capsid. The precise mechanism of how the A protein–RNA complex is taken up into the cell has not been worked out in any detail. It is assumed that these complexes can transit into the cell like DNA but this does not seem to have been firmly established.

Whatever the mechanism of cell entry, once inside the cell the phage RNA then serves as an mRNA (see below). Expression of phage proteins results in replication of the phage RNA via the formation of an RNA-dependent RNA polymerase consisting of one phage-encoded replicase subunit, the host proteins S1, and elongation factors Tu and Ts, and an additional host factor. This polymerase creates negative strand versions of the genome that in turn serve as templates for the production of progeny positive-sense genomes. In an exquisite example of timing controlled by macromolecular interactions, this replication phase of infection is reined in by a translational repression event. Translation of the replicase subunit becomes blocked by interaction of a coat protein dimer with a stem–loop operator site of just 19 nt in length that includes the start codon for that cistron.

The resultant coat protein–genomic RNA complexes then serve as the assembly initiation complexes for formation of progeny phage particles. At some point, the A protein must become a part of this complex. The final act of infection is lysis of the host cell by the action of a lysis protein leading to release of up to 10 000 progeny particles. During this process, the phage has dramatically differing needs for each of its gene products: replicase, coat protein, maturation protein, and lysis protein. Each protein also needs to act at different times. Remarkably, both the amounts and timing of the appearance of each of these products is very tightly regulated, even though each cistron is present once on every copy of the genomic RNA. The details of that regulation are described in the following sections.

Control of Phage Gene Expression

When the phage-encoded protein expression is analyzed (**Figure 2**), it can be seen that the first protein to be produced after the RNA gains entry to the cell is the coat protein, and its expression remains high throughout an infection cycle. There seems little regulation of this expression other than the sequence and stability of the initiator hairpin structure that binds the ribosome. There are also some data that suggest that upstream flanking sequences can act positively to promote translation, perhaps by forming structures that favor binding of the ribosome to this site.

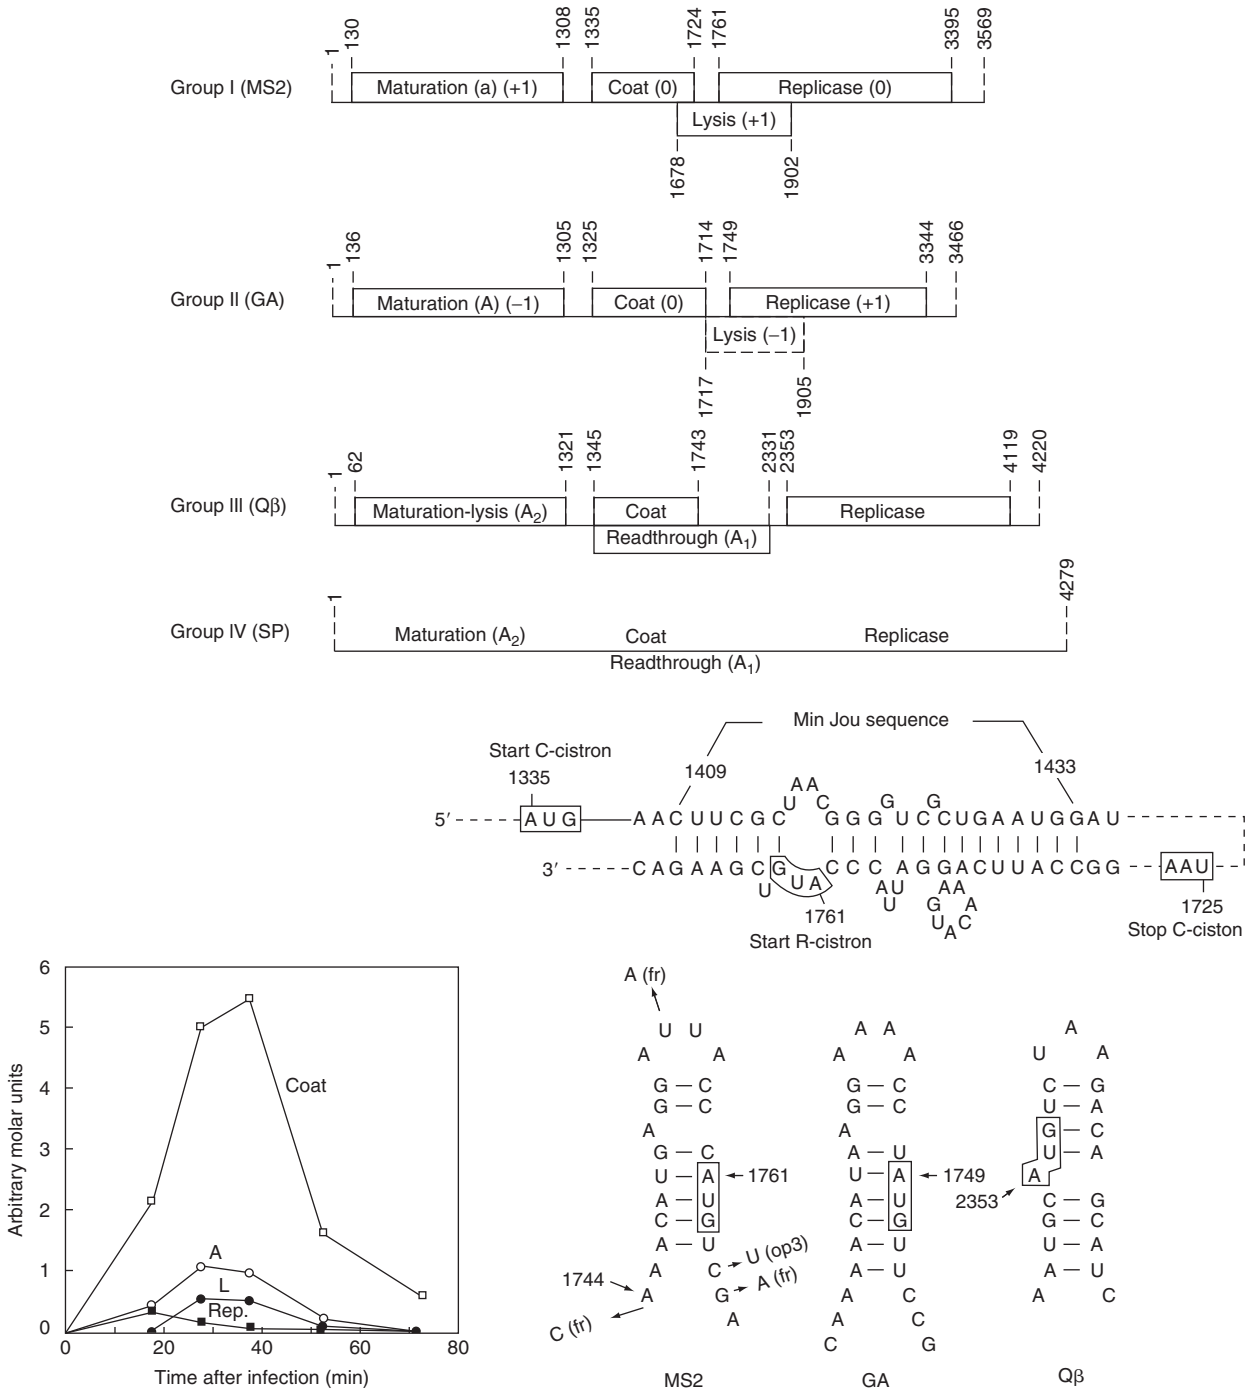

Figure 2 Genome organization and expression. The top panel shows cartoon representations of the genomes of representative members of each of the four subgroups of the RNA bacteriophages. The locations of the encoded proteins are also shown. The middle panel left shows the amounts of each of the encoded proteins produced during an infection cycle. Although each gene is present in equal amounts along each copy of every genome, there is a dramatic difference in the amounts of each protein in the cell, reflecting the requirements for different numbers of these protein products for replication, self-assembly of progeny phage, and lysis of the host. The implication is that the expression of these protein products is tightly controlled. The middle panel right shows one type of regulation that allows control of the amount of each protein product produced. At various times in the phage life cycle, the stem–loop structures shown at the bottom of the figure are sequestered by long range Watson–Crick base-pairing interactions to a segment of the coat protein gene (illustrated here for MS2). This section of the genome contains the start codon for the phage-encoded replicase subunit, so that the tertiary interaction prevents expression of replicase until the coat protein gene begins to be translated. As a ribosome transits this base-paired region, it frees up the downstream section allowing the ribosome-binding site and replicase translation to occur. At a later stage, the re-folded stem–loop is recognized by the coat protein – a coat protein dimer binds to the site and prevents further translational initiation, an example of translational repression (**Figure 3**). (a–c) Reproduced from Van Duin J (1988) Single-stranded RNA bacteriophages. In: Calendar R (ed.) *The Bacteriophages*, vol. 1, pp. 117–167. New York: Plenum, with permission.

The maturation protein is obviously needed in much smaller amounts and its appearance is slower and it is produced in much lower amounts than coat protein. It is believed that a number of regulatory features lead to this poor expression level. The start codon for the maturation gene is GUG instead of the more usual and more efficient AUG. In addition, it has been proposed that the ribosome-binding site in this cistron can be sequestered in internal base pairing with another section of the maturation protein message and, as a result, maturation protein is only expressed on nascent replicating genomic RNAs, that is, at a point when the downstream base pairing partners are yet to be replicated.

The replicase subunit is initially produced with similar kinetics and in similar amounts to the maturation protein but by 20 min after infection its levels are reduced. In fact, the phage makes more maturation protein than is strictly necessary, but the replicase is made at a level of ~5 copies/genome and its levels are always tightly controlled. This regulation is achieved in two distinct ways. Initially, the ribosome start site on the replicase subunit is sequestered in another long-range base-pairing interaction, this time with a section of the coat protein gene. Translation of the coat protein gene sequesters this complementary sequence, known as the Min Jou sequence after its discoverer, and thus frees the region around the start of the replicase gene so that it can fold to form a ribosome-binding site.

However, replication is further controlled via a translational repression complex that forms with the phage coat protein. A stem–loop operator hairpin (**Figure 3**) can form that is bound sequence-specifically by a dimer of the coat protein in a concentration-dependent fashion. This operator encompasses the start codon for replicase and formation of this repression complex effectively switches off replicase translation. The complex also acts to trigger self-assembly of the phage coat protein shell around the phage RNA. Regulated expression is obviously tightly controlled because of the importance of timing the switch in the viral life cycle from replication to assembly of progeny phage. There may also be an additional reason to ensure that large quantities of replicase are not produced because of its role(s) in creating the active replication complex.

The phage-encoded replicase subunit is the RNA-dependent RNA polymerase responsible for copying the phage genome. However, it does not function as a separate subunit. Instead, it forms complexes with at least three cellular proteins normally involved in other functions; these are the ribosomal protein S1, which functions during the loading and initiation of mRNAs on the ribosome, and translational elongation factors EF-Tu and EF-Ts. These species form a heterotypic tetramer that appears to be the active replication enzyme for positive-sense strands of the genome, that is, in the production of the negative-sense strand. The opposite reaction, that is, the generation of the positive-sense strand from the negative strand appears not to need the S1 subunit. An explanation for this altered stoichiometry in the replication machinery has been proposed based on the fact that the positive-strand must also serve as a template for peptide synthesis. This would lead to situations in which ribosomes and replication complexes, which would be moving in opposite directions on the RNA, would collide. It is believed that S1 functions in these cases by competing with the ribosome for loading onto the RNA, thus preventing replication on actively translating RNAs. The replication complexes also appear to interact with another host protein, which appears to be hexameric, but its role(s) is unclear.

A final reason for tight regulation of the expression of replicase is that the subunit or its complexes with cellular proteins are toxic to the cell. This would interrupt the phage life cycle before progeny phages are assembled. Cell death is however the ultimate goal of the infection, thus releasing progeny phage particles, but this is actively controlled by a phage-encoded lysis protein. This cistron is read from the +1 reading frame initiating within the coat protein gene. As can be seen from **Figure 2**, the lysis protein is the last to be produced, consistent with its final function in the phage life cycle. The reason for the delayed production of this gene product appears again to be a consequence of translational control. In this case, the ribosome binding site allowing initiation of the lysis protein translation appears inaccessible until the ribosome translating the coat protein completes the translation in its defined termination site. Experiments where the coat protein gene stop codons are moved further 3′ prevent lysis expression, implying that correctly regulated expression must be due to a defined RNA folding event similar to those controlling replicase translational repression. In principle, variations of the details of this mechanism may partially account for the frequency of read-through products in some of the coat proteins in some phages.

The Translational Repression/Assembly Initiation Complex

As discussed above, the expression of the phage-encoded replicase subunit is controlled by a translational repression event that occurs when a coat protein dimer binds to a 19 nt stem–loop structure (**Figure 3**), thus sequestering the AUG start codon from replicase. In a set of seminal experiments, Janette Carey and Olke Ulhenbeck were able to show that all the sequence information for the specific RNA–coat protein interaction was contained within this short fragment. Furthermore, they established rapid assays for the interaction *in vitro*, allowing extensive investigation of the effects of changes to nucleotide base sequence and the chemical functional groups on the RNA that contribute to this interaction.

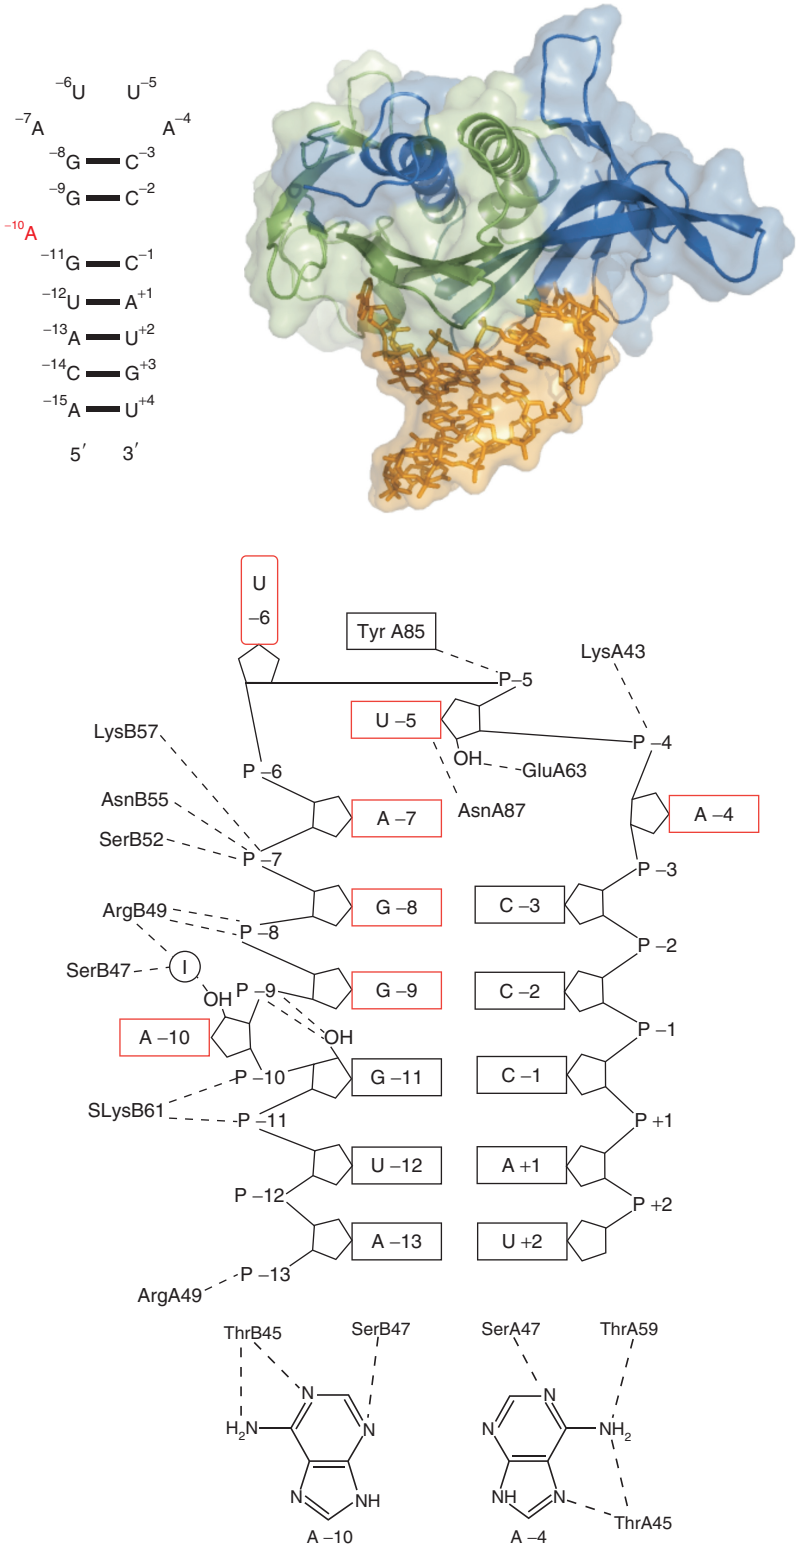

Figure 3 The MS2 translational repression complex. The top panel left shows the secondary structure of the translational operator stem–loop and the number of the bases relative to the replicase start codon. To the right is a detailed view of the X-ray structure of the interaction of the operator stem–loop with a coat protein dimer (shown as the A/B quasi-equivalent conformers). The polypeptide (blue and green) and RNA (gold) are shown as ribbon and stick models, respectively, within a transparent representation of the molecular surfaces. The bottom panel shows the intermolecular contacts that occur within the complex. The detailed contacts at A-4 and A-10 are shown below for clearity. The dotted lines indicate hydrogen bond interactions.

In addition, it has proved possible to determine X-ray crystal structures for the RNA stem–loop and over 30 of its variants in complex with the coat protein shell (**Figures 3** and **1**).

The detailed intermolecular contacts revealed and confirmed by these techniques have made this complex one of the most intensively studied examples of an RNA–protein complex. It has also been possible to determine structures for variants of the coat protein mutant at the RNA-binding site. The results of these studies suggest that the interaction is remarkably robust to simple changes outside a few key residues, principally the loop adenine at position –4 (the bases are numbered with respect to the first nucleotide of the replicase start codon). The half-life of the RNA–coat protein complex *in vitro* and presumably *in vivo* is very short (<1 min), implying that translational repression is short-lived. However, this is a simplification because the RNA–protein complex created then serves as a site of assembly initiation for formation of the intact capsid (see below). The repressive function of the coat protein reconfirms the mechanism of infection described above. If significant numbers of coat protein subunits were to enter the cell with the genomic RNA, the replicase gene would never be expressed. RNA variants that have higher affinity for coat protein can be identified *in vitro* but these would be lethal *in vivo*.

When cells are co-infected with MS2 and Qβ phages, the progeny phages that result consist of MS2 and Qβ RNAs inside their respective coat protein shells, that is, there is no evidence that the proteins can mispackage the competing genome. In part, this is because of the significant structural differences between the translational operator sites (**Figure 2**), but it also implies that there is direct coupling in the RNA–protein interaction leading to translational repression and assembly of progeny phage particles. It is believed that the RNA–coat protein complex that forms initially with a single coat protein dimer marks the phage RNA for assembly by addition of further coat protein subunits. All that is required to avoid misincorporation is that the coat proteins from different phages are unable to co-assemble and that seems to be the case even though there is a great deal of structural similarity between them.

The precise mechanism by which the phage capsid is generated is still unclear. When and how is the maturation protein incorporated into the structure, for instance? What we do know is that the stem–loop interaction appears to cause a conformational change in the coat protein subunits that bind, possibly between differing quasi-equivalent conformers, and provides a binding site for the stepwise addition of other coat protein dimers. These must somehow adjust their precise conformations in a structural context in order to produce a capsid of the correct size and symmetry. Recent evidence suggests that the folded genomic RNA may play a role in this process.

The major structural difference between quasi-equivalent conformers in a capsid occurs in a short loop of polypeptide connecting the F and G β-strands in each subunit. These FG loops have identical amino acid sequences in all subunits, but around the icosahedral fivefold symmetry axes they fold back toward the body of the subunit helping to create space to pack the subunits at this position. In contrast, at the icosahedral threefold axes, FG loops from two distinct quasi-equivalent subunits alternate in extended conformations, allowing six such loops to be packaged at these points. We now know that binding of the RNA translational operator causes a conformation change to occur at the FG loop, and it is tempting to assume that this interaction sets up the initial asymmetry to define a capsid structure via self-assembly. Precisely how the RNA is folded to fit into this structure and whether it folds during or before the assembly reaction is still a matter of debate.

Applications of RNA Phages – Three-Hybrid Assay

RNA phages have become model viruses for the development of a large number of novel scientific techniques. These are remarkably varied and include the controlled release of these phages into the wider environment as markers for the passage of viruses and of the ability of water treatment systems to remove viral particulates from drinking water. One such test was even performed on the International Space Station.

A more medically orientated set of applications has also been developed. For instance, it is known that viruses present defined epitopes to the immune system of their hosts. If those epitopes are common and unchanging, the immune response that occurs after an initial infection will render the host immune to further infection by that particular virus. Many viruses however constantly alter their outer protein surfaces presenting differing epitopes to the immune system, thus escaping immune neutralization. However, modern structural immunology techniques can identify conserved functional domains/sequences within these viral proteins that cannot be altered without also causing the virus to lose the ability to replicate or assemble. Raising immune responses against such refined constant epitopes leads to potent vaccines against a range of human and animal pathogens. In fact, work in this area has shown that the immune system is particularly well evolved to recognize repeated copies of particular epitopes, such as those that appear on the surfaces of pathogenic viruses. Therefore, researchers are busy trying to turn the tables on viruses by presenting conserved epitopes from pathogenic viruses as repeated arrays on the surfaces of harmless virus particles, such as the RNA phages. Not all such applications are directed at preventing

viral infections. One artificial construct based on the phage Qβ presents nicotine as an artificially linked epitope and it is hoped that this virus-like particle will allow 'vaccination' of smokers who otherwise have failed to break their addictions to tobacco.

Our detailed knowledge about the coat protein–RNA operator interaction that regulates replicase translation and triggers self-assembly of progeny phage particles has also been adapted to allow encapsidation of non-phage molecules ranging from large protein toxins, to peptides and DNA oligonucleotides. These potentially therapeutic species can then be directed to specific cells by decoration of the external phage capsid surface with ligands for cell-surface receptor molecules. Once complexed at the cell surface, receptor-mediated endocytosis results in internalization of the encapsidated drug into endosomes where the pH is slightly acidic, conditions that favor disassembly of phage shells, and hence release of the 'drug' entities into the cell. Encapsidation of the plant toxin ricin A chain, that normally needs an additional B chain to cross into cells, allows this highly toxic protein to be delivered into the interior of cells carrying defined external signals resulting in reagents with effective lethal doses in the picomolar range. Controls lacking the targeting ligand are essentially nontoxic, suggesting that encapsidation reduces the nonspecific uptake of ricin A chain known from other studies to create side effects. Such artificially created virus systems have additional advantages, since they can be produced carrying a range of different therapeutic cargoes that can all be targeted to the same cell via attachment of the identical targeting signals. The result is the possibility of refined multidrug therapy without the problems associated with each component having differing pharmacokinetic properties.

An important and very intensively used additional application of the translational repression complex is in the three-hybrid assay system. Macromolecular interactions *in vivo* are central to understanding the integrated functions of all gene products. However, there are relatively few techniques that can easily be used to detect such interactions. One screen, known as the two-hybrid assay, was developed to detect protein–protein interactions using a simple genetic phenotypic screen. It works by creating two fusion proteins. The first carries the information to encode a DNA-binding protein domain fused to a 'bait' protein whose cellular partners are sought. The second fusion protein carries a series of potential partners for the bait domain translationally fused to a transcriptional activation domain. Both fusion constructs are expressed in yeast that carries a binding site for the DNA-binding domain in close proximity to a reporter gene inferring resistance to some chemical challenge, for example, an antibiotic or essential metabolite. Only in those yeast cells where bait and target interact will the transcriptional activation domain drive production of the essential reporter gene. All other cells will not grow. Recovery of the live cells and sequencing of the constructs they carry thus reveals potential partners of the protein–protein interaction *in vivo*, although there is known to be a rate of false positives.

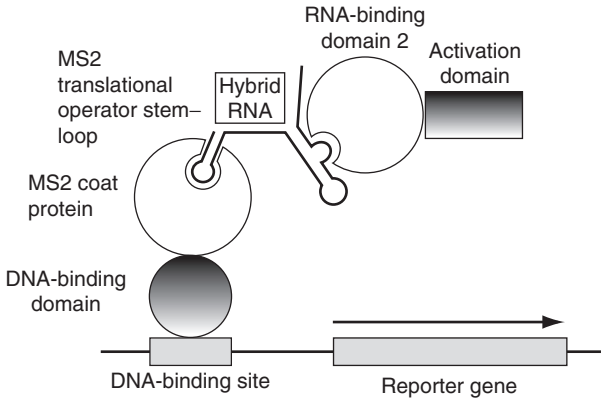

Figure 4 Three-hybrid assay. A schematic view of the components of the three-hybrid assay for detecting RNA–protein interaction *in vivo*. A DNA-binding domain is fused to the MS2 coat protein (RNA-binding domain 1). A second potential RNA-binding domain (#2) is fused to a transcriptional activation domain. Hybrid RNAs carrying the MS2 translational operator stem–loop are also expressed in yeast cells carrying the DNA-binding target adjacent to a reporter gene. Reproduced from SenGupta DJ, Zhang B, Kraemer B, Pochart P, Fields S, and Wickens M (1996) A three-hybrid system to detect RNA-protein interactions *in vivo. Proceedings of the National Academy of Sciences, USA* 93(16): 8496–8501, Copyright (1996) National Academy of Sciences, USA.

In the three-hybrid variant of this approach, the protein–protein interaction is replaced by a protein–RNA interaction. This is achieved by fusing the DNA-binding domain to the MS2 coat protein, thus producing a tethered protein that will bind to RNAs carrying the translational operator site. The translational operator sequence is then embedded in transcripts that include other potential RNA-binding domains. The transcriptional activation domain is then expressed as fusions with potential binding partners for specific RNA sites (**Figure 4**). The end result is the same as for a two-hybrid assay. Only those yeast cells in which the hybrid RNA is bound by a fusion partner will survive and the RNA sequences and or binding partners can then be identified by sequencing.

Icosahedral Tailed dsDNA Bacterial Viruses

R L Duda, University of Pittsburgh, Pittsburgh, PA, USA

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Contractile tail The tail type that defines the *Myoviridae*, composed of a baseplate that contacts the host surface, an outer protein cylinder or sheath, and an inner tail tube or core. When a host is bound the sheath contracts, driving the tube into the cell to deliver the genome to the host.
DNA packaging The energy-driven process by which a procapsid is filled by a phage chromosome to become a mature capsid.
Head or capsid The protein container for the *Caudovirales* phage genome, usually icosahedral in shape, that protects it from the environment until it is delivered to a new host.
Horizontal gene exchange Transfer of genetic material between different species.
Portal A grommet-like ring, composed of 12 copies of the portal protein, through which DNA is packaged and to which the tail is attached.
Prohead or procapsid An immature capsid that has a spherical shape and contains no DNA.
***T*-number** The triangulation number (*T*) is a formal descriptor for complex icosahedral structures which describes the geometric arrangement of subunits for a viral capsid. The number of capsid protein subunits is $\sim 60 \times T$.
Tail The part of the virion responsible for attachment to the host and genome injection. This is attached to one vertex of the capsid, at the portal.
Tail fiber An elongated protein fiber attached to a phage tail that helps recognize a host by binding to the host by the tip of the fiber.
Virion The entire viral particle composed of a capsid containing the viral genome, tail, tail fibers, and other appendages.

Introduction

The icosahedral, tailed double-stranded DNA (dsDNA) bacterial viruses or bacteriophages of the order *Caudovirales* are among the most widely recognized icons of modern molecular biology. Anyone who has participated in an advanced biology, genetics, or molecular biology class is likely to have been exposed to images of the familiar lunar-lander-shaped bacteriophage T4 virion (family *Myoviridae*) with its elongated icosahedral capsid and machine-like contractile tail (**Figure 1**(**a**)) or the plain icosahedral capsid and elegant, gently curving tail of bacteriophage λ (family *Siphoviridae*; **Figure 1**(**b**)). Both T4 and λ are bacteriophages that infect the enteric bacterial host *Escherichia coli* and have been studied extensively. Bacteriophages were originally discovered in the early twentieth century (1915–17) by English microbiologist Frederick W. Twort and French-Canadian microbiologist Felix d'Herelle. Although there was much early interest in bacteriophages because of their potential for use in treating bacterial diseases (phage therapy), research on

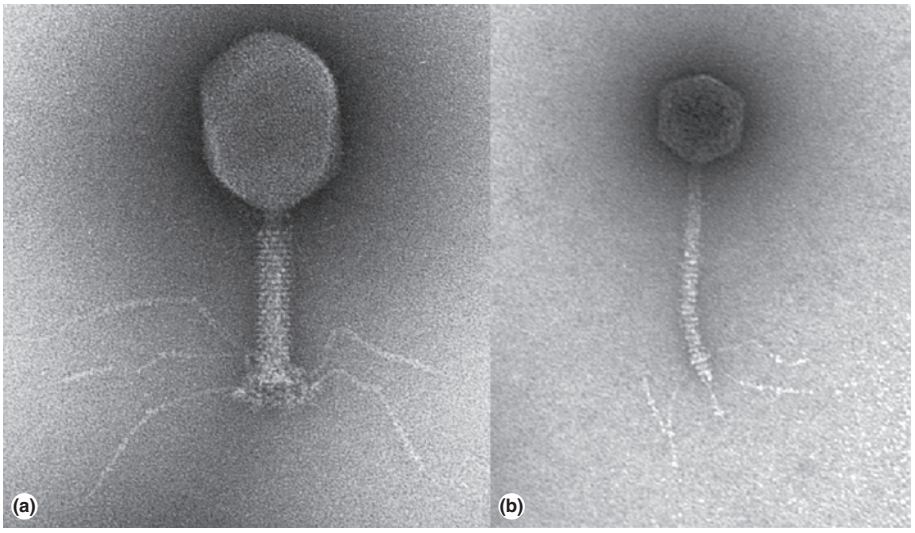

Figure 1 Electron micrographs of bacteriophage T4 and bacteriophage λ (variant Ur-λ). (a) Negatively stained electron micrograph of bacteriophage T4, the prototypical member of the *Myoviridae*. The T4 tail is 100 nm long and the T4 head has a width of 85 nm. Many of the features labeled in **Figure 2** are visible in the micrograph, including the baseplate, tail sheath, whiskers, collar, and long tail fibers. (b) Negatively stained electron micrograph of bacteriophage λ. The micrograph is of an original isolate of λ, called Ur-λ, that has long side tail fibers. Most common laboratory strains of λ carry a mutation in the side tail fiber gene that eliminates the fibers from the particle. The length of the lambda tail is ~150 nm (not including the protruding central fiber) and the lambda head is ~63 nm in diameter.

bacteriophages for disease therapy was largely abandoned after the discovery of antibiotics. Bacteriophage research was revived in the 1940s by Max Delbrück and colleagues (the well-known Phage Group that often met at the Cold Spring Harbor Laboratories on Long Island, NY), and the focused phage research started by this group of scientists led to many fundamental biological discoveries during the birth of molecular biology. The modern-day emergence of multiply antibiotic-resistant strains of human pathogens has rekindled an interest in developing phage therapy as a means of treating human diseases.

The Structure of Tailed dsDNA Bacteriophages

The invention and commercialization of the electron microscope led to the first images of phages as sperm-like particles with a head and tail using a technique called metal shadowing, in which images were formed by heavy metal atoms such as uranium that were evaporated in a vacuum and allowed to strike a dried specimen at an angle. The later introduction of negative stains (salts of heavy metals that dry as a thin layer without forming crystals and in which small particles such as phages could be embedded) for electron microscopy resulted in images that were far richer in detail than earlier methods and revealed the complexity and variety of phage morphology. **Figure 1** shows electron micrographs of phages T4 and λ made using the negative stain technique. Electron microscopy has remained a major tool in the study of bacteriophages and, in fact, the current taxonomic system for phages relies heavily on phage morphology as determined by electron microscopy as a major discriminating factor. **Table 1** shows a taxonomic table for the order *Caudovirales* and some of their characteristics. Members of the *Myoviridae* have contractile tails and include bacteriophages T4 (**Figures 1**(**a**) and **2**) and P1. Members of the *Siphoviridae* have long noncontractile tails and include phages λ (**Figure 1**(**b**)) and T5. Members of the *Podoviridae* have shorter stubby or stumpy tails and include phages P22 and T7. The utility of morphological classification as a basis for phage taxonomy has more recently come into question as new insights into phage evolution have revealed that horizontal exchange of genes is widespread among phages, and further that some structural genes of bacteriophages and viruses that infect organisms from other domains of life appear to share common ancestors.

Tailed Bacteriophage Structure and Function

Capsids

In the tailed dsDNA bacteriophages, the capsid is the container for the phage genome that protects it from the environment until it is delivered to a new host by the phage tail, the organelle of attachment and genome

Table 1 Tailed dsDNA bacteriophages: Order *Caudovirales*

Family	*Genus*	*Defining example*	*Capsid T*-number	*Genome size (bp)*
Myoviridae (phages with contractile tails)	T4-like viruses	Enterobacteria phage T4	$T=13$; $Q=20$	168 903
	P1-like viruses	Enterobacteria phage P1	$T=13$?	93 601
	P2-like viruses	Enterobacteria phage P2	$T=7$	33 593
	Mu-like viruses	Enterobacteria phage Mu	$T=7$	36 717
	SP01-like viruses	Bacillus phage SP01	$T=16$	~132 500
	ϕ-H-like viruses	Halobacterium virus ϕH	$T=7$?	~57 000
Siphoviridae (phages with thin noncontractile tails)	λ-like viruses	Enterobacteria phage λ	$T=7$	48 502
	T1-like viruses	Enterobacteria phage T1	$T=7$?	48 836
	T5-like viruses	Enterobacteria phage T5	$T=13$	121 750
	c2-like viruses	Lactococcus phage c2	$T=4$?; $Q=7$?	22 172
	L5-like viruses	Mycobacterium phage L5	$T=7$	52 297
	ψM1-like viruses	Methanobacterium ψM1	Unknown	~23 246
Podoviridae (phages with short stubby tails)	T7-like viruses	Enterobacteria phage T7	$T=7$	39 937
	ϕ-29-like viruses	Bacillus phage ϕ29	$T=3$; $Q=5$	19 366
	P22-like viruses	Enterobacteria phage P22	$T=7$	41 724

A ? denotes unknown or unconfirmed values.

injection. In many other types of viruses, the capsid is taken up by cells with the genome still inside and the virus particle uncoats or disassembles within the new host to initiate viral replication. The dsDNA bacteriophages' capsids do not have to disassemble in this manner to initiate infection, so they can be constructed to be highly stable – resistant to a wide variety of chemical and physical assaults from the environment – as they travel from one host to another. The dsDNA genome in bacteriophage capsids is packed to a very high density ($\sim 0.5\ \mathrm{g\ ml^{-1}}$) which results in high pressure, so the capsid shell has to be strong enough to withstand the high internal pressure from DNA. Most members of the *Caudovirales* have symmetric icosahedral capsids, but some have capsids with an elongated icosahedral shape, like T4 (**Figures 1(a)** and **2**) that have icosahedral ends and an elongated tubular middle section.

Tails and Tail Fibers

Phage tails function to identify and bind to the correct host and to deliver the phage genome into the new host to initiate replication. Phage tails have a large variety of morphological forms with many parts and appendages, such as those labeled on the diagram of T4 in **Figure 2** and visible in the electron micrograph in **Figure 1**. We know little about the functions of some tail parts, but others are understood in considerable detail. For example, in bacteriophage T4, both the long tail fibers and the short tail fibers (which are folded under the baseplate until after the long tail fibers are bound to the host; see **Figure 2**) recognize specific host receptors. The long tail fibers of phage T4 are the primary determinants of host range, and mutations that change the T4 host range cause alterations in the fibers near their distal tips. The whiskers that are attached to the top of the T4 tail have multiple functions. The whiskers act as assembly jigs for adding the long tail fibers to the virion, and they also act as environmental sensors that sequester the long tail fibers under unfavorable conditions and thus prevent attachment to a host.

The long tail fibers of T4 have an analog in bacteriophage λ, but in the ordinary laboratory strains of λ these fibers are not made because of a mutation in the side tail fiber gene. The electron micrograph in **Figure 1(b)** shows the long side tail fibers present on Ur-λ, a primordial λ that lacks this mutation. These long side tail fibers of Ur-λ speed up the adsorption of this phage to its host, but are not required for infection, because the primary interaction of λ with its host is mediated by the central tail fiber (a trimer of the tail protein gpJ) protruding from the end of the lambda tail. The central tail fiber of λ binds to a host maltose transport protein (called *lam*B or *mal*B) in the outer membrane of the host. Binding of phage λ to its receptor under suitable conditions acts as a signal that triggers the injection of the phage DNA genome into the host to initiate replication.

The structure and functions of many parts of the contractile tails of *Myoviridae* have been revealed in depth, especially for the phage T4 tail. After the T4 long tail fibers attach to the host, the short tail fibers unfold from the baseplate and bind to a second receptor on the host surface. The baseplate remains attached to the cell and undergoes a dramatic reorganization in which it changes from a hexagon to a star shape, causing the sheath to contract and drive the internal tail tube into the cell. As the nail-shaped tip of the inner tail tube passes through the outer membrane, tail lysozyme molecules are released to create a small hole in the cell wall peptidoglycan layer. These combined actions allow the tip of the tail tube to reach the inner membrane, where a channel is created that allows the dsDNA genome to enter the cell and initiate replication.

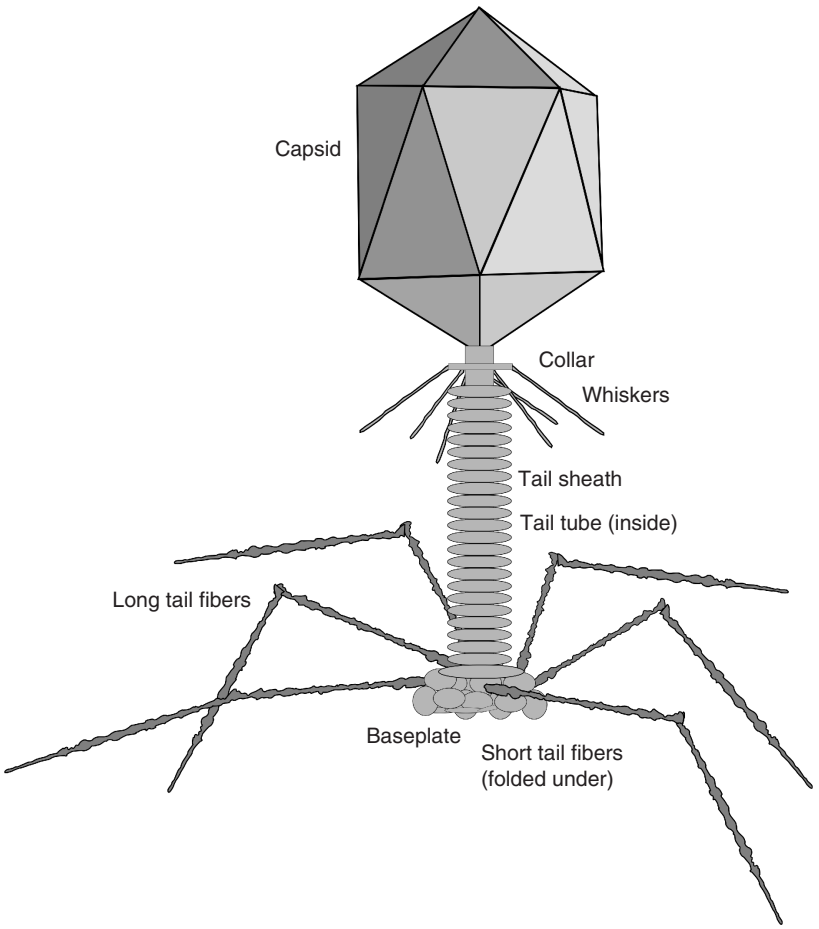

Figure 2 Schematic drawing of bacteriophage T4, with some of the structural components identified.

Temperate versus Virulent Bacteriophages

Virulent bacteriophages, once they have infected a host, are committed to go through their entire growth cycle including replication of the bacteriophage chromosome, production of progeny viral particles, and the lysis of the host cell. Temperate phages, on the other hand, are able to grow lytically like their virulent counterparts, but they are also capable of going into a dormant state within the host. This dormant state is called lysogeny, and often involves integration of the phage chromosome into the host chromosome, as occurs with phage λ, or conversion of the phage chromosome into an autonomously replicating plasmid. The seemingly normal host containing a dormant phage chromosome is called a lysogen. The dormant phage chromosome is maintained in a mostly silent state, until some change in the condition of the host (often related to stress, such as damage to the host DNA) acts as a signal to induce the phage to begin a lytic growth cycle, all the way through progeny release. The temperate phage in the lysogenic state makes a protein factor or repressor protein that can repress (nearly) all phage functions, except for the synthesis of the repressor. If the repressor is subsequently destroyed, as it may be after DNA damage occurs within the cell, the phage initiates a normal growth cycle, usually excising the phage chromosome from the host chromosome as an early step. How a temperate phage decides between a virulent and lysogenic mode of infection is a complex process that appears to depend on the conditions within the host cell at the time of infection. In a simplified version of the process, it is a balance between the production of sufficient repressor protein to shut down phage development and the antagonistic action of other factors that prevents repressor synthesis and function.

Injection

DNA Injection

As described above, all *Caudovirales* bacteriophage particles have tails consisting of highly specialized parts with specific roles to mediate attachment and infection. The

fundamental goal of attachment is the introduction of the viral DNA into the host to begin production of progeny virions. The detailed mechanism of DNA entry varies widely from phage to phage. Although this process is called DNA injection, the phage particles do not act like syringes, as the name implies. In some cases it appears that chromosome entry is largely passive, a result of the DNA being very densely packed into the virion under very high DNA pressure. The energy stored by packaging the chromosome under pressure is used to drive the DNA out of the capsid into the host; this appears to be true for many phages, including phage T4 and phage λ. Other viruses such as phage T7 (family *Podoviridae*) and phage T5 (family *Siphoviridae*), have more elaborate mechanisms of DNA injection with an initial stage that appears to be largely passive, followed by a pause after only a fraction of the chromosome has been injected. Such paused DNA injection resumes only after proteins (encoded by the genes injected in the initial stage) act to restart chromosome entry or to pull the rest of the chromosome into the host in a controlled manner.

Protein Injection

Many of these viruses inject both DNA and proteins into their hosts. The function of a few of these injected proteins is known, but in many cases remains mysterious. For example, phage T4 injects multiple copies of several proteins into the host. These include a protein that modifies the host RNA polymerase and other proteins of unknown function. Surprisingly, most of phage T4's injected proteins are not absolutely required for infection, and mutants that lack them are able to grow on many ordinary laboratory hosts. Phage T7 injects several large proteins that possibly play important roles in the injection process, for example, by forming channels for the passage of DNA and other proteins into the host. The injected proteins of phage T7 are essential for phage growth.

Host Interactions and Regulation of Gene Expression

Classes of Genes

A regulated program of gene expression begins soon after the virus has injected its DNA. The expression of phage genes can be divided by function, such as host takeover, replication, virion assembly, or lysis, but more often they are sorted by their temporal order of expression. In most cases gene expression is divided into early genes and late genes, although for some phages there may be a cascade of gene expression modes that occur sequentially. In a cascading series, early phage gene products control the expression of a set of middle gene products, which in turn control the expression of late genes.

Early Genes

Phage early genes are usually transcribed by the normal host RNA polymerase, while the expression of late genes is dependent on the expression of the early genes. The earliest genes expressed might be ones that produce proteins to counteract the host's antibacteriophage defensive systems, as occurs in phage T7. Early genes of temperate phages are those required to make the decision to become dormant or to grow normally and carry out the first steps of these processes, including, for example, the repressor gene and integration genes, or DNA replication and recombination genes. Early genes of virulent bacteriophages, such as phage T4, include genes for genome replication and genes that shut down unneeded host functions, such as host transcription and host protein synthesis, and may include other genes required to recycle host resources, for example, by specifically degrading the host chromosome to intermediates that can be reused during the replication of the phage genome.

Late Genes

The proteins encoded by the late genes include the structural proteins required for the assembly of the bacteriophage virion, as well as those needed for packaging the genome into the virion and for cell lysis. Late gene expression is often dependent on early (or middle) gene expression because the late genes have transcriptional promoters that are not recognized by the normal host polymerase. The early genes may direct the synthesis of transcription factors that either (1) change the specificity of the host RNA polymerase or (2) modify the polymerase in other ways, in order to express the whole set of late genes at the appropriate time with high efficiency. Alternatively, one of the early genes may encode for an entirely new RNA polymerase with a new specificity that recognizes late gene promoters. Expression of the structural proteins to high levels allows the production of a large number of progeny phages.

Virion Assembly

Assembly Pathways

The assembly of *Caudovirales* virions is a highly ordered process in which separate subassemblies of the virion are built and then joined to form the mature virion. The assembly of capsids, tails, and tail fibers each follows an independent assembly pathway in which individual protein components are added, usually sequentially, to a growing structure until it is complete.

Tail Assembly

The major components of a *Caudovirales* tail are a baseplate or tail tip, major tail proteins (one for a noncontractile tail,

and two for contractile tails (an inner tube protein and an outer sheath protein)), and termination or capping proteins to stabilize the completed tail and connect it to the head. Tail assembly begins with the formation of an initiator complex, which may be either a complete tail tip or a complete baseplate that is assembled via a separate pathway. The initiator complex includes a template that specifies the length of the tail, the tape measure protein complex in a compact form. The major tail proteins bind to the initiator complex and assemble into a tube around the tape measure protein until the full length of the tape measure protein is enclosed and the termination proteins can bind and stabilize the tail.

Capsid Assembly

The capsids of these viruses are built as precursor procapsids, into which the phage genome is later packed. Procapsids are initially assembled from several types of components: a portal complex (which will connect the capsid to the tail), a major capsid protein, a scaffolding protein (which may be a separate protein or may be a disposable part of the major capsid protein), and decoration or stabilization proteins (which add to and stabilize the capsid only after the genome is packed inside). The number of capsid protein subunits needed for assembly is equal to $\sim 60 \times T$ subunits, where T is the triangulation number listed in **Table 1** (or, for phages with elongated capsids, $\sim 30 \times (T + Q)$ subunits, where T and Q are specified in **Table 1**). So for a $T = 7$ virus, such as λ, ~420 copies are needed and more copies are needed for larger phages. Capsid assembly begins with the completion of the assembly initiator complex, usually the portal. The major capsid protein together with hundreds of copies of the scaffolding protein co-assembles onto the initiator to produce a complete shell with the scaffolding protein on the inside. After assembly is complete, the scaffolding protein is expelled intact or digested by a special protease that is also incorporated into the procapsid. Procapsids appear spherical and usually have a smaller diameter than mature capsids. When DNA is packaged into the procapsid, the capsid usually expands and changes shape, transforming into the typical angular, icosahedral shape of mature capsids. The decoration proteins add to the outside of the capsid after it expands and help to stabilize the structure. Once DNA is packaged, the capsid is made ready to join to a tail by the addition of proteins that bind to the portal.

Lysis

Lysis of an infected host requires two phage-encoded protein factors, an endolysin or lysozyme, and a second protein called a holin. The endolysin is a soluble enzyme with the capacity to break the bonds holding the host cell wall together. The endolysin molecules accumulate within the host cytoplasm during the late stages of infection, but are unable to attack the cell wall because they are sequestered within the cytoplasmic membrane. Holin proteins allow the endolysin to get across the cytoplasmic membrane by forming holes in the inner membrane. Holins are synthesized and inserted into the membrane in a form that does not form holes at first. As the bacteriophage infection proceeds, the holins accumulate in the membrane until a predetermined time at which they suddenly and catastrophically induce membrane breakdown. The membrane holes produced by holins allow the endolysin molecules to attack the bacterial cell wall, causing rapid cell lysis and releasing the progeny virus from the cell.

Genomes and Genomics

Chromosome Diversity and Replication

The chromosomes that are packaged into the capsids of the *Caudovirales* are linear dsDNA. *Caudovirales* virions always contain an entire genome or slightly more than an entire genome to ensure that a complete genome is packaged into each and that every particle can initiate an infection. To achieve this, a site-specific mechanism may be used, in which DNA packaging begins and ends at defined sites that are recognized by the packaging machinery to create exactly unit-genome-length DNA chromosomes. Alternatively, the amount of virion DNA may be regulated by a head-full packaging mechanism which fills a capsid that has the capacity to hold slightly more than one genome's worth of DNA. The head-full-packaged chromosomes have the same sequence at each end and are said to be terminally redundant.

After injection, the phage genomes often rearrange to form a circular chromosome that is the primary replicative form of the genome of many dsDNA phages; however, many other phages replicate without forming such DNA circles. Chromosome replication often takes place bidirectionally from a single origin, but more complex replication schemes and multiple replication origins have also been observed. Late in infection, most phages switch to a mode of replication that produces DNA concatamers, or long strings of genome copies joined end to end, either by a rolling circle mode of replication from circular chromosomes, or by recombination between multiple overlapping genome copies. Such DNA concatamers, whether linear or branched, are the forms of the genome that are the usual substrate for DNA packaging for both head-full and site-specific mechanisms. When it does occur, circularization of the phage chromosome takes place via one of the two mechanisms. The first is by the annealing of complementary single-stranded DNA sticky ends left by the packaging enzymes (in the cases where the packaged chromosomes have defined endpoints). The second is

by a recombination-like mechanism that joins the complementary regions of the overlapping, terminally redundant chromosome ends to form circular DNA molecules. Circular chromosomes are the most common form for bacterial chromosomes, but some bacteria also have linear chromosomes, and a small subset of members of this order also forms linear chromosomes that replicate as linear plasmids when in their lysogenic form.

Diversity in Genome Size and Organization

The genomes of these viruses range in size from ~20 000 bp in phage ϕ29, to ~170 000 bp in phage T4, and up to ~500 000 bp in other known examples. The smaller phages have proportionally fewer genes than the large phages, but are nonetheless functional and successful phages. Given this wide range of sizes and diversity of these viruses, it is not surprising that there is not a common conserved genome structure in the members of the order *Caudovirales*. Within a genus of phages there is often a common genetic structure, but within and across families there is often little resemblance in genome organization. There are notable exceptions to these generalizations; for example, the genus 'P22-like viruses' and the genus 'λ-like viruses' have rather closely related genomes.

Common Themes in Genome Structure

Despite the differences mentioned, there are many common general features in *Caudovirales* genomes. The genes for the structural proteins, such as those for capsids, tails, or tail fibers, tend to be found clustered together, and within these clusters, the genes that encode proteins that physically interact with each other also tend to be grouped together. For example, the capsid protein genes for the portal, the scaffolding protein, and the major capsid protein usually occur together and in the order listed. Sets of late genes are often grouped together in clusters and, in some cases, the entire set of structural genes are grouped together in clusters and transcribed together from a single promoter, as is the case for phage λ.

Horizontal Exchange of Genes Is Widespread

A large number of complete bacteriophage genomes have been fully sequenced, and hundreds of these have been deposited in GenBank and other databases. In addition, there are also many temperate phages residing in the genomes of bacterial chromosomes – some defective (or cryptic), and some complete and able to form a viable phage. Analyses of the sequences of these genomes have shown that many of the genes have highly similar counterparts in other genomes and in many cases the similarity can be inferred to be truly homologous. An important conclusion of these analyses is that there is extensive horizontal exchange of genes between phages that are not within the same species or genus or order. It appears that genetic exchange between phages by both homologous and nonhomologous recombination mechanisms is widespread and that many phages are mosaic combinations of genes found elsewhere. Many of the homologous arise genes within the *Caudovirales*, but some are from outside this order. In some cases, large modules of genes in a pair of phages are closely related (e.g., the head genes of phage HK97 (*Siphoviridae*) and phage SfV (*Myoviridae*)) despite belonging to different taxonomic groups. In other cases, a single phage tail fiber encoding gene in one phage may contain several distinct regions of homology with several other different phages.

Common Ancestry

The exact nature of the evolutionary relationships among phages and how it relates to phage taxonomy is a controversial subject, but at the level of individual protein-coding genes, it is fairly certain that proteins with a high degree of sequence similarity in analogous proteins almost certainly share a common evolutionary ancestor. The power and utility of bioinformatics to tease out weak (sequence) similarities between distantly related proteins provides the evolutionary scientist powerful tools to detect relationships that escape casual examination. However, the reliance on sequence similarity matches to detect homologous relationships breaks down when homologous proteins have diverged so far that sequence similarity is undetectable. A notable case is that of the major capsid proteins of bacteriophages and other viruses. The three-dimensional structure and protein fold of the major capsid protein of phage HK97 was determined to high resolution by X-ray crystallography. Sensitive bioinformatic techniques were able to detect weak sequence similarities between the HK97 capsid protein sequence and the capsid proteins of a large number of other members of the *Caudovirales*, suggesting that the HK97 capsid protein fold is quite common. Subsequently, the determination of the protein folds of phages T4 (*Myoviridae*), P22, ϕ29, and ε15 (*Podoviridae*) by structural methods has shown that all of these phages also have the same protein fold as HK97, despite the lack of any detectable sequence similarity.

Idaeovirus

A T Jones and H Barker, Scottish Crop Research Institute, Dundee, UK

© 2008 Elsevier Ltd. All rights reserved.

Introduction

The genus *Idaeovirus* contains a single virus species, *Raspberry bushy dwarf virus*, named after the disease (characterized by stunting and proliferation (bushiness) of canes) with which it was first associated in red raspberry (*Rubus idaeus*). This mechanically transmissible virus was detected consistently in such diseased plants. Later, however, it was shown that raspberry bushy dwarf virus (RBDV) on its own in young raspberry plants did not induce obvious disease but, in mixed infection with black raspberry necrosis virus (BRNV), an aphid-borne virus, it intensified the degeneration in vigor caused by infection with BRNV alone. RBDV therefore does play a causal part in the total 'bushy dwarf' syndrome.

RBDV is serologically indistinguishable from loganberry degeneration virus and synonymous with raspberry yellows virus and is probably the same as raspberry line pattern virus reported from Poland.

Studies on the molecular biology of RBDV have shown it to possess a novel combination of properties and it has been assigned, as the sole known member, to the genus *Idaeovirus.* Though RBDV has a bipartite genome, its closest affinities are with viruses that have tripartite genomes in the family *Bromoviridae.*

Biological Properties

Geographical Distribution

RBDV probably occurs wherever red raspberry (*R. idaeus, R. strigosus*), black raspberry (*R. occidentalis*), or blackberry (*R. fruticosus*), is grown. The virus has been reported from Australasia, China, Eastern and Western Europe, North and South America, South Africa, and the former Soviet Union. However, at least three variants of RBDV have been characterized and some are more restricted in their geographical distribution.

Common or Scottish (S) isolates

The Scottish type isolate (S) is representative of isolates that have been identified in almost every country where raspberry is grown and are therefore sometimes referred to as isolates of the 'common strain'. They produce characteristic symptoms in herbaceous test plants and, under suitable environmental conditions, in sensitive raspberry cultivars. They are distinguished by a restricted *Rubus* host range, and many red raspberry cultivars are highly resistant, probably immune to infection. S isolates also fail to infect some hybrid berry cultivars.

Resistance-breaking (RB) isolates

These isolates are largely indistinguishable biologically from S isolates except that they are able to infect red raspberry cultivars and hybrid berry cultivars immune to S isolates. Indeed, they infect by grafting nearly all *Rubus* species and cultivars tested. RB isolates seem restricted in their distribution to Central and Eastern Europe, Russia and Siberia, and, probably through importation of infected material, to isolated areas in England and some parts of Western Europe.

Black raspberry (B) isolates

Two isolates of RBDV from the American black raspberry (*R. occidentalis*), which were serologically closely related to S isolates, were distinguishable from them by spur formation in double-diffusion serological tests in agarose gel. This is the only evidence of serological variability in field isolates of RBDV. B isolates are more difficult to maintain in culture in herbaceous plants and their particles are more difficult to purify in quantity than those of S isolates. They are also difficult to detect in *R. occidentalis*

extracts by inoculation to *Chenopodium quinoa* test plants but are readily detected by enzyme-linked immunosorbent assay (ELISA), suggesting that they may have a low specific infectivity. Only B isolates were found in naturally infected *R. occidentalis*. However, more data are needed to determine whether B isolates are restricted to *R. occidentalis* and whether S isolates can occur in *R. occidentalis* in nature. B isolates have been found in nature only in North America, the sole region where *R. occidentalis* is grown extensively.

Natural and Experimental Transmission

In red raspberry and black raspberry, RBDV is readily transmitted to progeny seedlings via either the pollen or the ovule of infected plants and transmission is greatest when both parents are infected. Transmission in association with pollen is confirmed in field and glasshouse studies. Healthy plants can be infected after the first flowering season when planted close to virus sources.

Experimentally, RBDV is readily transmitted from *Rubus* by grafting to infectible *Rubus* species and cultivars. However, graft-inoculated plants usually need to go through a dormant season before the virus becomes fully systemic. RBDV is also transmissible from infected *Rubus* to herbaceous test plants by mechanical inoculation of sap extracts in aqueous solutions of either 2% nicotine or 1% polyethylene glycol (PEG) (mol. wt. 6000 Da). Mechanical transmission from RBDV-infected herbaceous plants to some infectible red raspberry cultivars is also possible by the same procedure, but with great difficulty.

Disease Symptoms and Effects

Naturally infected plants

In nature, RBDV occurs in wild and cultivated *Rubus* species and cultivars. When infecting alone, RBDV is often symptomless in *Rubus* plants, especially in Britain. However, in sensitive raspberry cultivars and under ill-defined environmental conditions, it induces symptoms of yellows disease. This disease is characterized by an initial yellowing of the main or minor veins of the lower leaves or leaflets that progressively extends to other veins and ultimately to the interveinal lamina, sometimes affecting the whole leaf (**Figure 1**). Some raspberry cultivars may also develop chlorotic/yellow rings or line patterns in leaves.

RBDV infection also causes 'crumbly fruit' in some raspberry cultivars. This condition, arising from the abortion of some drupelets and the uneven development of others, frequently results in an abnormally shaped fruit, which, on picking, may disintegrate into individual drupelets or drupelet clusters (**Figure 2**). The same disease syndrome can be induced by other unrelated causes, such as poor pollination conditions, infection with other viruses, or genetic aberrations.

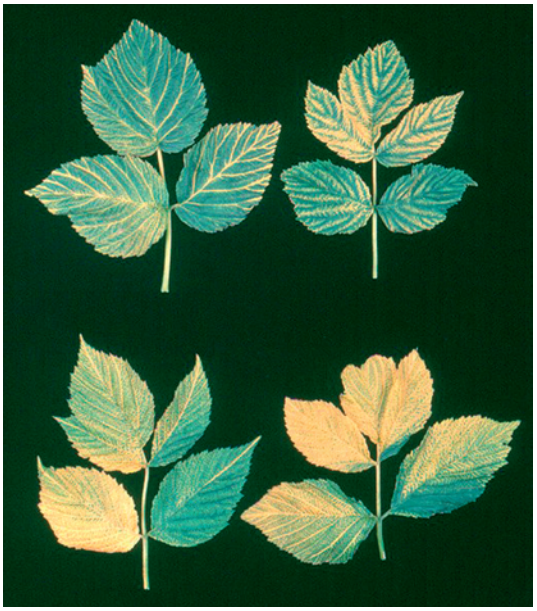

Figure 1 Leaves of RBDV-infected red raspberry showing, from upper left through to lower right, the progressive development of yellows disease symptoms. Reproduced with the permission of the Scottish Crop Research Institute (SCRI).

Figure 2 Symptoms of crumbly fruit of red raspberry caused by RBDV infection. Reproduced with the permission of the Scottish Crop Research Institute (SCRI).

Additional symptoms have been attributed to RB isolates. In field studies in England, an association was reported between infection with RBDV-RB and premature defoliation of fruiting canes, decreased vigor, leaf curling, necrosis and death of laterals, and increased winter kill in some red raspberry cultivars that are immune to S isolates of this virus. Although this evidence is only

circumstantial, it suggests that these severe symptoms are caused by infection with RBDV-RB.

Experimentally infected plants

RBDV has been transmitted by graft inoculation from *Rubus* to perennial plants in other genera. It symptomlessly infected *Fragaria vesca* and *Prunus mahaleb* seedlings and induced pronounced chlorotic veinbanding and line patterns in *Cydonia oblonga* cv. C7-1. RBDV has a moderately wide host range in herbaceous test plants, but infects most hosts symptomlessly. By mechanical inoculation of RBDV-infective sap, over 50 plant species from 12 dicotyledonous families were infected.

Particle Properties

Properties of Virus Particles

RBDV particles are best purified from leaf tissue of *C. quinoa*. Purified virus particles are about 33 nm in diameter, and appear quasi-isometric (**Figure 3**) because they tend to collapse and deform on the electron microscope grid. They appear more spherical in shape when aldehyde-fixed. Particle preparations have A260/A280 of 1.62, suggesting that RBDV particles contain about 24% RNA. The particles are unstable and readily disrupt in the presence of 0.01% sodium dodecyl sulfate, indicating that they are stabilized by protein–RNA linkages.

The particles sediment as a rather broad band in sucrose density gradients, with a sedimentation coefficient of 115 S in 0.05 M citrate buffer, pH 6. Formaldehyde-fixed virus particles, centrifuged to equilibrium at 20 °C in solutions of CsCl or RbBr, form a band at a density of 1.37 g ml^{-1}. Very rarely, preparations also contain particles *c.* 15 nm in diameter that sediment at *c.* 34 S and are serologically identical to the 33-nm-diameter particles and may be re-aggregates of viral coat protein.

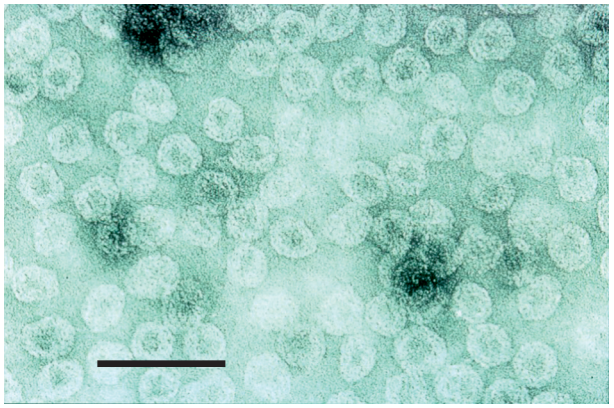

Figure 3 Electron micrograph of a purified preparation of RBDV particles stained in uranyl formate. Scale = 100 nm. Reproduced with the permission of the Scottish Crop Research Institute (SCRI).

Composition of Virus Particles

Purified preparations of RBDV particles typically yield a single major protein estimated by polyacrylamide gel electrophoresis to have an M_r of *c.* 30 kDa. However, some preparations, even highly purified ones, contain minor amounts of smaller proteins, presumably of plant origin.

The particles contain three species of single-stranded RNA (ssRNA) with M_r about 2.0×10^6 (RNA-1), 0.8×10^6 (RNA-2), and 0.3×10^6 (RNA-3). The three RNA species are sometimes present in approximately equimolar amounts but in some preparations and with some isolates, RNA-3 (or RNA material of about the same size) is often present in much greater molar concentration than RNA-1 and RNA-2. The way in which the RNA molecules are packaged in the particles is unknown, but it is unlikely that all three RNA species are contained within the same particle.

Molecular Biology

Nucleotide Sequences

The complete nucleotide sequences have been determined for the three RNA species present in particles of isolates S and RB. **Figure 4** is a diagram of the genome structure of RBDV deduced from these sequences. RNA-3 is 946 nt long and contains a single ORF, which encodes the 30 kDa coat protein. This predicted size corresponds to that of protein obtained from purified virus particles and that of the main polypeptide made by *in vitro* translation of RNA-3.

RNA-2 is 2231 nt long and its 3′ half contains the entire sequence of RNA-3; RNA-3 is thus a subgenomic mRNA. In addition, RNA-2 contains, in its 5′-half, a second ORF which encodes a 39 kDa protein. Polypeptides obtained by

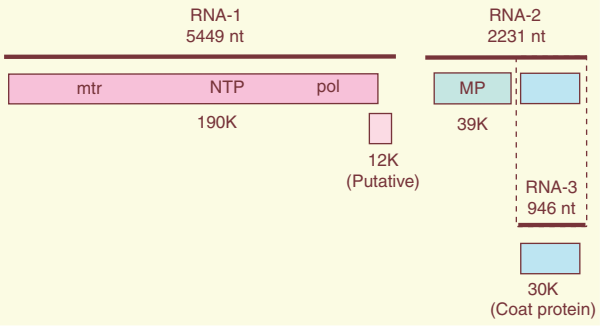

Figure 4 Diagram showing the genome structure of RBDV based on the RNA sequences. RNA molecules are represented by solid lines and the putative positions of the products of the ORFs are indicated as boxes. The positions of domains in the polyproteins are shown as: MP, residues shared among putative transport proteins; mtr, methyltransferase; NTP, NTP-binding; pol, RNA-dependent RNA polymerase. The dotted lines indicate that RNA-3 is derived from the 3′ terminal portion of RNA-2. Reproduced with the permission of the Scottish Crop Research Institute (SCRI).

in vitro translation of RNA-2 appeared to be larger than this: translation in wheat germ extracts produced a 46 kDa protein and translation in reticulocyte lysate produced a 42 kDa protein.

RNA-1 is 5449 nt long and contains one large ORF which encodes a 190 kDa protein. This protein corresponds in size to the largest polypeptide made by *in vitro* translation. A small ORF is also present in a different translation frame and overlapping the ORF for the 190 kDa protein (**Figure 4**). This small ORF encodes a 12 kDa polypeptide. All RBDV isolates sequenced to date contain this ORF in this 3′ region. No corresponding subgenomic RNA was detected in RNA extracted from RBDV-infected plants, and infectious RNA transcripts of a 12 kDa deletion mutant of RBDV were still able to infect herbaceous host plants indicating that the 12 kDa protein is not essential for infectivity. Intriguingly, the position of this gene corresponds to that of the 2b gene in the tripartite genome of cucumber mosaic virus (CMV) that encodes a 10 kDa polypeptide and overlaps the C-terminal 69 codons of ORF 2a that encodes the RNA polymerase protein. In their respective RNA molecules both the CMV 2b and putative RBDV 12 kDa proteins are encoded in the +1 reading frame of the major ORF. The CMV 2b protein is important in both long-distance systemic movement and the suppression of post-transcriptional gene silencing but it is also not necessary for infectivity. However, experiments failed to demonstrate the activity of the 12 kDa RBDV protein in suppressing post-translational gene silencing.

There are similarities among the 5′ or 3′ terminal noncoding sequences of each of the three RBDV RNA species. At the 5′ end of RBDV RNA, the first six to eight nucleotides are similar in all three RNA species, the consensus being UAUUU. At the 3′ end, RNA-3 is identical to RNA-2 (being derived from it), and RNA-1 and RNA-2 share sequence and structural similarities. The 3′-terminal 18 nucleotides are identical in RNA-1 and RNA-2, and the terminal 71 nucleotides of each RNA can be folded into similar stem–loop structures.

The noncoding region between the two ORFs in RNA-2 contains the start of RNA-3 and presumably also contains sequences responsible for the initiation and promotion of its transcription. Like the comparable region of bicistronic RNAs of other viruses, this part of RBDV RNA-2 is rich in A and U residues. No double-stranded RNA (dsRNA) was found in infected tissue which could correspond to a double-stranded form of RNA-3, and RNA-3 is therefore probably transcribed from a minus-sense copy of RNA-2.

Virus Protein Sequences

The 30 kDa protein (coat protein)

The coat protein of RBDV shows no striking similarities with the coat proteins of other viruses. In comparisons made by using CLUSTALV, RBDV coat protein had a sequence identity of between 10% (alfalfa mosaic virus, AMV) and 19% (tobacco streak virus, TSV) to coat proteins of viruses in the family *Bromoviridae*. An alternative to this sequence-based alignment program is to use secondary structure predictions to produce an alignment. The RBDV coat protein structure predicted by such an alignment was of a long N-terminal sequence containing two α-helices and followed by a region containing eight β-sheets. If correct, this arrangement would resemble that of the coat proteins of many viruses that have isometric particles. The N-terminal parts of the coat proteins of RBDV and of viruses in the family *Bromoviridae* are relatively rich in basic amino acids which are thought to be internal and to interact with the encapsidated RNA.

The 39 kDa protein

RNA-2 of RBDV corresponds in size and gene content to RNA-3 of viruses in the family *Bromoviridae*. The ORF for the 39 kDa protein therefore corresponds in position to the ORF for the putative movement protein of, for example, AMV. A small sequence identity was detected in multiple alignment tests between the 39 kDa protein and the putative or actual movement proteins of several viruses. In further alignment tests of this sort, Mushegian and Koonin have detected a match between part of the 39 kDa protein sequence and a motif conserved in the movement proteins of some other viruses, such as red clover necrotic mosaic virus and soil-borne wheat mosaic virus. These proteins were proposed to belong to a '30 kDa superfamily' of movement proteins.

The 190 kDa protein

The sequence of the 190 kDa protein has similarities with replicase proteins of viruses in the Sindbis-like supergroup. There was good correspondence between parts of the 190 kDa protein and parts of the 183 kDa protein of tobacco mosaic virus but the greatest similarity was with a hypothetical composite protein consisting of the 90 kDa protein of AMV (encoded by RNA-2) attached to the C-terminus of the AMV 125 kDa protein (which is encoded by RNA-1). The three regions of greatest similarity correspond to the locations in the AMV proteins of the methyltransferase, NTP-binding, and RNA-dependent RNA polymerase domains. The first two domains occur in the 125 kDa protein of AMV and the polymerase domain occurs in the 90 kDa protein of AMV. RBDV RNA-1 therefore corresponds in size and gene functions to RNA-1 plus RNA-2 of AMV and related viruses. Comparisons of the three domains of several viruses by using CLUSTALV suggested that RBDV is marginally more similar to viruses in the family *Bromoviridae* than to other viruses. The maximum similarity was to AMV.

Detection and Control

Detection in Plants

In *Rubus*, RBDV may induce yellowing, line patterns, or crumbly fruit, but such symptoms are unreliable for diagnosis because they may be due to infection with other disease agents or to other causes. Furthermore, RBDV often infects plants symptomlessly. Detection and diagnosis therefore depend on bioassays and/or serological tests.

RBDV can be reliably detected by one or other of the various forms of ELISA and this is the preferred detection method for B isolates, which seem to have a low specific infectivity. Other studied isolates are readily detected by mechanical transmission to *C. quinoa* test plants. However, identification of RBDV in symptom-bearing herbaceous test plants is dependent on serological tests. As the distribution of RBDV in individual *Rubus* plants can be erratic, leaves/leaflets for mechanical transmission or ELISA should be taken and pooled from at least three different nodes.

Polyclonal antisera raised to S isolates have a moderate titre of *c.* 1/512 in gel double diffusion tests. RBDV antigen in purified virus preparations or in infective sap of *C. quinoa* reacts with such antisera in microprecipitin tests and in agarose gel double-diffusion serological tests. As already mentioned, spur formation in this latter test can be used to distinguish S isolates from B isolates. In Canada, monoclonal antibodies to RBDV were able to distinguish three different epitopes of a Canadian isolate of RBDV. However, these monoclonal antibodies reacted in double antibody sandwich ELISA (DAS-ELISA) with all tested isolates from red raspberry, including B, S, and RB isolates.

Therapy

Unlike many other viruses infecting *Rubus*, RBDV is not readily eradicated from *Rubus* plants by heat treatment alone. However, heat treatment for several weeks at 36 °C followed by propagation from shoot tips or apical meristems eliminated the virus from some plants. Using only tissue culture of meristem tips, it was necessary to subculture up to three times to eliminate the virus.

Control in Crops

Because RBDV is transmitted in association with infected pollen, the only methods of controlling it in crops are to grow resistant cultivars, or to plant healthy stock of infectible cultivars and grow them in isolation from possible sources of infection. Many red raspberry cultivars are resistant, possibly immune, to S isolates (the most widespread isolates worldwide). This resistance is conferred by the presence of a single dominant gene, *Bu.* However, almost all *Bu*-containing cultivars are infectible by grafting with RB isolates. Resistance to graft inoculation with RB isolates was detected in only very few red raspberry cultivars. Studies on this form of resistance indicated that its mode of inheritance was complex but seemed to depend on the presence of gene *Bu*, together with a second resistance component whose inheritance was probably multigenic. In field studies, some raspberry cultivars, including some that do not contain gene *Bu*, are more resistant than others to natural infection with RB isolates. This might suggest that inherent resistance to field infection with RB isolates may exist in some cultivars that are infectible by grafting.

Relationships with Other Viruses

RBDV resembles viruses in the genus *Ilarvirus,* family *Bromoviridae* in having easily deformable particles that are transmitted in association with pollen. RNA-2 resembles RNA-3 of ilarviruses in the arrangement and sizes of its encoded gene products, the generation of a 3′ terminal subgenomic RNA (sgRNA) and in the structured nature of the 3′ ends of the molecules. Nevertheless, RBDV is serologically unrelated to all recognized ilarviruses tested. Also, RBDV differs from ilarviruses in the sedimentation behavior of its particles, in the number and sizes of its RNA molecules, and in having a bipartite genome. Taken together, these properties distinguish RBDV from all other well-characterized viruses and justify its classification as the sole member of the genus *Idaeovirus.* The genus has not been assigned to a family, but, because of its molecular properties, the genus *Idaeovirus* may be tentatively classified in the family *Bromoviridae*, albeit as an atypical member of a family whose four recognized genera contain viruses with tripartite genomes. The sequence of the translation product of RBDV RNA-1 resembles in different parts, sequences in the translation products of viruses in the family *Bromoviridae* and to a lesser extent the sequences of the helicase + polymerase protein ($M_r \sim 183 \times 10^3$) of tobamoviruses. Idaeoviruses, therefore, belong to the 'Sindbis-like' supergroup.

Glossary

Internal ribosome entry site (IRES) Complex secondary RNA structure that allows translation initiation independent of a 5′ cap (m^7GpppN) structure.
UTR Untranslated region in an mRNA molecule on either the 5′ or 3′ side of an open reading frame.

Introduction

Iflaviruses have been described so far in lepidopteran and hymenopteran insects as well as in bee parasitic mites. In insects these viruses can cause mortality or developmental malformations. Sacbrood virus (SBV), for instance, lethally affects honeybee larvae (*Apis mellifera*) and the first descriptions of sacbrood disease date back as early as 1913. SBV was initially characterized in 1964. Other examples of iflaviruses causing disease in honeybees are deformed wing virus (DWV), which causes morphological abnormalities, and the related Kakugo virus (KV), the causative agent of aggressiveness in infected bees. Bee parasitic Varroa mites (*Varroa destructor*) function as vectors for these (and other) bee viruses, but DWV and the related Varroa destructor virus 1 (VDV-1) can also replicate in these mites. Infectious flacherie virus (IFV) infects the silkworm *Bombyx mori* and is a major cause of cocoon loss in silk production in Japan. In 1998 IFV was the first iflavirus for which the complete genome sequence was determined. Iflaviruses were previously referred to as insect picorna-like viruses together with viruses currently classified as *Dicistroviridae*.

Characteristics and Classification

Iflaviruses are characterized by icosahedral particles, which are nonenveloped and have a size of approximately 30 nm (**Figure 1**). The virions contain a single copy of a single-stranded, linear RNA molecule of positive polarity. The RNA genome is nonsegmented and encodes one large polyprotein, which is cleaved post-translationally into structural (capsid) and nonstructural proteins.

Infections flacherie virus is the type species of the genus *Iflavirus* which is not yet assigned to a virus family. Other species with an official status in this genus are *Sacbrood virus* and *Perina nuda virus*. Tentative species in this genus according to the Universal Virus Database (ICTVdBAse, version 4) are Deformed wing virus, Kakugo virus, Varroa destructor virus 1, and Ectropis obliqua picorna-like virus. The recently discovered Venturia canescens small RNA-containing virus (VcSRV) also has typical iflavirus features.

In the past, the name insect picorna-like viruses has been used to indicate insect viruses that share major features with vertebrate picornaviruses but are now classified either in the genus *Iflavirus* or in the family *Dicistroviridae*. Since the vernacular name 'picorna-like viruses' does not refer to a definite taxonomic unit, it is better avoided. In the light of this, the species *Ectropis obliqua picorna-like virus* will probably change in the future to *Ectropis obliqua virus*, similar to the classified *Perina nuda virus* which was known as *Perina nuda picorna-like virus* in older literature. However, to prevent confusion with other viruses isolated from these insect species, such as *Perina nuda nuclear polyhedrovirus*, the addition of iflavirus in the species name needs to be considered (i.e., *Perina nuda iflavirus*).

Viral Capsid Proteins

Three major capsid proteins have been detected for iflaviruses (VP1–VP3), ranging in size between 28 and 35 kDa. Although structural analyses have not been performed for iflavirus capsids, it is anticipated that heterotrimers of these three capsid proteins serve as the building blocks of the viral capsids in a similar fashion as for mammalian picornaviruses and cricket paralysis virus (CrPV; *Dicistroviridae*).

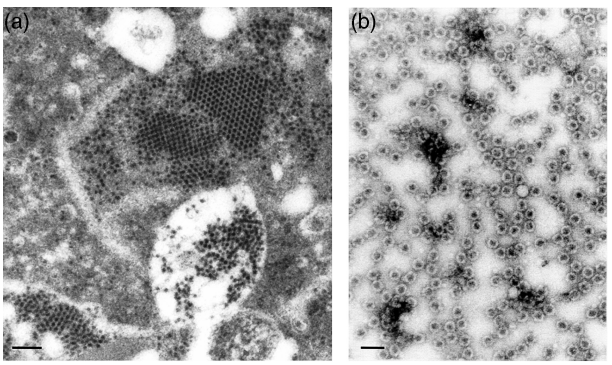

Figure 1 Virus particles of VOV-1. (a) Electron microscope photograph of a thin section of mite tissue with VDV-1 particles. (b) Purified VDV-1 particles. Scale: 150 nm (a), 50 nm (b). Photographs courtesy of Dick Peters.

A smaller less prominent structural protein is described as VP4 (4–12 kDa). The position of VP4 in the iflavirus capsids is unresolved and cannot be extrapolated from related viruses due to the variation in VP4 conformations observed in the virion structures. The various names used in the literature to refer to the structural proteins of iflaviruses are confusing. Here the nomenclature used in the *Eighth Report of the International Committee on Taxonomy of Viruses* will be followed where the capsid proteins appear in the order VP2, VP4, VP3, and VP1 from N to C in the polyprotein (**Figure 2**). The final maturation step for the iflavirus virion is proposed to be the cleavage between VP3 and VP4, thereby making the virus infectious. In picornaviruses, which have a different order of VP proteins in the polyprotein (VP4, VP2, VP3, and VP1 from N to C), this final cleavage occurs between VP4 and VP2.

The viral entry mechanism into cells is unknown, but most likely involves the release of the VP4 capsid protein as the first step after host cell recognition, similar to the situation in dicistroviruses and mammalian picornaviruses.

Genome Organization

As of February 2007, a total of seven complete iflavirus genome sequences are available (IFV, SBV, Perina nuda virus (PnV), Ectropis obliqua picorna-like virus (EoPV), DWV, KV, and VDV-1). The main characteristics of these genomes are summarized in **Table 1**. The genome size of these viruses varies between 8832 and 10 152 nt, excluding a 3′ polyA tail.

The RNA genome is nonsegmented and is translated into one large polyprotein, as shown by *in vitro* translation experiments. The polyprotein is cleaved into functional proteins by a virus-encoded protease. The information for the capsid proteins is located in the 5′ part of the genome and is followed downstream by a cluster encoding the nonstructural proteins (**Figure 2**).

For PnV and VDV-1 nucleotide sequence information was combined with N-terminal protein sequencing data for capsid proteins, allowing the demarcation of the protease cleavage sites and therefore the borders of the capsid proteins. In the iflavirus polyprotein, the structural proteins are preceded by a leader protein (L) of unknown function. This iflavirus L protein is not homologous to the leader protein of mammalian picornaviruses, which has protease activity.

The nonstructural proteins appear in the polyprotein in the order helicase (NTP-binding protein), protease, and RNA-dependent RNA polymerase (RdRp), as is the case in all members of a proposed picornavirus-like superfamily (see below). The RdRp harbors a canonical RGD motif typical for RNA polymerases of positive-sense single-stranded RNA (ssRNA) viruses.

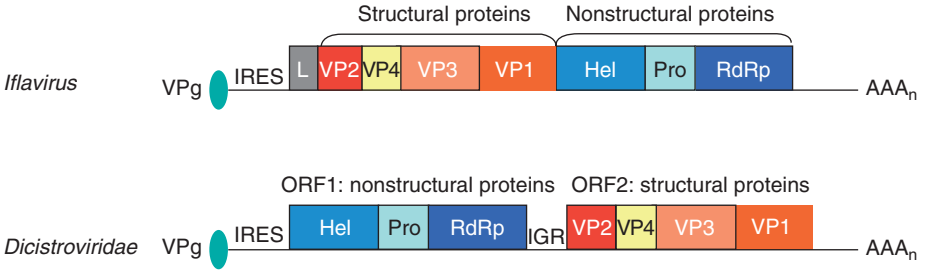

Figure 2 Genome organization of viruses in the genus *Iflavirus* compared to *Dicistroviridae*. Iflavirus genomes encode a single polyprotein with the structural proteins VP1–VP4 located in the N-terminal part and the nonstructural proteins (helicase, protease, and RNA-dependent RNA polymerase (RdRp)) in the C-terminal part. A function for the N-terminal L polypeptide has not been assigned yet. The presence of an internal ribosomal entry site (IRES) element in the 5′ untranslated region (UTR) has been confirmed for several iflaviruses. Dicistroviruses have a bicistronic genome, encoding two polyproteins separated by an intergenic region (IGR) that serves as IRES for the second open reading frame (ORF). ORF1 encodes the nonstructural proteins, ORF2 the capsid proteins.

Table 1 Iflavirus genome data[a]

Virus name	*Genome size*	*ORF size*	*5′ UTR length*	*3′ UTR length*	*Accession number*
IFV	9 650	9255	156	239	AB000906
SBV	8 832	8574	178	80	AF092924
PnV	9 476	8958	473	45	AF323747
EoPV	9 394	8961	390	43	AY365064
DWV	10 166	8682	1139	345	AY292384

VDV-1	10 112	8682	1117	313	AY251269

[a]All sizes in nt.

Comparative surveys of variation in iflavirus genomes have been performed for both DWV and VDV-1 in mites collected from beehives in distinct European locations. This study showed similarities of 96–99% between the various isolates, indicating that iflavirus genomes are not a fixed entity but subject to genetic variation in the field.

Relation to Other Taxa

Iflavirus genomes share several features with other viruses with positive-sense RNA genomes, for which a picornavirus-like superfamily has been proposed containing the families *Comoviridae*, *Picornaviridae*, *Potyviridae*, and *Sequiviridae*. The overall genome organization of iflaviruses strongly resembles that of mammalian picornaviruses, and iflaviruses have therefore been described as entomogenous picornaviruses. In these two groups of viruses the RNA genome encodes one large open reading frame (ORF) with the structural proteins followed by the nonstructural ones, although the order of the capsid proteins in the polyprotein and the number of proteases differ. The position of VP4 in iflaviruses is between VP2 and VP3, whereas in the *Picornaviridae* VP4 is the N-terminal capsid protein. The order of the capsid proteins in the polyprotein is similar in iflaviruses and dicistroviruses (**Figure 2**). Picornaviruses encode a 2C protease that is not found in iflavirus and dicistrovirus genomes.

In phylogenetic trees iflaviruses form a clade separated from dicistroviruses: their distinct genome structures justify their classification in different taxa (**Figure 3**). The major genomic difference between iflaviruses and dicistroviruses is that the latter encode separate polyproteins for nonstructural and structural proteins (hence have bicistronic genomes), while iflavirus genomes are monocistronic and encode a single polyprotein. In order to translate these ORFs into polyproteins dicistroviruses have both a 5′ and an intergenic internal ribosomal entry site (IRES) element (**Figure 2**). These two IRES elements vary from each other in terms of sequence, structure, and mechanism of action.

Another insect virus related to iflaviruses is kelp fly virus (KFV), which encodes one large polyprotein with an inhibitor of apoptosis (IAP) preceding the capsid and nonstructural protein segments. The encoded IAP protein has homology with baculovirus IAP proteins. Whether this *iap* gene is functional and plays a crucial role in the infection process is not known. Phylogenetic analysis using the RdRp sequence placed KFV in a clade separated from iflaviruses and dicistroviruses (**Figure 3**).

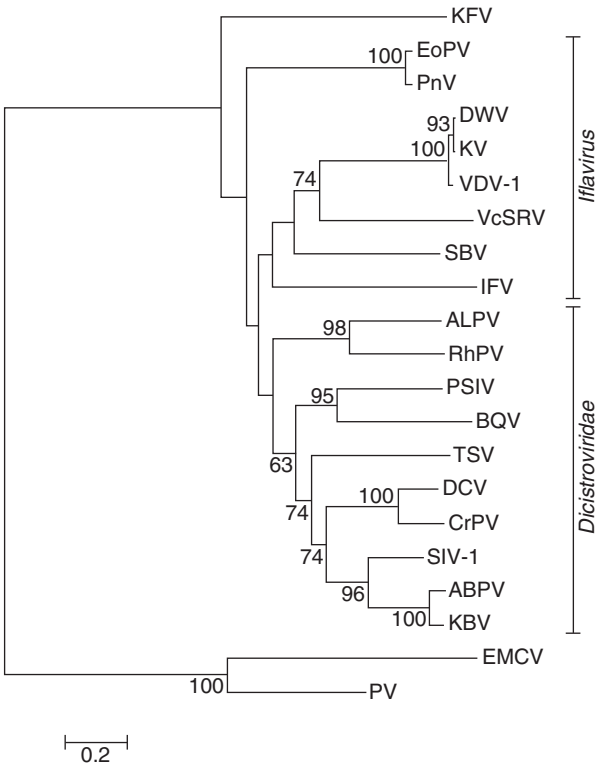

Figure 3 Phylogenetic relationship between viruses in the genus *Iflavirus* and the family *Dicistroviridae* based on RdRp sequences. Encephalomyocarditis virus (EMCV [ABC25550]) and poliovirus (PV [CAA24465]) were used as outgroups. Phylogenetic and molecular evolutionary analyses were conducted using MEGA version 3.1. Amino acid sequences were aligned using the Clustal W module and phylogenetic relationships and evolutionary distances were calculated using the neighbor-joining method. Bootstrap analysis was performed with 100 replicates. The distance marker indicates 0.2 substitutions per amino acid. The RdRp sequences were extracted form GenBank: acute bee paralysis virus (ABPV) [AAN63803], aphid lethal paralysis virus (ALPV) [NP_733845], black queen cell virus (BQV) [NP_620564], CrPV [NP_647481], DWV [AAP49283], drosophila C virus (DCV) [NP_044945], EoPV [NP_919029], IFV [NP_620559], KV [YP_015696], Kashmir bee virus (KBV) [NP_851403], KFV [YP_415507], PnV [NP_277061], plautia stali intestine virus (PSIV) NP_620555], rhipalopsiphum padi virus (RhPV) [NP_046155], SBV [AAL79021], solenopsis invicta virus 1 (SIV-1) [YP_164440], tauro syndrome virus (TSV) [ABB17263], VDV-1 [AY251269], and VcSRV [AY534885].

Tissue Tropism, Pathology, and Transmission

The primary infection sites of iflaviruses may vary. For IFV, the goblet cells of the midgut epithelium are the primary targets, suggesting virus uptake via food contamination. IFV infection finally leads to a flacherie phenotype, where excessive amounts of body fluids accumulate under the skin. This flacherie is also observed in other lepidopterans infected by iflaviruses.

Bee iflaviruses may spread by food contamination, although they also exploit other infection routes. An important site of infection for DWV and VDV-1 (and probably also KV) in honeybees are the feeding sites of *Varroa* mite nymphs and female adults on bee larvae. These mites can serve as vectors for the transmission of bee viruses. In addition, their constant feeding makes bees more susceptible to pathogens in general, due to exhaustion and immunomodulation. Direct transmission from bee to bee without the intervention of *Varroa* mites cannot be ruled out, but the incidence of infection is much lower in colonies which are not infested by these mites.

DWV and VDV-1 have been detected in head, thorax, and abdomen of bees. DWV infection may result in the development of bees with underdeveloped, malformed wings. KV, which varies only slightly from DWV in sequence, exhibits a strong neurotropism and is correlated with aggressive behavior of infected bees. Iflaviruses may also persist in insect populations in a latent symptomless state.

Replication

Replication of iflaviruses occurs in the cytoplasm where crystalline aggregates of progeny virus can be detected (**Figure 1**(**a**)). Iodination of purified IFV RNA showed that it was covalently linked to a protein of 11.5 kDa. This so-called VPg protein was removed upon translation of IFV RNA in a rabbit reticulocyte lysate, as is also the case for VPg protein of mammalian picornaviruses. It is anticipated that the 5′ ends of both the genomic RNA and the complementary strand RNA are covalently linked to a terminal VPg, implying that the iflavirus VPg protein also serves as a primer for RNA synthesis in iflaviruses, similar to the situation in the *Picornaviridae*. The location of VPg in the polyprotein is unresolved.

The presence of negative-strand iflavirus RNA is a hallmark to demonstrate replication of these positive-strand RNA viruses in insects and/or mites. For DWV and VDV-1, for example, negative-strand RNA and hence replication has been demonstrated in honeybees, as well as in bee-parasitic *Varroa* mites.

Translation

The sequenced iflaviruses can be grouped based on the length of their 5′ untranslated region (UTR) (**Table 1**). SBV and IFV have very short 5′ UTRs (156–178 nt) with hardly any predicted secondary structure. PnV and EoPV have longer 5′ UTRs (390–473 nt), which are homologous to each other and for which a mostly nonbranched secondary structure has been predicted. DWV, KV, and VDV-1 have much longer 5′ UTRs, which also have mutual homology and for which complex-branched secondary structures have been predicted. The existence of covariation in these homologous sequences, where a mutation at one side is accompanied by a second mutation to preserve secondary structures, is a measure for the likelihood of these predicted secondary structures. A three-branched or clover-leaf structure is shared between the DWV/VDV-1/KV group of iflaviruses and the entero/rhino IRES type of mammalian picornaviruses.

The presence of an IRES in the 5′ UTR, which would allow translation of the polyprotein in a cap-independent manner, has been shown for both VDV-1 and EoPV, using bicistronic plasmid constructs. For EoPV this was combined with mutational analysis to determine the functional domains in the IRES element. The EoPV core IRES was located in the third and fourth stem loop (out of six). Due to the high degree of similarity in sequence and predicted secondary structure between EoPV and PnV on the one hand and between VDV-1 and DWV/KV on the other, IRES elements are also predicted for these viruses. The presence of a functional IRES element in the very short unstructured IFV and SBV 5′ UTR sequences seems unlikely and is probably unnecessary but this awaits further analysis.

The interaction of host translation initiation factors with these IRES elements has not been studied yet. Nor is it known how iflavirus infection affects the translational machinery of the host.

Detection Methods

Iflaviruses can be detected and identified by serological methods such as enzyme-linked immunosorbent assay (ELISA) and Western blot analysis. However, this does not always result in easily interpretable data as virus preparations may contain mixtures of iflaviruses, leading to the production of nonspecific antisera. For instance, DWV and VDV-1 have been shown to coexist in a variety of European beehives. A more specific and therefore reliable method is reverse transcriptase-polymerase chain reaction (RT-PCR) with specific primers based on unique genome sequences. However, relying on single PCR primer pairs for detection is not a reliable method since iflavirus genomes are prone to variation.

RT-PCR also allows the discrimination between positive- and negative-strand RNA molecules by choosing a plus- or minus-strand-specific primer for the reverse transcription step. This makes it possible to establish if a virus is replicating in a certain insect species. Virus titers can be determined by quantitative PCR (QT-PCR), for instance to compare susceptibility of various developmental stages or to determine transmission rates.

Glossary

Cross-protection A virus-infected plant often exhibits resistance to infection by strains of the same or closely related viruses. The degree of cross-protection has been used as a measure of the relatedness of viruses.

Dicistronic An RNA that encodes two gene products, often with a noncoding region separating them.

Recovery A phenomenon in which a virus-infected plant displays severe symptoms after initial infection, but then symptoms decline; this is often associated with a decline in virus concentration.

Subgenomic RNA A segment of RNA generated from a genomic RNA molecule through an internal promoter sequence. Since eukaryotic systems only efficiently translate the open reading frame located at the 5′ terminus of mRNA, this permits efficient translation of downstream open reading frames.

Suppressor of virus-induced gene silencing A molecule produced through virus infection that mitigates the natural plant defense system.

Virus-induced gene silencing A natural plant defense system that uses small fragments of double-stranded RNA to direct the RNA-degrading or silencing enzymes to a target RNA molecule. Double-stranded RNA results from the synthesis of complementary minus- and plus-sense RNA sequences during virus replication.

Taxonomy

The genus *Ilarvirus* was officially recognized in 1975. It is currently placed within the family *Bromoviridae* that also includes the genera *Alfamovirus*, *Bromovirus*, *Cucumovirus*, and *Oleavirus*. The quasi-isometric nature of ilarvirus particles and their relative instability in the absence of antioxidants are reflected in the sigla which originates from the descriptive phrase: isometric labile ringspot viruses. Other distinguishing features of the genus are the distribution of the genome over three plus-sense RNA segments and the absolute requirement for the coat protein to activate the RNA genome to initiate infection. These traits are shared with the genus *Alfamovirus*.

Experimental host ranges of ilarviruses are quite broad, although many have a relatively narrow range of natural hosts consisting of woody plants. Woody hosts may require several years after initial infection for the virus to uniformly infect the plant. The ringspot symptom for which the genus is named is a common symptom of many virus–host combinations. Infections by ilarviruses frequently result in a shock phase during which severe chlorotic or necrotic rings form, followed by a period of recovery with greatly reduced symptoms. This recovery phenomenon has now been described for many virus groups. No inclusion bodies have been described in tissue infected with members of the genus *Ilarvirus*.

Members of the genus *Ilarvirus* are currently divided into six subgroups (**Table 1**). Historically, this separation was based solely on serological reactivity, but it is generally supported by comparison of the amino acid sequences of structural proteins (**Figure 1**). The exception is the coat protein sequence of *Humulus japonicus* latent virus (HJLV) of subgroup 3 which is most similar to that of prune dwarf virus (PDV) of subgroup 4 rather than other members of subgroup 3. *Alfalfa mosaic virus* (AMV) is the monotypic member of the *Alfamovirus* genus; the sequence of the coat protein encoded by AMV also segregates with HJLV and PDV in this analysis. Analyses of amino acid sequences of the nonstructural proteins encoded by all three RNA segments are consistent with current subgroup designations.

In addition to the currently recognized members of the genus *Ilarvirus*, many synonyms have appeared in the literature, most of which refer to specific strains of virus species. These are listed in **Table 1**. The taxonomy of ilarvirus isolates that infect hop plants (*Humulus lupulus* L.) is still evolving. Viruses designated as hop virus C, NRSV-intermediate, and NRSV-HP-2 are related serologically to prunus necrotic ringspot virus (PNRSV) and to apple mosaic virus (ApMV) while hop virus A, apple mosaic virus-hop, and prunus necrotic ringspot virus-HP-1 are serologically related to ApMV only. Analyses of coat protein sequences of viruses obtained from hop plants of diverse geographic origins indicate that both serotypes are strains of ApMV.

Particle Structure and Genome Organization

The virions of ilarviruses are generally quasi-isometric (**Figure 2**), and the size of particle can vary within a species in relation to RNA content; particles range in diameter from 20 to 35 nm. Some ilarviruses also produce a small proportion of bacilliform particles. Virus particles contain subunits of a single structural protein (coat protein). The molecular mass of the coat protein subunits in the range of 19–30 kDa, with the majority of members having coat protein subunits within the rather narrow range of 24–26 kDa. The entire genome of ilarviruses is distributed over three RNA molecules; each is encapsidated separately. However, preparations of virions contain a fourth RNA species that is 3′-co-terminal with RNA3; this subgenomic RNA encodes the coat protein. Recently, a fifth RNA species corresponding to the 3′-untranslated region (UTR) of RNAs 1–3 was found to be encapsidated in virions of PNRSV. This is believed to represent the chance encapsidation of partially degraded RNA that is frequently found within purified virus particles. All of the major RNA species bear a 5′-7-methyl-G cap structure.

The relationship between the genera *Alfamovirus* and *Ilarvirus* is particularly close. The unique dependence on coat protein for infectivity of viral RNA is shared by members of both genera. Moreover, the coat proteins of AMV and some ilarviruses can reciprocally activate infectivity of RNA of the other. This phenomenon has led some investigators to suggest that the genera *Ilarvirus* and *Alfamovirus* should be combined. In as much as these viruses also share several features in common with other genera of the family *Bromoviridae*, the two genera remain separate. Studies of AMV have contributed much of the basic information from which the structure and replication of ilarviruses were determined and will be included here in subsequent comparisons of ilarviruses.

The type member of the genus *Ilarvirus* is *Tobacco streak virus* (TSV). The total genome of the WC isolate of TSV consists of 8622 nucleotides distributed over three RNA segments of 3491, 2926, and 2205 nucleotides (**Figure 3**). The largest segment of RNA, RNA1, contains a single open reading frame (ORF1) encoding a protein of 123.4 kDa. This protein is the replicase and contains the methyltranferase and helicase motifs. RNA2 contains ORF2a encoding a protein of 91.5 kDa. This protein is the RNA-dependent RNA-polymerase based on the presence of conserved RNA-binding motifs. RNA2 of TSV and other members of subgroups 1 and 2 contain a second potential overlapping ORF, ORF2b; AMV and ilarviruses of the remaining subgroups apparently lack this second ORF on RNA2. The function of the ORF2b product with a molecular mass of 22.4 kDa has not been determined. The dicistronic organization of RNA2 detected in ilarvirus subgroups 1 and 2 is similar to that of members of the genus *Cucumovirus*; the putative product of ORF2b of cucumoviruses has been proposed to be a key element in suppressing virus-induced gene silencing. The sequence of *Fragaria chiloensis* latent virus (FCiLV) of ilarvirus subgroup 6 is unique in that its RNA2 has the potential to encode a second small protein located toward the 5′ end of RNA2 (nucleotide positions 350–856 of RNA2). However, the putative product of this ORF bears no significant similarity to protein 2b of the cucumoviruses, nor other proteins thought to be encoded by ilarviruses.

RNA3 of ilarviruses is dicistronic with two potential ORFs. ORF3a encodes a protein of 31.7 kDa with cell-to-cell movement function (MP) and ORF3b encodes the structural coat protein (CP) with a molecular mass of 26.2 kDa. RNA3 of FCiLV contains a third potentially functional ORF, whose putative product does not have any sequence similarity to proteins expressed by other ilarviruses. It is unknown if this ORF is expressed *in vivo*.

Virus Replication

Members of this genus require an 'activated' RNA genome to initiate infection, that is, viral RNA must form a complex with the coat protein to be infectious. This is a distinguishing feature of ilarvirus and alfamovirus replication that differentiates them from other genera in the family *Bromoviridae*. Activation of the genome can be accomplished either through the co-inoculation of viral RNA with coat protein, or by the inclusion of subgenomic RNA4 that is then translated to produce the activating coat protein *in vivo*. This activation can be accomplished through heterologous complex formation, that is, the coat protein from one ilarvirus can bind to and potentiate the replication of RNA from several other but not all members of the genus *Ilarvirus*. Furthermore, the coat protein of AMV can activate the genome of several ilarviruses and vice versa. More recently, it has been demonstrated that RNA3 is able to fulfil the role of either coat protein or RNA4, but with much reduced efficiency. The presence of RNA4 or coat protein increases the efficiency of infection up to 1000-fold relative to the RNA activation achieved by RNA3. This is the result of very inefficient expression of the coat protein gene directly from the dicistronic RNA3.

The mechanism by which genome activation occurs is the result of the specific interaction of the coat protein with sequences located at the 3′ terminus of viral RNA. All ilarviruses for which sequences are known possess sequences at the 3′ terminus of genomic RNAs that are predicted to assume secondary structures that play a role in regulating the relative efficiency of the RNA species for transcription versus translation. Indeed, in the presence of coat protein, transcription of viral RNA is inhibited and translation is favored. The 3′-UTR of each RNA segment contains a series of conserved (A/U) (U/A/G)GC motifs that occur as single-stranded regions at the base of stem-loop structures that are recognized by and bound to coat protein molecules (**Figures 4** and **5**). The sequence and

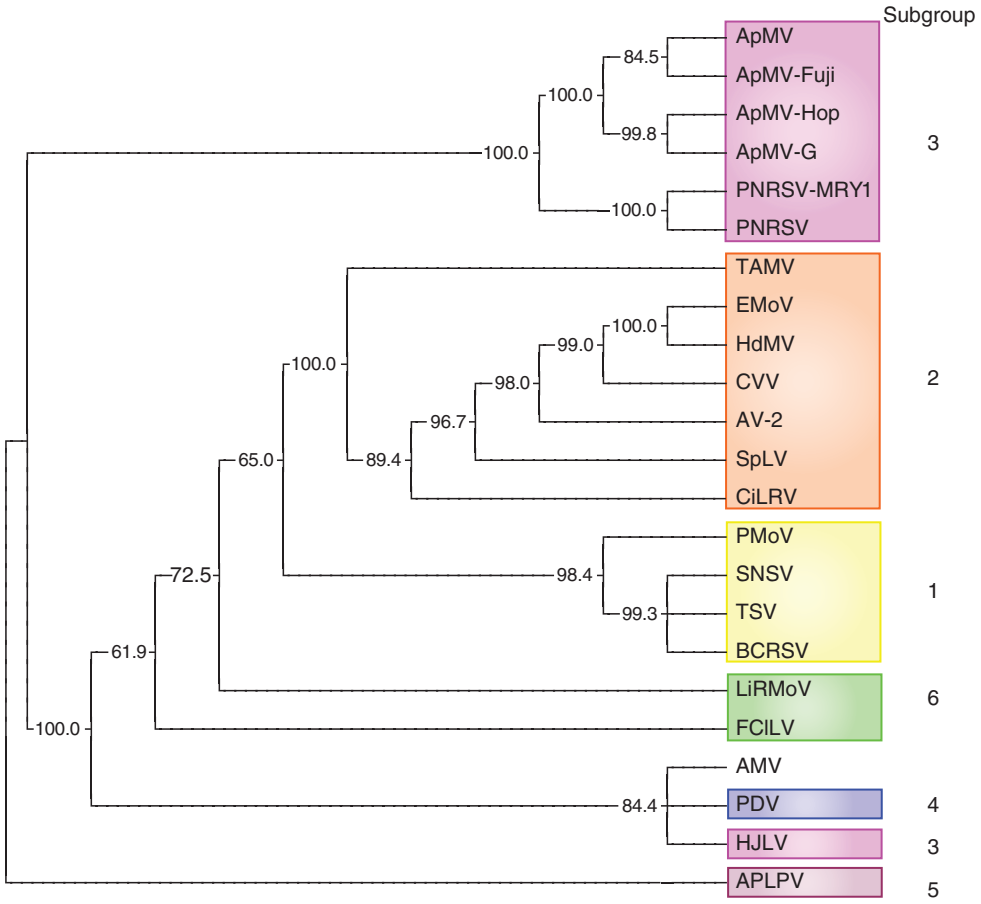

Figure 1 Cladogram illustrating the sequence relationships of ilarviruses based on the deduced amino acid sequence of the coat protein encoded by ORF3b of RNA3. Numbers at branch points indicate the percentage of bootstrap replicates in which that branch occurs. Subgroup designations are derived primarily from serological as well as molecular data and are indicated to the right of the shaded boxes. The sequence of the alfamovirus alfalfa mosaic virus is included in the analysis. See **Table 1** for abbreviations.

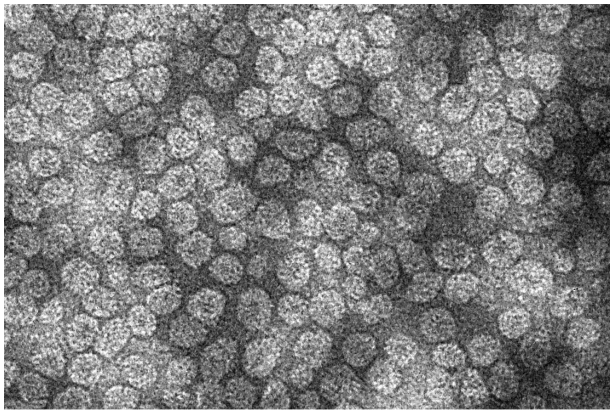

Figure 2 Electron micrograph of negative-stained particles of prune dwarf virus. In addition to quasi-isometric particles 20 and 23 nm in diameter, preparations from some ilarviruses including prune dwarf virus also contain bacilliform particles 19 × 33 nm and 19 × 38 nm.

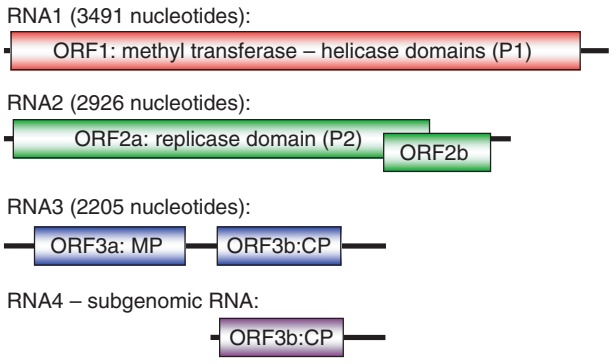

Figure 3 Genome organization of tobacco streak virus (TSV). The positive-sense RNA genome of the WC isolate of TSV is distributed between three segments. ORF2b is present only in genus *Ilarvirus* subgroups 1 and 2. ORF3a encodes a protein (MP) associated with virus movement and ORF3b encodes that coat protein (CP).The subgenomic RNA4 is transcribed from an internal promoter in the intercistronic region of minus-sense RNA3; RNA4 is 3′ co-terminal with RNA3. ORF2b is present only in genus *Ilarvirus* subgroups 1 and 2.

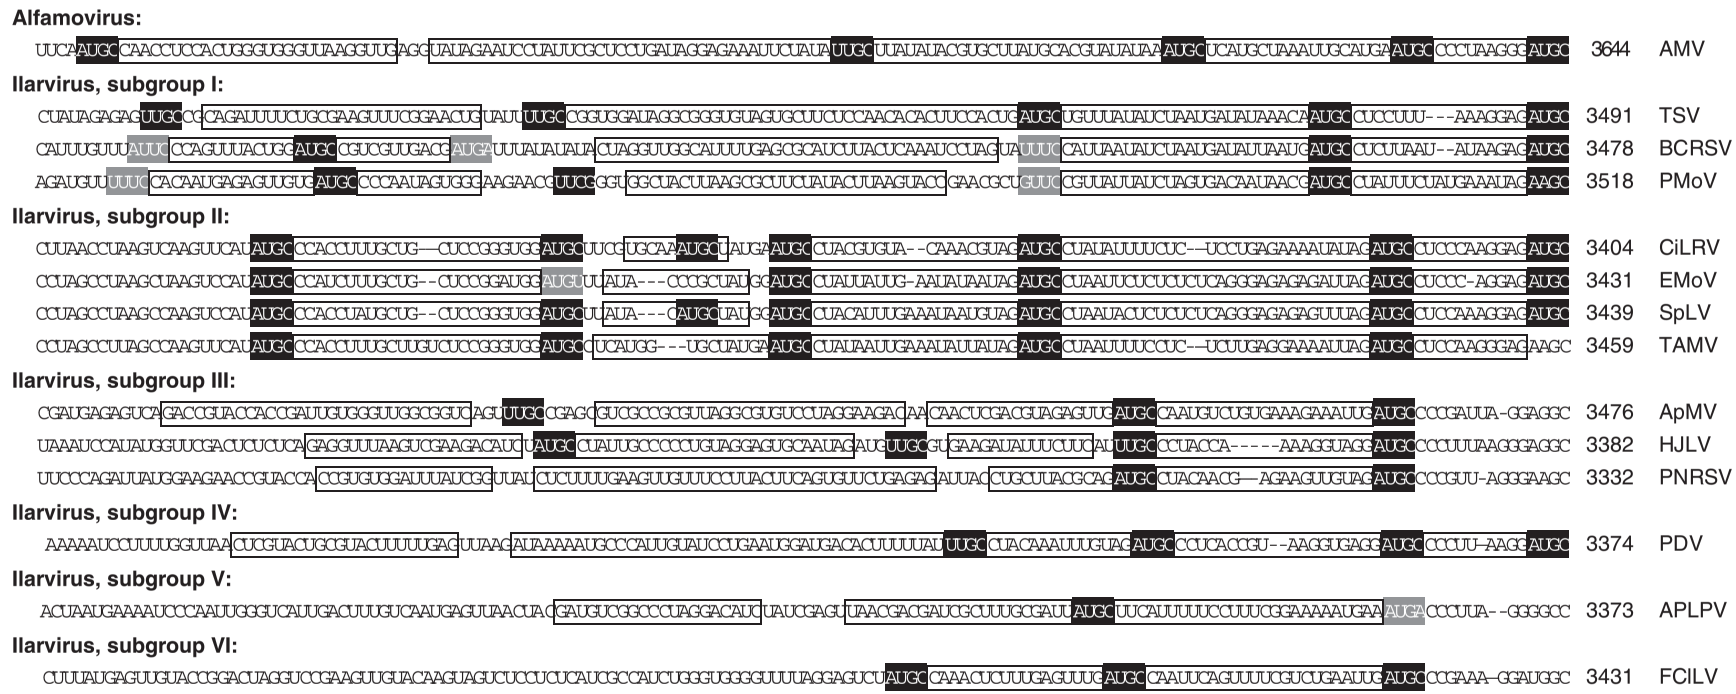

Figure 4 The 3′-untranslated region of RNA1 of ilarviruses contains a repeated (A/U) (U/A/G)GC sequence. The repeated single-stranded regions are indicated by black highlighting. Corrupted copies of (A/U) (U/A/G)GC motifs are highlighted in gray. Potential stem–loop structures are indicated by boxes.

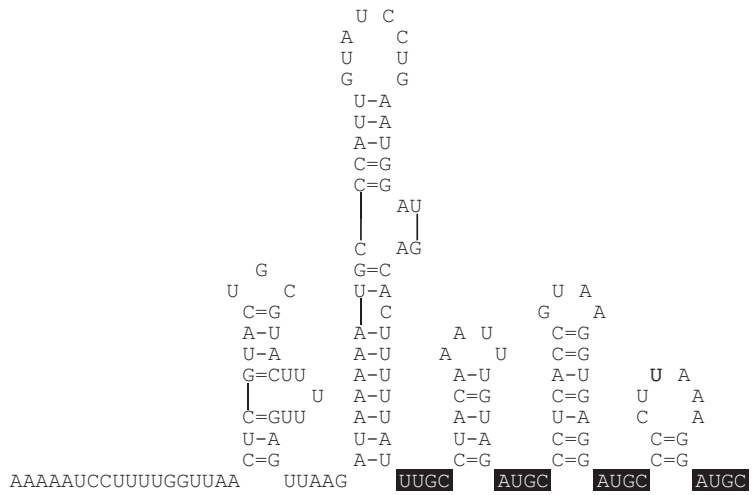

Figure 5 The 3′-untranslated region of RNA1 of ilarviruses contains a repeated (A/U) (U/A/G)GC sequence. These conserved regions are single-stranded motifs (black highlighting) that appear between base-paired stem-loops and are critical for coat protein binding and potentially for replicase binding. The secondary structure of the 3′ terminus of prune dwarf virus RNA1 illustrates the potential stem-loops configuration with intervening conserved single-stranded motifs.

the size of the stem–loop structures vary considerably when all of the ilarviruses are considered. However, within each subgroup of ilarvirus, the overall length and secondary structures of the binding region(s) are well conserved. In the case of TSV, the (A/U) (U/A/G)GC motif is repeated five times flanking four potential stem–loop structures within the 260 nucleotides located at the 3′ terminus of RNA1. This region may represent two coat protein binding sites as has been demonstrated for AMV. Ilarviruses belonging to the subgroups 4, 5, and 6 possess shorter discernable recognition sequences and may contain single coat protein binding sites. Deletion analyses of AMV RNA4 have shown that the first and third 3′-most stem loops are critical for coat protein binding and hence translation, whereas the other stem loops play a role in enhancing efficient transcription but are not strictly required for that function. There is an absolute requirement for the single-stranded (A/U) (U/A/G)GC motifs in virus function.

The role of the RNA–coat protein complex was elucidated through studies with recombinant viruses. The 3′-UTR and its ability to form a complex with coat protein subunits is functionally analogous to a poly-A tail; a poly-A tail of 40–80 residues can experimentally compensate for the absence of activating coat protein molecules. The formation of a RNA–coat protein complex or the addition of a poly-A tail both act to stimulate the translation of viral RNA resulting in the synthesis of proteins needed for virus replication. In eukaryotes, translation efficiency of mRNA is enhanced through the formation of a loop formed by the interaction of a poly-A binding protein (PABP) with poly-A, and then subsequent binding of this complex to the 5′-cap structure of RNA in combination with other cellular initiation factors. It has been suggested that the complex formed between viral RNA and coat protein mimics the complex formed by the PABP and the poly-A tail. This proposal is further strengthened by the observation that the RNA–coat protein complex binds elongation factors associated with cellular mRNA translation. Based on data from AMV, it appears that the binding of coat protein to 3′-terminal sequences of viral RNA not only facilitates translation, but also effectively blocks transcription of the RNA.

The essential complex formation between the coat protein and RNA has been examined in detail to determine critical features of the coat protein. Limited digests indicate that the N-terminus of the coat protein is primarily responsible for RNA binding. Inspection of the amino acid sequences at the N-terminus of the coat protein reveals a high percentage of basic amino acid residues that are consistent with a nucleic acid binding function. More detailed RNA protection assays and competitive binding studies suggest that a consensus sequence represented by (Q/K/R) (P/N)TXRS(R/Q) (Q/N/S) (W/F/Y)A is involved in coat protein binding to the 3′-UTR of AMV and ilarvirus genomic RNA (**Figure 6**). Although this functional domain is not strictly conserved in all ilarviruses, a core motif centered on the critical arginine residue is generally well preserved in all ilarviruses and AMV, suggesting a key role in virus function. Despite significant variation in primary sequence, the striking similarity in protein characteristics across all ilarviruses and AMV may account for the reciprocity in the ability of coat protein from several ilarviruses and AMV to activate the virus genome in heterologous combinations.

In addition to the functional domain of the coat protein described above, additional features of the coat protein may contribute to RNA binding. The critical basic arginine residue and its flanking residues are

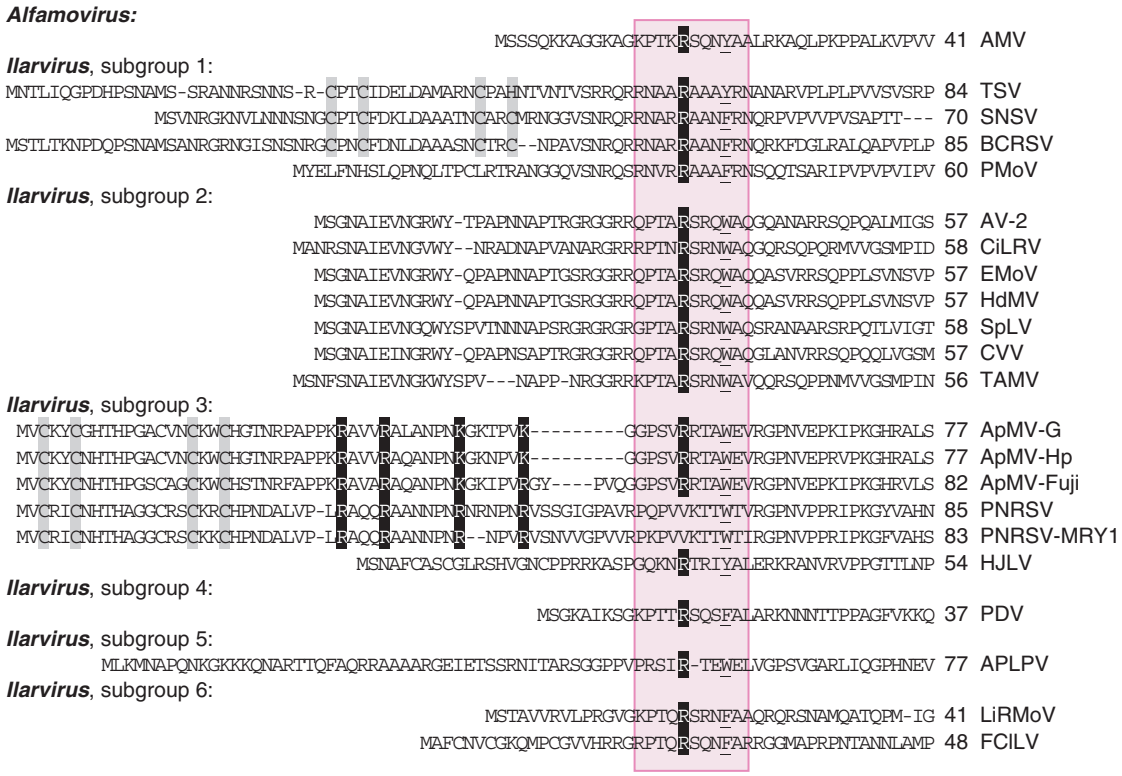

Figure 6 Alignment of the N-terminus of the coat proteins of ilarviruses. The box shaded in red indicates the putative RNA binding region with the consensus sequence (Q/K/R) (P/N)TXRS(R/Q) (Q/N/S) (W/F/Y)A and the central arginine residue highlighted in black. It has been demonstrated that in prunus necrotic ringspot virus, four arginine residues upstream of the conserved binding site are essential for RNA binding; these are highlighted with black, as are comparable residues in the apple mosaic virus coat protein sequence. Members of subgroups 1 and 3 also contain a putative zinc finger that may be involved in RNA binding; the cysteine/histidine residues potentially involved in chelating zinc cations are highlighted in gray. See **Table 1** for abbreviations.

preceded by a putative zinc finger in the coat proteins of members of subgroups 1 and 3, but not in other subgroups of ilarviruses, nor in AMV (**Figure 6**). Zinc fingers are typically involved in nucleic acid binding. Cysteine and/or hisitidine residues are critical elements of the motif represented by $CN_2CN_{10}(C/H)N_2(C/H)$; the cysteine and histidine residues are the functional amino acids capable of chelating zinc cations. The participation or requirement of this putative zinc finger in virus replication is uncertain, particularly since it is not present in all ilarviruses.

The RNA-binding region of the coat protein that is conserved in other ilarviruses appears to be absent or at least highly diverged in PNRSV. In particular, an arginine expected to be critical for RNA binding is absent in the coat protein of PNRSV in this central conserved position, although a basic lysine residue is located nearby. Moreover, electrophoretic shift assay suggests that other basic residues are involved in RNA binding. Four arginine residues of PNRSV coat protein have been experimentally determined to be involved in RNA binding and are located towards the N-terminus of the site of the conserved motif present in other ilarviruses (**Figure 6**). A similar distribution of four basic residues is observed in ApMV in addition to the conserved (Q/K/R) (P/N) TXRS(R/Q) (Q/N/S) (W/F/Y)A motif.

RNA folding predictions suggest that the 3′-UTR of some ilarviruses can fold into complex tRNA-like structures or pseudoknots that do not accommodate coat protein binding. By analogy to information obtained from AMV, the pseudoknot conformation favors transcription and hence synthesis of viral RNAs. Mutational analysis indicates that stem–loop structures located just upstream of the coat protein binding site as well as the ability to form a tRNA-like pseudoknot are required for transcription and synthesis of minus-sense RNA. Thus, the relative abundance of RNA in the pseudoknot conformation relative to that bound to coat protein provides a feedback mechanism to coordinate phases of virus replication. Translation to form nonstructural proteins is favored in the presence of coat protein, while transcription as part of the replication process is favored in the absence of the coat protein.

In addition to a requirement for regulating the use of positive-sense RNA for translation versus transcription, is the requirement for coordinating the rates of synthesis of positive-sense versus minus-sense RNA molecules. The virus replication cycle requires the switch from

minus-sense RNA synthesis to the repetitive transcription into positive-sense progeny viral RNA. The genomic features responsible for this transition are not well understood. However, recent experiments with transformed plants suggest that coat protein is not involved in this process. Secondary structural features of the minus-sense RNAs are believed to regulate the synthesis of plus-sense RNA.

The subgenomic RNA encoding the coat protein, RNA4, is transcribed from a minus-sense copy of RNA3. In brome mosaic virus, the intercistronic region between the ORFs of RNA3 contains a subgenomic promoter region consisting of sequences enriched for A/U flanking the core promoter and a poly-U tract that enhances transcription. However, the intercistronic regions of AMV and the ilarviruses are considerably shorter than that of brome mosaic virus. Moreover, although still slightly enriched in U residues, the poly-U tract and strong bias for U are absent. The transcriptional start site and a strong promoter for the synthesis of positive-sense subgenomic RNA4 occurs immediately 3′ of the position corresponding to the termination codon of ORF3a. The subgenomic promoter of AMV has been characterized; a critical component of the promoter region is a three-nucleotide loop on a base-paired stem that bears a 'bulge' at the fifth nucleotide from the loop along the base-paired stem. The stem sequence below the bulge is less critical for promoter activity. Potential stem–loop structures are evident in the intercistronic regions between ORF3a and ORF3b of ilarviruses and these may fulfill the same critical role as those in AMV and brome mosaic virus.

Based on studies of transgenic plants conducted with AMV, replication of RNA1 and RNA2 are coordinated in that a mutation leading to changes in the encoded protein of either RNA product prevents the replication of both. Moreover, this requirement is for a *cis*-encoded function since transgenic expression of the wild-type protein does not rescue the mutated RNA. In contrast, the replication of RNA3 can be supported by RNA1 and RNA2 gene products expressed in *trans*. This is a critical distinction highlighting the independence of RNA3 replication from that of RNA1 and RNA2. During the natural infection cycle, binding of the coat protein in the inoculum to the 3′ terminus of RNA1 and RNA2 is sufficient to facilitate their translation into a replication complex in the cytoplasm of the infected cell. This is accomplished by the interaction of the coat protein–RNA complex with host initiation factors. However, replication of viral RNA can only be initiated once the coat protein is dissociated from the 3′ of the RNA molecules, allowing the 3′ terminus to assume the tRNA-like pseudoknot conformation. Regulation of this dissociation process is unknown. However, it has been speculated that the association of the replication complex with membrane structures could displace the coat protein, or proteolysis of the coat protein could result in its removal from RNA. Alternatively, the coat protein could be displaced by binding of the replicase to stem–loop structures upstream of the coat protein binding sites. Replication then proceeds through synthesis of minus-sense RNA and the replication of progeny plus-sense RNA segments, including the synthesis of the plus-sense subgenomic RNA encoding the coat protein. It has been demonstrated that both the coat protein and the movement protein are required for systemic infection. It appears that the infective agent moves through modified plasmodesmata as a protein–RNA complex rather than as intact virions.

Epidemiology and Control

One or more modes of transmission have been demonstrated for each member of the genus *Ilarvirus*. All ilarviruses can be transmitted by mechanical inoculation to experimental hosts, although some with difficulty. Ilarviruses tend to have a wide experimental host range, but many have woody plants as their primary natural hosts. The role of mechanical transmission between woody plants is likely small. However, succulent hosts such as hop and asparagus plants may be more prone to field spread through mechanical transmission associated with horticultural practices.

The dissemination of viruses through vegetative propagation is one of the most critical factors affecting the distribution of ilarviruses that infect perennial crops. Budding and grafting are important means of transmission of ilarviruses that infect woody plants such as fruit trees and roses. These plants are routinely budded onto rootstock to allow rapid expansion of a particular clone into hundreds or thousands of plants. Other hosts such as hop or asparagus plants can be vegetatively propagated by stem cuttings and/or crown division. In both cases, there is high likelihood that virus will be present in the progeny plants. Chance grafting of root systems is also an important means of transmission of some viruses of perennial crops.

Many ilarviruses are transmitted through seed when the seed-bearing plant is infected. Transmission of pollen-borne virus occurs to seedlings with variable frequency, and transmission of virus from pollen to the pollinated plant has also been demonstrated for PNRSV, PDV, and TSV. Seed and pollen transmission poses a particularly high risk in fruit trees since seedling rootstocks are frequently used in production and virus infection can originate from the rootstock, the scion, or both. The most effective means of control is through the use of virus-tested material during the establishment of plantings. This approach is implemented through programs where plants are propagated from virus-tested plants and grown under conditions that minimize re-infection by viruses, including the pollen-borne ilarviruses. Many industries rely on

informal virus control programs whereas others have developed official certification programs. The use of spatial separation of the propagation source material from potentially infected host plants is a basic strategy to minimize the introduction of virus through pollen. The risk associated with seed transmission is further reduced by screening samples of seed lots for the presence of virus. Where seed is produced from perennial plants such as *Prunus* species and asparagus, routine virus testing and rouging of mother plantings is implemented to limit the distribution of virus through seed.

The association of virus transmission with pollen raises concern about the role of bees in virus epidemiology. In the case of PNRSV and PDV, it has been shown that the virus is detectable by serological assays on honeybees emerging from hives weeks after exposure to flowers with virus-laden pollen. Pollen from hives is no longer viable at this stage, but the virus is infectious. The ability of this virus to infect trees then depends on whether the virus is transmitted to the tree by fertilization or by some other physical process. This issue remains largely unresolved. Holding bees in hives for several days before allowing them to enter a new orchard has been suggested as one means of minimizing this risk.

It has been demonstrated that TSV is transmitted to natural hosts in a process known to be facilitated by thrips. The thrips species demonstrated to transmit TSV include *Frankliniella occidentalis* (Pergande), *Frankliniella schultzei* (Trybom), *Microcephalothrips abdominalis* (Crawford), *Thrips tabaci* (Lindeman), and *Thrips parvispinus* (Karny). The association of thrips with pollen transmission of TSV is one of the major factors leading to the increased importance of this virus in vegetable production in many areas of the world. The thrips facilitate transmission by mechanical abrasion of the leaf cells, allowing pollen-associated virus particles to enter cells and initiate infection. Pollen-to-leaf transmission has been demonstrated, but leaf-to-leaf transmission has not. There have been many attempts to confirm the role of thrips in the transmission of ilarviruses other than TSV. Other ilarviruses have been transmitted from pollen to the leaves of experimental hosts in a thrips-mediated manner, but transmission to natural hosts by thrips has not been convincingly demonstrated. Unlike AMV, there is no evidence of aphid transmission of any members of the genus *Ilarvirus*.

Most ilarviruses have a limited natural host range. This feature in combination with a narrow temporal window for transmission imposed by the short flowering period of many hosts means that plant-to-plant spread of ilarviruses is relatively slow. TSV is an exception where a wide natural host range sustains sources of infection throughout the year. This may explain the growing impact of TSV on production of vegetables and legumes such as soybean. Agronomic strategies such as removing perennial weeds that would otherwise provide a green bridge for the thrips vectors and the virus has helped reduce the carryover of virus inoculum in a limited number of situations. Since rainfall abates thrips populations, in some areas, sowing seed so that germination will occur during periods of increased rain also helps reduce crop losses caused by TSV. As with the ilarviruses that infect fruit trees and asparagus, the use of certified, virus-tested seed is critical for effective virus control.

Rugose mosaic is a serious debilitating disease of sweet cherry (*Prunus avium* L.) that is caused by a severe strain of PNRSV. The long latent period between infection and visible expression of disease symptoms complicates efficient control strategies. In this case, trees can be inoculated prophylactically with less severe strains of PNRSV. The inoculated plant is then resistant to subsequent infection by the severe virus strain. This phenomenon is termed cross-protection. In combination with accurate diagnosis and prompt inoculum removal, cross-protection is an effective tool in controlling rugose mosaic disease.

Immune Response to Viruses: Antibody-Mediated Immunity

A R Neurath, Virotech, New York, NY, USA

Milestones in History

The primeval notion about immunity to disease arose in Greece about 25 centuries ago from the observation that those who recovered from an apparently contagious disease became resistant to a subsequent similar sickness. The earliest known attempts to intentionally transfer immunity to an infectious disease occurred in China in the tenth century. It involved exposing uninfected people to material from lesions caused by smallpox. This not always successful practice was introduced in the seventeenth century to the Ottoman Empire and subsequently to England and its colonies in North America.

This approach was revolutionized by replacing material from human lesions by that derived from cowpox lesions first in 1774 in England by a farmer, Benjamin Jesty, who used it on his family, and 22 years later by Edward Jenner. Thereafter, the widely used vaccination has been considered as the first example of immunization with a life-attenuated virus. Nevertheless, both the cause of the disease and the success of vaccination remained unexplained.

An understanding started to emerge about a century later when (1) Koch and Pasteur set forth the germ theory of infectious diseases, and Pasteur developed attenuated vaccines against anthrax and rabies; and (2) Von Behring and Kitasato demonstrated that immunity could be transferred by a soluble serum component(s). Several decades later, these components were shown to be antibody immunoglobulins (Heidelberger and Kabat) whose fundamental structure was elucidated by Porter and Edelman in the late 1950s, and further characterized by numerous X-ray crystallography and sequencing studies.

However, several findings indicated that antibodies are not the only mediators of specific immunity. Immune responses corresponding to delayed hypersensitivity and allograft rejections appeared unrelated to the presence of serum antibodies. Immunity could also be transferred by cells from immunized to naive animals (Landsteiner and Chase). It was shown by Gowans and colleagues in 1962 that lymphocytes are essential for immune responses.

Antibodies to very many distinct antigens can be produced upon immunization. Therefore, it was presumed that the diverse antibodies were not preformed but would be generated on demand following antigenic stimuli. In theory, there were two possibilities: that an antigen either directs or selects for the formation of a specific antibody. Further studies fully supported the clonal selection theory (Burnet, Jerne, and Talmage). The repertoire of diverse antibodies undergoing a process of maturation leading to high-affinity antibodies is generated by somatic rearrangements and hypermutation of immunoglobulin genes (Tonegawa).

Although it became evident that both immunoglobulins and cells are essential for immunity, the details of the process whereby antigens and viruses elicit immune responses were contributed to by results of studies in transplantation biology and notably the discovery of the major histocompatibility complex (MHC; HLA molecules on human cells) (Benaceraff, Dausset, and Snell). Their role in presentation of antigen fragments and interactions of specific antibody producing B-cells with T-cells, as well as the function of cytokines, chemokines, and adhesion molecules will be discussed in later sections of this article.

Immunoglobulins, lymphocytes, MHC molecules, and antigen receptors are all components of adaptative (acquired) immunity. Components of innate immunity, responding rapidly to an invading pathogen, play a key role in initiating and orchestrating the adaptive response (Janeway).

The major milestones in the history of immunology and their time lines are summarized in **Table 1**.

Table 1 History of immunology timeline

1798	Smallpox vaccination	Edward Jenner
1876	Validation of germ theory of disease by discovering bacterial basis of anthrax	Robert Koch
1879	Chicken cholera vaccine development	Louis Pasteur
1890	Discovery of diphtheria 'antitoxin' in blood	Emil Von Behring and Shibasaburo Kitasato
1882	Isolation of the tubercle bacillus	Robert Koch
1883	Delayed type hypersensitivity	Robert Koch
1884	Phagocytosis; cellular theory of immunity	Elie Metchnikoff
1891	Proposal that antibodies are responsible for immunity	Paul Ehrlich
1891	Passive immunity	Emil Roux
1894	Complement and antibody activity in bacteriolysis	Jules Bordet
1900	A, B, and O blood groups	Karl Landsteiner
1901	Cutaneous allergic reaction	Maurice Arthus
1903	Opsonization by antibody	Almroth Wright and Stewart Douglas
1907	Discipline of immunochemistry founded	Svante Arrhenius
1910	Viral immunology theory	Peyton Rous
1917	Haptens discovered	Karl Landsteiner
1921	Cutaneous reactions	Carl Prausnitz and Heinz Kustner
1924	Reticuloendothelial system	Ludwig Aschoff
1939	Discovery that antibodies are gamma globulins	Elvin Kabat
1942	Adjuvants	Jules Freund and Katherine McDermott
1942	Cellular transfer of sensitivity in guinea pigs (anaphylaxis)	Karl Landsteiner and Merill Chase
1944	Immunological hypothesis of allograft rejection	Peter Medawar
1948	Demonstration of antibody production in plasma B-cells	Astrid Fagraeus
1949	Distinguishing self vs. nonself and its role in maintaining immunological unresponsiveness (tolerance) to self	Macfarlane Burnet and Frank Fenner
1952	Discovery of agammaglobulinemia (antibody immunodeficiency)	Ogden Bruton
1953	Immunological tolerance hypothesis	Rupert Billingham, Leslie Brent, Peter Medawar, and Milan Hasek
1955–59	Clonal selection theory	Niels Jerne, David Talmage, and Macfarlane Burnet
1957	Discovery of interferon	Alick Isaacs and Jean Lindenmann
1958	Identification of first autoantibody and first recognition of autoimmune disease	Henry Kunkel
1959–62	Elucidation of antibody structure	Rodney Porter and Gerald Edelman
1959	Lymphocytes as the cellular units of clonal selection; discovery of lymphoid circulation	James Gowans
1961	Discovery of thymus involvement in cellular immunity	Jacques Miller
1968	Recognition of B- and T-cells in immunodeficiencies	Robert Good
1968	Distinction of bone marrow- and thymus-derived lymphocyte populations; discovery or T- and B-cell collaboration	Jacques Miller and Graham Mitchell
1965	Demonstration of allelic exclusion in B-cells	Benvenuto Pernis
1968–70	Elaboration of two-signal model of lymphocyte activation	Peter Bretscher and Melvin Cohn
1970	Discovery of membrane immunoglobulins	Benvenuto Pernis and Martin Raff
1971	Recognition of hypervariable regions in Ig chains	Elvin Kabat
1972	Elucidation of the major histocompatibility complex	Baruj Benacerraf, Jean Dausset, and George Snell
1974	Discovery of MHC restriction	Rolf Zinkernagel and Peter Doherty
1974	HLA-B27 predisposes to an autoimmune disease	Derek Brewerton
1975	Monoclonal antibodies used in genetic analysis	Georges Kohler and Cesar Milstein
1976	First demonstration of cross-priming	Michael Bevan
1978	Direct evidence for somatic rearrangement in immunoglobulin genes	Susumu Tonegawa
1978	Recognition that dendritic cells are distinctive and highly potent antigen-presenting cells	Ralph Steinman
1979	Discovery of leukocyte adhesion molecules and their role in lymphocyte trafficking	Eugene Butcher
1984–87	Identification of genes for the T-cell antigen receptor	Mark Davis, Leroy Hood, Stephen Hedrick, and Gerry Siu
1987	Crystal structure of MHC peptide solved	Pam Bjorkman, Jack Strominger, and Don Wiley
1989	Emerging field of innate immunity, infectious nonself model of immune recognition ('stranger hypothesis')	Charlie Janeway

Immunoglobulin Phylogeny

The adaptive immune system, based on clonally diverse repertoires of antigen recognition molecules, arose in jawed vertebrates (gnasthostomes) about 500 million years ago. Homologs of human immunoglobulins, T-cell antigen receptors (TCRs), MHC I and MHC II molecules, and recombination activating genes (RAGs) have been identified in all classes of gnasthostomes. This has provided evolutionary advantages allowing the recognition of potentially lethal pathogens, including viruses, and the initiation of protective responses against them (**Figure 1**), and represented an add-on to a preexisting innate immune system. For immunoglobulins, somatic variation was further expanded through class switching, gene conversion, and somatic hypermutation. Jawless vertebrates (agnathans) were shown to also have an adaptive immune system based on recombinatorial assembly of genetic units different from those of gnasthostomes, to generate a diverse repertoire of lymphocytes, each with distinct receptors (**Figure 2**). The assembly relies on highly variable leucine-rich repeat (LRR) protein modular units.

Most gnasthotomes generate a large part of their immunoglobulin diversity in ways similar to those in humans. However, exceptions have occurred. Two of these, relevant to passive immunotherapy and development of diagnostics using the corresponding immunoglobulins, are mentioned here. (1) Only three classes of H-chain genes, corresponding to IgM, IgY, and IgA, exist in chicken. Class switching occurs from IgM to either IgY or IgA. IgY is considered to be the ancestor of 'present-day' IgG and IgE. Unlike human IgG, IgY does not bind to cellular Fc receptors and to proteins A and G, respectively, and does not activate the complement system. (2) H-chain antibodies devoid of light chains occur in the Camelidae species (camels, dromedaries, and llamas). Single-domain fragments from such antibodies react with specific antigens with high affinity constants (nanomolar range). The binding involves longer than average third variable loops of the antibody molecules. These unique antibodies and their antigen-specific fragments are expected to become important for biotechnological and medical applications, including intrabodies (intracellular antibodies).

Innate Immunity

The innate immune system provides an early defense against pathogens and alerts the adaptive immune system when initial invasion by a pathogen has occurred. The innate system predates evolutionarily the adaptive system and relies on antimicrobial peptides and on germline-encoded pattern-recognition receptors (PRRs). Antimicrobial peptides can damage enveloped viruses and interfere with processes involved in fusion of viruses with target cell membranes. PRRs recognize microbial (viral) components defined as pathogen-associated molecular patterns (PAMPs). Different PRRs are specific for distinct PAMPs, have distinct expression patterns, activate different signaling pathways, thereby eliciting distinct responses against invading pathogens. PRRs can be subdivided into two classes: Toll-like receptors (TLRs) and non-Toll-like innate immune proteins.

Toll was originally identified as a differentiation protein in *Drosophila*, and later (1996) shown to play a role in defense against fungal infection. Searching the entire DNA sequence database for similarities with the coding sequence for *Toll* resulted in identification of Toll-like sequences, and ultimately in discovery of at least 10 functional TLRs in humans. TLRs are type 1 integral membrane glycoproteins the extracellular domain of which contains several LRR motifs and a cytoplasmic signaling domain homologous to that of the interleukin-1 receptor (IL-1R). TLRs 2, 3, 4, 7, 8, and 9 recognize PAMPs characteristic for viruses. Viral DNAs rich in CpG motifs are recognized by TLR9, leading to activation of pro-inflammatory cytokines and type 1 interferon (IFN) secretion. TLR7 and TLR8, expressed within the endosomal membrane, are specific for viral single-stranded RNA (ssRNA). Double-stranded RNA (dsRNA), generated

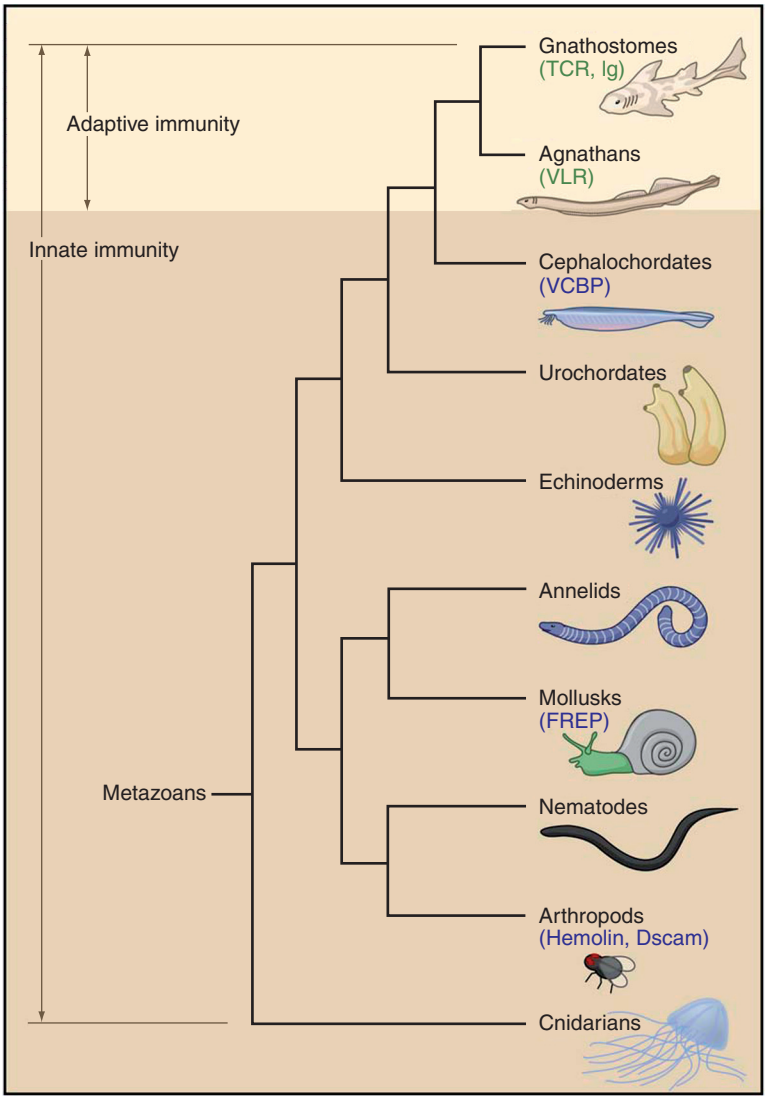

Figure 1 Phylogenetic tree indicating theoretical evolutionary relationships of metazoans and the emergence of adaptive immunity in conjunction with innate immunity. Families of immune molecules, other than Toll-like receptors (TLRs), are indicated in blue: chitin-binding domain-containing proteins (VCBPs), fibrinogen-related proteins (FREPs), hemolin and Down's syndrome cell adhesion molecule (Dscam). The recombinatorial based immune receptors are indicated in green: T-cell receptors (TCRs), immunoglobulins (Ig's), and variable lymphocyte receptors (VLRs). during viral infection as an intermediate for ssRNA viruses or during transcription of viral DNA, is recognized by TLR3. TLR3 is expressed in dendritic cells (DCs) and in a variety of epithelial cells, including airway, uterine, corneal, vaginal, cervical, biliary, and intestinal cells. Cervical mucosal epithelial cells also express functional TLR9, suggesting that TLR3 and TLR9 provide an antiviral environment for the lower female reproductive tract. Some viral envelope glycoproteins are recognized by TLR2 and TLR4, each expressed at the cell surface, leading to production of pro-inflammatory cytokines. In general, the engagement of TLRs by microbial PAMPs triggers signaling cascades leading to the induction of genes involved in antimicrobial host defenses. This includes the maturation and migration of DCs from sites where infection occurs to lymphoid organs where DCs can initiate antigen-specific immune responses. Triggering distinct TLRs elicits different cytokine profiles and different immune responses. Engagement of TL3 and TRL 4, respectively, upregulates polymeric immunoglobulin receptor expression on cells. Thus, bridges between innate and adaptive immune responses are established.

TLRs are expressed either at the cell surface or in lysosomal/endosomal membranes. Therefore, they would

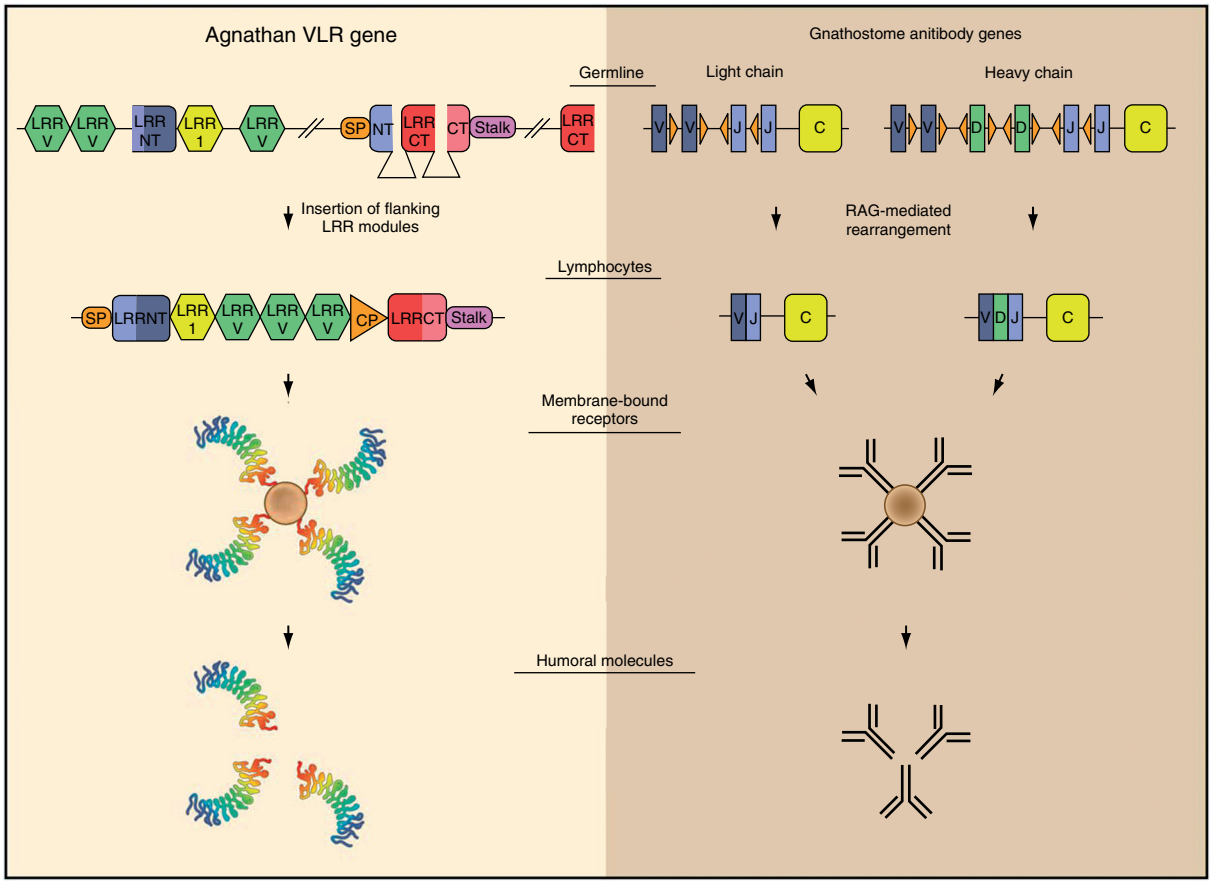

Figure 2 Two recombinatorial systems used for generating diverse antigen receptors in vertebrates. The figure compares the assembly of leucine-rich repeat (LRR) modular genetic units in agnathan lymphocytes to generate variable lymphocyte receptor (VLR) genes vs. the rearrangement of Ig gene segments in gnathostome B-lymphocytes to generate diverse antibody genes. Variable 24-amino-acid LRR (LRRV, green); N-terminal capping LRR (LRRNT, blue); variable 18-amino-acid LRR (LRR1, yellow); signal peptide (SP, orange); first six amino acids of LRRNT (NT, light blue); C-terminal capping LRR (LRRCT, red); last nine amino acids of LRRCT (CT, pink); variable 13 amino acid connecting peptide (CP, orange); and invariant VLR stalk (Stalk, purple). The small orange triangles adjacent to the representative V (blue), D (green), and J (light blue) gene segments represent recombination signal sequences (RSSs). The C (yellow) indicates the immunoglobulin constant region. Reproduced from Cooper MD and Alder N (2006) The evolution of adaptive immune systems. *Cell* 124: 815–822, with permission from Elsevier.

not recognize pathogens that succeeded in invading the cytosolic compartment. These pathogens are detected by a variety of cytoplasmic PRRs. They include retinoic acid inducible protein (RIG-1) with a helicase domain recognizing viral dsRNA, and a related protein, MDA5. Other proteins which may be involved in innate antiviral immunity include a triggering receptor on myeloid cells (TREM-1), myeloid C-type lectins and siglecs, recognizing sialic acid. One of the elements of both innate and adaptative immunity is the complement system. Some viruses or virus-infected cells can directly activate the complement cascade in the absence of antiviral antibodies.

Many viruses are endowed with properties subverting innate immune responses. Vaccinia virus produces proteins suppressing TLR- and IL-1R-induced signaling cascades. Paramyxoviruses produce proteins which associate with MDA5, and thus inhibit dsRNA-induced activation processes. Adenoviruses avoid immune surveillance by TRL9. A nonstructural protein of hepatitis C virus blocks signaling by RIG-1 and MDA5. Marburg and Ebola viruses, members of the family *Filoviridae*, elicit direct activation of TREM-1 on neutrophils. This can lead to vigorous inflammatory responses contributing to fatal hemorrhagic fevers in infected humans. Thus, some viruses have developed strategies to overcome either innate or adaptive (see next section) immune responses.

Adaptive Immunity

Adaptive immunity is a complex anticipatory system triggered by exposure to antigens, including viruses. Its hallmarks are selectivity, diversification, specificity, and memory. The principal effector molecules of the system

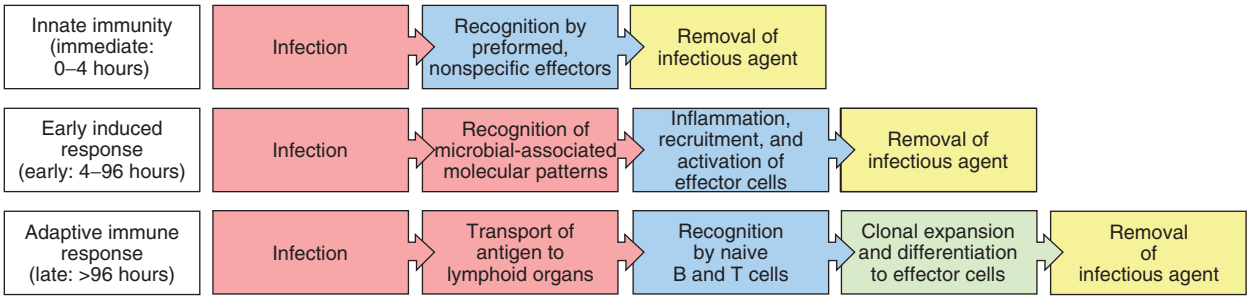

Figure 3 Three phases of a response to an initial infection. Copyright 2005 from Janeway CA, Jr., Travers P, Walport M, and Shlomchik MJ (2005) *Immunobiology*. *The Immune System in Health and Disease*, 6th edn, figure 2.1, p. 37. New York: Garland Science. are antigen-binding receptors (immunoglobulin (Ig) and T-cell receptors (TCR)). The following simplified overview (see **Figure 3**) will be limited to Ig's and humoral immune responses.

Differentiation of B-cells into antibody-generating plasma cells occurs through distinct pathways. Two pathways lead to rapid IgM and IgA antibody production by B-1 cells against T-cell-independent antigens. These antibodies have low antigen-binding constants, and immunological memory does not evolve. The third pathway involves clonal selection. The B-cells synthesize IgM and IgD low affinity antibodies which are expressed as antigen receptors on the surface of cells. Each B-cell produces a different receptor recognizing a distinct epitope. Encounter with the appropriate epitope on an antigen elicits cell division, and generation of selected clones with identical receptor specificities. The clones further differentiate into specific antibody-secreting cells. The remarkable diversity of antibodies is attributable to the fact that genes coding for Ig variable regions are inherited as sets of gene fragments, each encoding a portion of the variable region of a particular Ig polypeptide chain. The fragments are joined together to form a complete gene in individual lymphocytes. The joining process involves addition of DNA sequences to the ends of fragments to be joined, thus increasing diversity. Further diversity arises from the assembly of each Ig protein from pairs of H- and L-chains, each B-cell producing only one kind of either chain (**Figure 4**). In addition, the assembled genes for Ig's mutate rapidly when B-cells are activated by binding an antigen. These hypermutations lead to new receptor variants representing the process of affinity maturation of an immune response. Moreover, B-cells and their progeny can produce an additional variation by altering the constant part of the H chain due to gene rearrangements (=Ig isotype and subclass switching) (**Figures 5–7**). These antibodies have identical paratopes but distinct effector functions (complement activation, phagocytosis, transcytosis, etc.). As a consequence of the aforementioned processes, there are B-lymphocytes of at least 100 million distinct specificities in every human individual at any given time.

The majority of Ig is produced in mucosa-associated tissues, predominantly in the intestine, rather than in the bone marrow, spleen, and lymph nodes, in the form of IgA. This harmonizes with the fact that mucosal surfaces represent the predominant sites for entry of pathogens, including viruses. Coincidentally, it has been demonstrated that the gut is the major site for HIV-1 replication and depletion of CD4+ cells. There are two subclasses of IgA, IgA1 and IgA2, which occur in monomeric, dimeric, tetrameric, and polymeric (pIgA) forms. A distinguishing feature of secretory IgA is its association with another glycoprotein, the secretory component (SC) (**Figure 8**). SC is also the extracellular portion (which can be generated by proteolytic cleavage) of an integral epithelial cell membrane protein, the polymeric Ig receptor (pIgR) mediating transcytosis of pIgA and IgM. The latter process allows neutralization of pathogens within intracellular vesicular compartments.

An essential aspect of adaptive immunity is its ability to recall past encounters with a pathogen for decades or even an entire lifetime. This fundamental feature is the foundation of successful vaccination. Germinal center-derived memory B-cells have the following attributes: antigen specificity; hypermutated Ig variable gene segments; and ability to bestow immunological memory following their adoptive transfer to immunologically naïve recipients. The CD27 surface antigen is a marker for memory B-cells.

The multifaceted performance of B-cells is the result of a thoroughly orchestrated ensemble involving CD4+ helper T-cells, DCs, MHC class II antigens, cell-differentiation antigens (CDs), cytokines, etc. In summary, in addition to occupancy of the Ig receptor, B-cells must interact with antigen-specific T-cells. The T-cells, through specific TCRs, recognize peptide fragments generated from the antigen internalized by the B-cell, and displayed on the surface of the B-cell as a peptide–MHC class II complex.

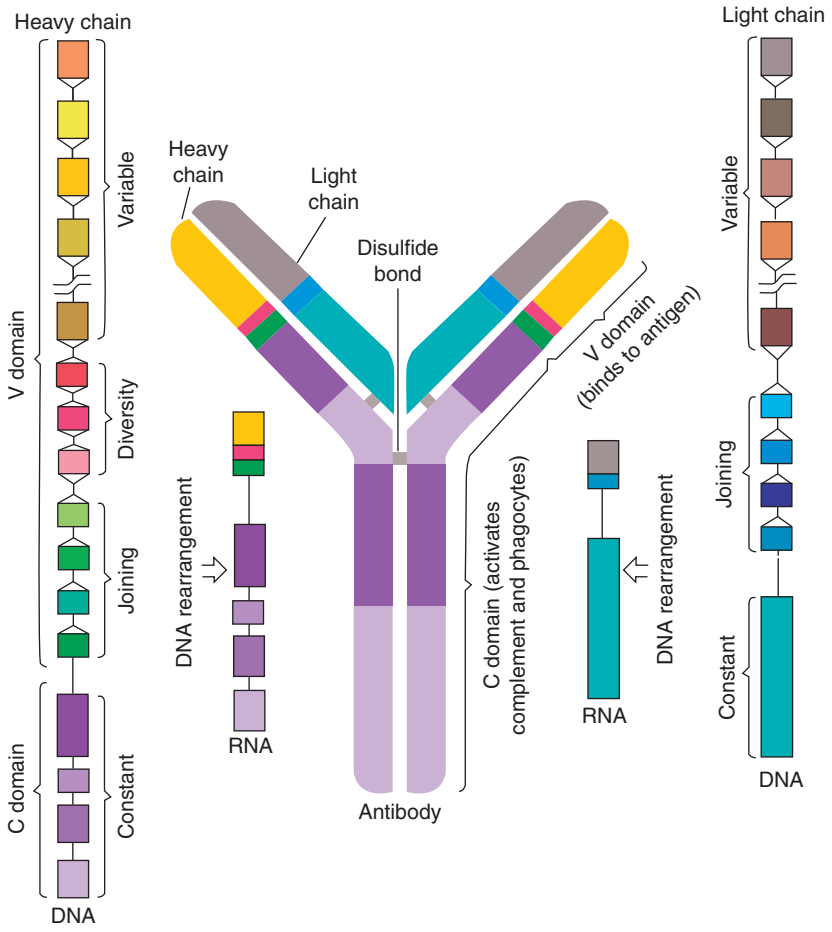

Figure 4 Antibody molecule consisting of pairs of H- and L-chains each encoded by genes assembled from different DNA segments. The segments rearrange to generate genes for chains that are distinct in each B-cell. The joining is variable so that the gene segments can encode the estimated 100 million specific antibodies each human is capable of producing. Reprinted from Janeway CA, Jr. (1993) How the immune system recognizes invaders. *Scientific American* (Sep.): 73–79, with permission of Scientific American and Ian Worpole (artist).

Helper T-cells stimulate the B-cell following binding of the CD40 ligand on the T-cell to CD40 on the B-cell; the interaction of tumor necrosis factor (TNF)–TNF receptor family ligand pairs; and the release of specific cytokines. Further details of these interactions are shown in **Figures 9–11**.

The intricacies of all these tightly coordinated events seem to minimize the possibility that 'rationally designed' synthetic vaccines will be able to successfully recreate the specificity of virus neutralization B-cell epitopes or neotopes.

Biological Functions of Antiviral Antibodies

The surface of viruses is represented by a mosaic cluster of protein or glycoprotein subunits. The subunits correspond to a single or two or more species. The pattern of repetitiveness is usually a key factor responsible for the efficiency of early and rapid B-cell responses, potent IgM antibody production, and efficient downstream antibody class switching. However, the immune response is not restricted to antigenic sites (epitopes and neotopes) on the surface of viruses. Virus particles, following initial infection or provided as a vaccine, also separate into constituent parts. Consequently, unassembled surface subunits (their epitopes and cryptotopes) and internal virus components become exposed to the immune system, ultimately resulting in the production of antibodies having multiple specificities. Only some of these are directed against intact viruses, and may have virus-neutralizing properties. The formation of antibodies with distinct specificities may not be simultaneous but rather sequential. Especially in case of some not directly cytopathic viruses (hepatitis B and C, lymphocytic choriomeningitis,

and HIV-1, prone to elicit a chronic carrier state), virus-neutralizing antibodies (VNAbs) appear with a delay after non-neutralizing antibodies. The latter may function as a 'decoy' if they are targeted like VNAb to virus surface epitopes.

Virus-Neutralizing and Protective Antibodies

VNAbs are crucial for protection against reinfection by a virus the VNAbs are specific for. Protection by efficacious vaccines correlates closely with *in vitro* determined VNAb titers of sera from immunized individuals. Protection by passive immunization relies on VNAb recognizing neutralization epitopes (or neotopes) on the virus surface. Coating of virus particles by antibodies is necessary but not always sufficient for virus neutralization. The effectiveness of virus neutralization correlates with the rate of antibody binding to critical epitopes and is augmented by slow dissociation of the formed antigen–antibody complexes. These kinetic parameters can be determined experimentally.

Spatial adaptive complementarity, electrostatic interactions, hydrogen bonds, and van der Waals forces contribute to the binding. Experimentally determined virus neutralization can depend on the target cells used. Virus neutralization is a multihit process and is successful when the number of unencumbered viral molecules, essential for initiation of the virus replicative cycle, is brought below a minimum threshold level. The mechanism of neutralization depends on processes obligatory for reproduction of a particular virus, and may involve the following steps: attachment to cell receptors; post-attachment events, internalization (endocytosis); fusion with cell

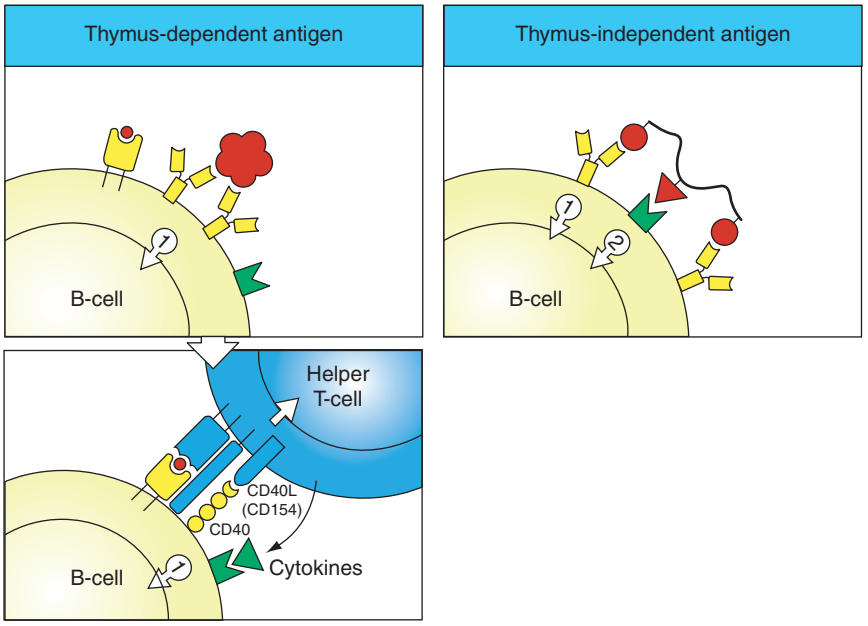

Figure 9 T-helper-cell-dependent initiation of the humoral immune response (two left panels). The first signal required for B-cell activation is delivered by binding of antigen (virus) (large red particle) to Ig cell receptors corresponding to monomeric IgM. Internalization and degradation of the antigen, and complex formation of the resulting peptide(s) (small red circle) with MHC class II molecules on the B-cell, allow the second signal to be delivered, that is, by the interaction between CD40 on the B-cell and the CD40 ligand (=CD154) on the CD4+ helper T-cell, and the engagement of the T-cell receptor (TCR) with the peptide-MHC class II complex on the B-cell. The activation is promoted by binding of cytokines to their specific receptors (see **Figure 10**). For comparison (right panel), in case of T-helper-cell-independent antigens, the second signal can be delivered by the antigen itself, either through binding of a part of the antigen to a receptor of the innate immune system (e.g., TLRs; green), or by extensive cross-linking of the membrane IgM by a polymeric antigen. Copyright 2005 and permission as shown in legend for **Figure 3** (source figure 9.2).

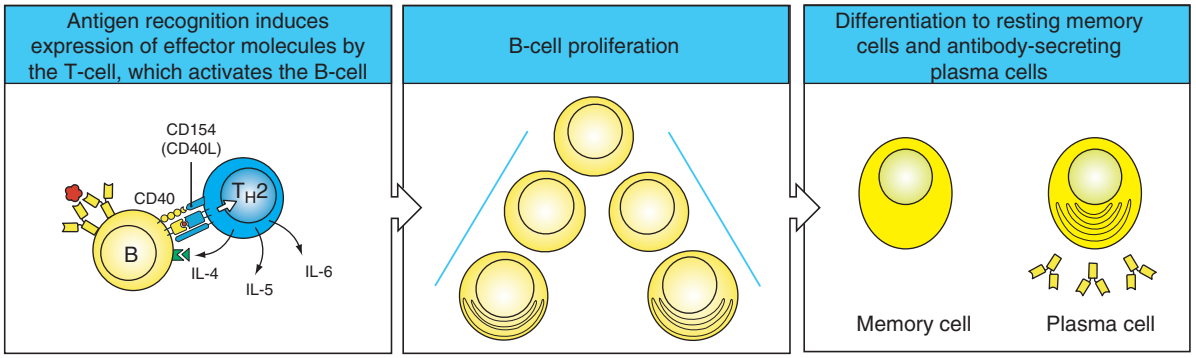

Figure 10 Antigen recognition induces the expression of B-cell stimulatory interleukins IL-4, IL-5, and IL-6 (and/or others) by the T-cell, driving the proliferation and differentiation of B-cells into antibody-secreting plasma cells. Activated B-cells can alternatively become memory B-cells. Copyright 2005 and permission as shown in legend for **Figure 3** (source figure 9.3).

membranes or endosomal vesicles; uncoating and/or intracellular localization; and enzymatic activities (e.g., transcription). Direct occupancy by VNAb of cell receptor binding sites on the virus surface might not be obligatory for neutralization. Steric hindrance or induction of deleterious conformational changes may be sufficiently effective. A unique feature of several anti-HIV-1 human monoclonal VNAb, having distinct specificities, is a very long finger-like third complementarity determining region of the immunoglobulin heavy chain allowing access to a recessed critical site on HIV-1 gp120. Such feature is rare in the human immunoglobulin repertoire but is common in the Ig's of Camelidae.

The mechanism and magnitude of VNAb neutralizing effects are influenced by their immunoglobulin isotype and subtype which affect interactions with complement,

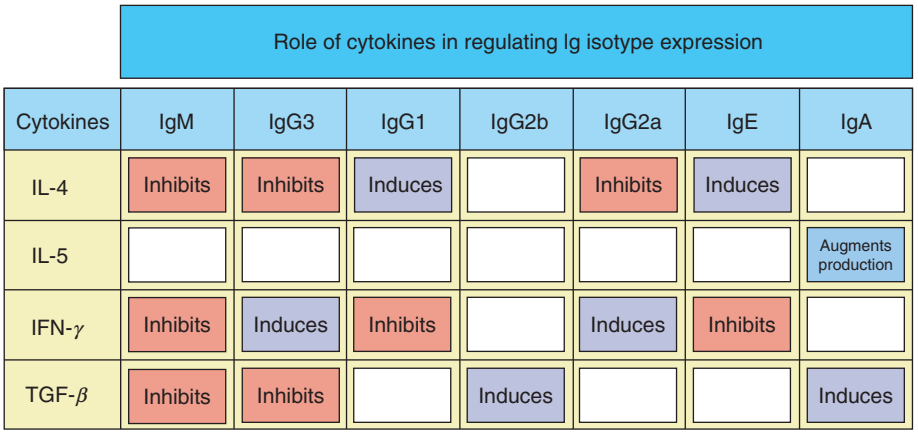

Figure 11 Role of cytokines in regulating Ig isotype switching. The individual cytokines either induce (violet) or inhibit (red) the production of particular Ig isotypes. IFN, interferon; TGF, transforming growth factor. Copyright 2005 and permission as shown in legend for **Figure 3** (source figure 9.7).

Fc receptors, and transcytosis through mucosal epithelia. Non-neutralizing virus-surface-binding antibodies sometimes enhance the effectiveness of VNAb, limit viral spread in the early phases of infection, and contribute to its suppression through antibody-mediated cellular cytotoxicity (ADCC). Antibodies directed to epitopes (or neotopes) on distinct surface proteins may act synergistically in virus neutralization.

The principle that VNAbs specific for virus surface components provide protection against disease is not absolute. The flavivirus nonstructural protein NS1 elicits a protective immune response against yellow fever, dengue, and tick-borne encephalitis viruses. The paratope binding site containing F(ab′)2 fragments are ineffective. Thus the immunoglobulin Fc portion is obligatory for the protective effect.

Antibody-Dependent Enhancement of Viral Diseases

Some viruses make use of antiviral antibodies to gain entry into target cells thus widening cell receptor usage to initiate infection. The infectious virus–antibody complexes rely upon the Fc portion of IgG antibodies to gain entry into monocytes/macrophages and granulocyte through Fc (FcR) or complement receptors (CR) expressed on these cells.The characteristic feature of the viruses is their propensity to establish persistent infections and their antigenic diversity. Antibody-dependent enhancement (ADE) has been demonstrated to occur *in vitro* with members of the families *Bunyaviridae*, *Coronaviridae*, *Flaviviridae*, *Orthomyxoviridae*, *Paramyxoviridae*, *Retroviridae*, *Rhabdoviridae*, and *Togaviridae*. A link between *in vitro* ADE and clinical manifestations cannot be always established. A relationship between ADE and disease exacerbation has been observed for dengue, measles, yellow fever, and respiratory syncytial viruses (RSVs). ADE may occur in children infected at a time when the level of transferred maternal antiviral antibodies declines to insufficient levels. ADE could represent an obstacle for development of vaccines, as has been the case for anti-RSV vaccines. A vaccine consisting of formaldehyde-treated measles virus hemagglutinin (ineffective to elicit antibodies to the virus fusion protein) induced antibodies causing ADE and led to aggravated atypical disease following infection with measles virus.

FcR- and CR-independent ADE was shown to occur following binding to HIV-1 of antibodies eliciting conformational changes in the gp120 envelope glycoprotein, allowing direct virus binding to cellular co-receptors while bypassing the primary binding to the primary CD4 cell receptor.

Immune System Evasion by Viruses

Persistence in an infected host and repeated reactivation of many viruses rely on several specific evasion strategies of adaptive immunity. Thus common protective responses are redirected or altered to the advantage of the infectious agent. This includes antiviral antibody responses and involves (1) specific paratope–epitope interactions (Fab fragments) and (2) effector mechanisms mediated by the Fc portion of antibodies.

The first mechanism is provided by genetically determined amino acid replacements leading to changes of virus epitopes (or neotopes) involved in virus neutralization. The sites of these escape mutations are usually on the viral surface, result in structural changes in antibody/virus contact sites, and lead to much less favorable kinetic parameters for antibody binding or completely abrogate binding. Presentation of new glycan chains on enveloped viruses or elimination of these chains due to mutations of N-glycosylation sites may cause substantial epitope alterations. The rate of escape mutation appearance is promoted

by error-prone replication of the viral genome. Antibodies with new specificities must be produced to bring the mutant viruses under control. The process is repeated, and if not successful, persistent infection is established. A similar process leads to evasion from T-cell-mediated protective responses.

Secondly, several viruses bypass clearance processes facilitated by the Fc portion of bound antibodies by encoding and expressing Fc receptor analogs. Subversion of the complement cascade provides another way how to block clearance of cell-free virus and infected cells.

Additional scenarios for escaping immune surveillance include: interference with MHC class I restricted antigen presentation involving also inhibition of MHC class I cell surface expression or synthesis of viral MHC class I homologs; blocking MHC class II restricted antigen presentation; downregulation of cellular CD4 or its degradation; interference with cytokine effector functions; and other strategies.

Immunoglobulins for Passive Immunization against Human Viruses

Transfer of immunity from an immune donor to an unprotected recipient by serum is one of the early landmarks in the history of immunology (Von Behring). The active serum components have later been identified as immunoglobulins. The half-life of immunoglobulin isotypes in serum is 6–21 days (**Figure 5**). Consequently, administered antivirus immunoglobulins can provide only short term prophylactic and therapeutic benefits, respectively, unless they are administered repeatedly or incorporated into a slow-release medical device. The most common applications are pre-exposure (travel, protection against community-wide infection(s), medical professionals, immunosuppressed individuals, combination with live vaccines to minimize their potential side effects) and post-exposure prophylaxis (passive immunization may provide immediate protection while the benefits from vaccination are delayed). Local mucosal applications of immunoglobulins 'as needed' appear promising against perinatal and sexual transmission, respectively, of several viruses (e.g., herpesviruses and HIV-1).

The immunoglobulins are isolated from serum of individuals pre-screened for high levels of antibodies against a particular virus or from vaccinated individuals. The immunoglobulins are purified, treated to remove or inactivate infectious agents which might be present in the pooled serum source, notwithstanding rigorous screening of the individual sera entering the pool. The products are further processed depending on their intended intramuscular or intravenous applications. All these immunoglobulins are polyclonal with respect to the 'indicated' virus and contain other antibodies originally present in the pooled sera. Oral administration of antibodies produced in bovine colostrums or chicken yolk has been recently suggested.

Alternatively, monoclonal antibodies (mAbs) specific for epitopes, known to elicit virus-neutralizing and protective immune responses, are used. They are prepared using hybridoma technologies, immortalized human peripheral B-cells, transgenic mice and bacteriophage expression libraries. If derived from animal species, the mAbs are 'humanized' using recombinant DNA techniques by replacing amino acid sequences outside the antigen-binding sites with sequences corresponding to human immunoglobulins. By an *in vitro* directed evolution process allowing manipulation of antigen-binding kinetics, mAb variants having much faster antigen association rates and much slower dissociation rates can be produced. Such antibodies have a much improved capacity to neutralize the target virus and may have a great clinical potential. Their production in high yield in plants offers an economically advantageous approach applicable to both IgG and secretory IgA antibodies.

While polyclonal antibodies from human sera provide immunological diversity, mAbs are highly specific for a single virus epitope. Potential alterations of such epitopes may generate virus neutralization escape mutants and decrease or eliminate the effectiveness of mAb prophylactics/therapeutics. Polyclonal antibody preparations prepared from pooled sera are not uniform and vary with the source of serum pools.

This problem can be overcome by the development of human recombinant antigen-specific polyclonal antibodies by a novel Sympress technology (Symphogen, Lyngby, Denmark).

Immunoglobulins, either already in clinical use or in development, are directed against one of the following viruses: hepatitis A and B; cytomegalovirus; rabies; respiratory syncytial virus; smallpox; vaccinia; varicella zoster; measles; mumps; rubella; parvovirus B19; Epstein–Barr virus; herpes simplex; tick-borne encephalitis; poliovirus; Hantavirus; West Nile virus; rotavirus; poliovirus; HIV-1; Ebola virus; and severe acute respiratory syndrome-associated coronavirus.

Unlike vaccines, passive immunization can rapidly deliver protective levels of antibodies directly to susceptible mucosal sites where many virus infections are initiated. Secretory IgA because of its polyvalency and relative stability may have advantages over IgG for passive immunization at these sites.

Antibodies function also as immunomodulators which can bridge innate and acquired, and cellular and humoral immune responses, respectively. Infected host cells can be targeted by linking anticellular toxins to antiviral antibodies or by bispecific antibodies in which one Fab fragment of the antibody is virus specific and the other one recognizes a host cell component or receptor.

Research on antibody-mediated immunity and understanding of antibody-based prophylaxis and therapies for virus diseases have provided a foundation for research on and development of antivirus vaccines.

Vaccines against Human Viral Diseases

Vaccination is the most successful medical intervention against viral diseases. Vaccines prevent or moderate illnesses caused by virus infection in an individual and prevent or diminish virus transmission to other susceptible persons, thus contributing to herd immunity. This effect is expected to be long term, depends on establishment of immunological memory at both the B- and T-cell levels, and may require consecutive or repeated vaccinations. The effectiveness of vaccination might be diminished or compromised for viruses occurring in the form of simultaneous quasi-species or undergoing time-dependent changes of antigenic properties (antigenic drift and antigenic shift). However, in some cases, vaccination predisposes to aggravated disease elicited by infection with a virus identical or related to that used for vaccination, that is, antibody enhancement of virus infection occurs (dengue and respiratory syncytial viruses and HIV-1).

The following categories of vaccines can be distinguished (**Table 2**): (1) live attenuated; (2) whole virus (inactivated); (3) glycoprotein subunit vaccines; and (4) protein vaccines based on recombinant DNA technologies. One vaccine in category (3), hepatitis B surface antigen (HBsAg), is derived from plasma of hepatitis B virus carriers. It is remarkable that vaccines in categories (3) and (4) correspond to multi-subunit self-assembled particles having antigenic specificities closely similar or identical to those expressed on the surface of virus particles. On the other hand, individual virus protein or glycoprotein subunit molecules or their peptide fragment have been less suitable candidates for vaccine development because of insufficient similarities with intact viruses.

Table 2 Past and present vaccines against human viral diseases

Live attenuated	*Killed whole virus*	*Glycoprotein subunit*	*Genetically engineered*
Influenza (nasal)	Influenza	Influenza	Papillomavirus
Rabies	Rabies	Hepatitis B	Hepatitis B
Poliovirus	Poliovirus		
Yellow fever	Japanese encephalitis		
Measles	Tick-borne encephalitis		
Mumps	Hepatitis A		
Rubella			
Adenovirus			
Varicella zoster			
Rotavirus			
Smallpox (vaccinia)			

Vaccine formulations require the incorporation of an immunological adjuvant to enhance their immunogenicity. Adjuvants are designed to optimize antigen delivery and presentation, enhance the maturation of antigen-presenting dendritic cells, and induce immunomodulatory cytokines.

Currently, most vaccines are administered parenterally using syringes with needles.The procedure is disliked by many, and is questionable for mass vaccination programs in developing countries. Therefore, efforts are being made to produce vaccines which can be delivered onto mucosal surfaces, that is, mostly orally or nasally. In addition, high-workload needle-free injection devices are being developed. At this juncture, the bifurcated needle, developed by Benjamin Rubin over 40 years ago, must be mentioned. It proved to be essential for the successful campaign to eradicate smallpox worldwide.

Veterinary Vaccines

The development and use of veterinary vaccines has the following aims: cost-effective prevention and control of virus diseases in animals; induce herd immunity; improve animal welfare and food production for human consumption; decrease the usage of veterinary drugs, thereby minimizing their environmental impact and food contamination; and decrease the incidence of zoonoses (e.g., infections by avian influenza, rabies, West Nile, Rift Valley fever viruses, respectively).

Research, development, and production of some veterinary vaccines have been on the forefront of the general field of vaccinology. The foot-and-mouth disease virus vaccine was the first one produced at an industrial scale (Frenkel method). A vaccinia-rabies virus G protein recombinant vaccine was among the first biotechnology-based vaccines licensed. The world's first DNA vaccine (against West Nile virus in horses) was approved by the US Department of Agriculture in July 2005. DIVA (Differentiating Infected from Vaccinated Animals; also termed marker) veterinary recombinant vaccines and companion diagnostic tests have been developed. They can be applied to programs to control and eradicate virus infections. These are examples to be considered for the development of human vaccines. The latter will require rigorous evaluations for safety and efficacy which are more difficult to obtain than in veterinary settings. A list of licensed veterinary vaccines is shown in **Table 3**.

Glossary

Antigen presentation The process by which proteins are degraded into peptides that are loaded onto MHC molecules and these complexes are targeted to the cell surface.

Central-memory T cell A population of memory T cells which primarily reside in secondary lymphoid organs; characterized by the expression of CD62L and CCR7.

Chemokines Chemotactic cytokines which stimulate the migration of cells.

Cytokines Secreted proteins that regulate cellular actions by signaling via specific receptors.

Cytotoxic T lymphocyte (CTL) T cells which can kill virus-infected cells upon activation.

Effector T cell Cells capable of immediate functional activity resulting in pathogen removal.

Effector-memory T cell A population of memory T cells poised for immediate effector

function that primarily resides outside the lymphoid organs.
Immune homeostasis Maintenance of lymphocyte populations at steady-state levels.
Immunodominance The hierarchy of T-cell responses to the array of individual epitopes which are presented during any given viral infection.
Immunological memory The ability of the host to mount rapid recall responses upon re-exposure to the inducing antigen.
Immunopathology Tissue damage that results from the actions of the host's immune response.
Major histocompatibility complex (MHC) A cluster of genes involved in immune recognition and regulation; MHC class I molecules couple with β2 microglobulin to present peptides to CD8 T cells; MHC class II molecules present peptides to CD4 T cells.
T-cell exhaustion The progressive loss of antiviral T-cell functions which can culminate in the complete deletion of specific T-cell populations during chronic viral infections.
T-cell receptor (TCR) Heterodimeric receptor expressed by T cells that binds specific peptide–MHC complexes.
T helper 1 (Th1) cell Effector CD4 T-cell subset characterized by the production of IFN-γ; associated with immune responses to intracellular bacteria and viruses.
T helper 2 (Th2) cell Effector CD4 T-cell subset characterized by the secretion of IL-4, IL-5, and IL-13; important for helminth infections; linked to allergies and asthma.

General Overview

Cell-mediated immune responses play a critical role in combating viral infections. They are comprised of T-cell responses, which fundamentally differ from antibody (humoral) responses in the way they bring about infection control. The cardinal trait of cell-mediated responses is that the physical presence of reactive T cells is required for immunity, whereas humoral responses are conferred by the presence of soluble antibodies. T cells, together with B cells, form the adaptive immune response to viral infections. The hallmarks of adaptive immunity include antigen specificity and memory. These features allow T cells to elaborate responses which specifically target the numerous viruses which may infect the host. The ability to establish long-lived immunological memory provides a unique mechanism to better protect the host during subsequent viral exposures.

Due to their importance in controlling pathogens, cell-mediated immune responses are widely studied. Significantly, much of our understanding of cell-mediated immunity, including the fundamental concepts of major histocompatibility complex (MHC) restriction, tolerance, T-cell diversity, and immunological memory, has been determined by analyzing immune responses to viruses. Cell-mediated immune responses are dynamic, diverse, and display a broad range of phenotypic and functional properties.

T-Cell Recognition

T cells differ from antibodies (humoral responses) in the way they recognize viral antigens. Antibodies are capable of binding to intact viral proteins, including structural components of viral particles and also viral proteins present at the surface of infected cells. By being able to bind to conformationally complex structures, antiviral antibodies have the unique ability to neutralize the infectivity of viral particles present in the circulation or at mucosal surfaces, a function that cannot be performed by T cells. T cells cannot recognize intact viral proteins and therefore play no role in directly neutralizing whole viral particles. Instead, T cells recognize short peptide fragments presented at the cell surface in a noncovalent association with MHC molecules (see **Figure 1**). Thus, T-cell recognition is referred to as being MHC-restricted, since an individual T cell will only bind strongly to one particular MHC molecule, and is also peptide specific, as a T cell will predominately only recognize one specific short antigenic peptide.

T-Cell Receptors

CD4 and CD8 T cells express a unique surface receptor, the T-cell receptor (TCR) that determines the MHC restriction and peptide specificity of an individual T cell. In the vast majority of T cells, this is a heterodimeric receptor comprised of the TCR α- and β-chains. A smaller population of T cells (~5% of circulating T cells in humans) express an alternative form of the TCR, formed by the noncovalent association of TCR γ- and δ-chains; however, the roles of γδ T cells in controlling viral infections are not well defined. Each T cell expresses only one unique version of the TCR whose precise sequence and structure represents the end result of a series of gene rearrangements. This recombinatorial process, which occurs during T-cell ontogeny in the thymus, generates a massive repertoire of T cells with tremendous diversity between their individual TCR sequences. Estimates of the size of the T-cell repertoire suggest that 2.5×10^7 different TCRs are detectable in human blood. This large ensemble of

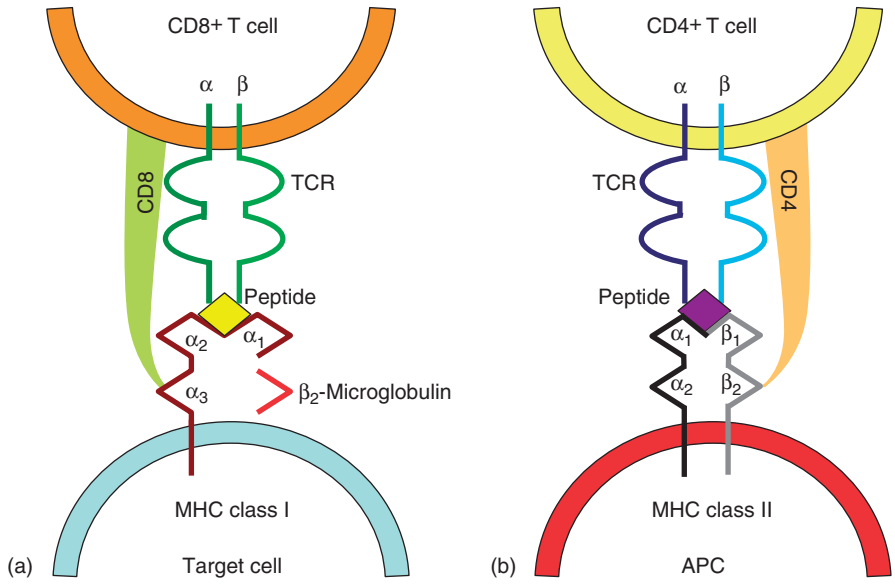

Figure 1 Similarities and differences between CD4 and CD8 T-cell recognition. Both CD4 and CD8 T cells express unique T-cell receptors at the cell surface which determine their antigen specificity and MHC restriction. (a) CD8 T cells recognize MHC class I molecules together with a non-covalently associated antigenic peptide, typically of 8–10 amino acids in length. MHC class I complexes are widely expressed and usually present endogenously synthesized antigens, including peptides derived from the degradation of viral proteins. (b) CD4 T cells recognize peptide antigens presented by MHC class II molecules. These antigenic peptides are typically 13–17 amino acids in length. These peptides are usually derived from extracellular antigens which have been endocytosed into professional antigen-presenting cells where they are proteolytically processed and re-presented at the cell surface bound to MHC class II molecules. MHC class II complexes have a much more limited tissue distribution than MHC class I molecules and are primarily expressed by macrophages, dendritic cells, and B cells.

individual T-cell clones is collectively capable of recognizing and responding to the vast array of antigens, including virally encoded antigens, which may be encountered during the lifespan of the host.

Antigen Processing and Presentation

CD8 T cells recognize MHC class I complexes (**Figure 1**). MHC class I molecules are expressed on virtually all cell types and usually present peptides derived from endogenously synthesized proteins. Antigen processing occurs continuously as newly synthesized proteins become degraded into peptide fragments by proteasomes. These fragments, typically of 8–10 amino acids in length, enter the endoplasmic reticulum and, if they have sufficient binding affinity, associate with MHC class I heavy chains together with the nonpolymorphic protein β2-microglobulin. These assembled MHC peptide complexes are then transported to the cell surface. This process allows MHC class I molecules to sample peptide fragments derived from proteins which are produced within the cell, including normal cellular proteins as well as virally encoded proteins, and present them for inspection by CD8 T cells. This ongoing immunological surveillance allows CD8 T cells to detect, respond to, and remove host cells which express 'non-self' viral proteins.

Although the endogenous pathway of antigen presentation provides a valuable mechanism for revealing the presence of virally infected cells to CD8 T cells, an alternative 'cross-presentation' pathway also operates. During cross-presentation, viral particles (or other antigens) are endocytosed by professional antigen-presenting cells and then undergo proteolytic degradation. The resulting peptide fragments can then bind to MHC class I molecules, and traffic to the cell surface. This enables antigen-presenting cells, such as dendritic cells, to display virally derived peptides to CD8 T cells even if the antigen-presenting cell itself is not capable of supporting virus replication.

CD4 T cells differ from CD8 T cells as they recognize peptides presented by MHC class II rather than MHC class I complexes (**Figure 1**). Unlike MHC class I complexes, which are ubiquitously expressed, MHC class II molecules are only presented by certain cell types such as dendritic cells, macrophages, and B cells. This limits CD4 T-cell recognition to professional antigen-presenting cells, since it is these specialized cells that have the capacity to display peptide–MHC class II complexes to CD4 T cells. Due to structural differences in the peptide-binding groove of MHC class I and MHC class II complexes, the viral peptides that are presented to CD4 T cells are typically longer (~13–17 amino acids in length) compared to those displayed by MHC class I molecules. In addition, whereas MHC class I complexes primarily present endogenously synthesized antigens, MHC class II molecules usually present antigens derived from

extracellular sources. These exogenous antigens can include viral particles and also remnants of virally infected cells. Following uptake by professional antigen-presenting cells, these antigens are degraded into peptide fragments within acidified endosomes. Alternatively, if the antigen-presenting cell is actively infected with the virus, then intracellular vesicles containing viral proteins can serve as a source of peptides for associating with MHC class II complexes. Once at the cell surface these presented antigens can be detected by, and activate, CD4 T cells which express TCRs that are capable of specifically recognizing the peptide–MHC class II combination.

Immunodominance

Individual viruses encode multiple potential T-cell epitopes; therefore T-cell responses elicited during viral infections are not monoclonal or monospecific. Instead, oligoclonal subsets of cells are induced and, although each individual T cell is responsive to only one particular peptide–MHC combination, the overall pool of cells is sufficiently diverse to ensure that numerous epitopes can be detected. The kinetics, magnitudes, phenotypic and functional traits, as well as the stability of T responses to each individual virally encoded epitope can differ. Consequently, an ordered hierarchy can emerge as certain epitopes elicit more abundant, or immunodominant responses, whereas others are less prevalent and give rise to subdominant responses (**Figure 2**).

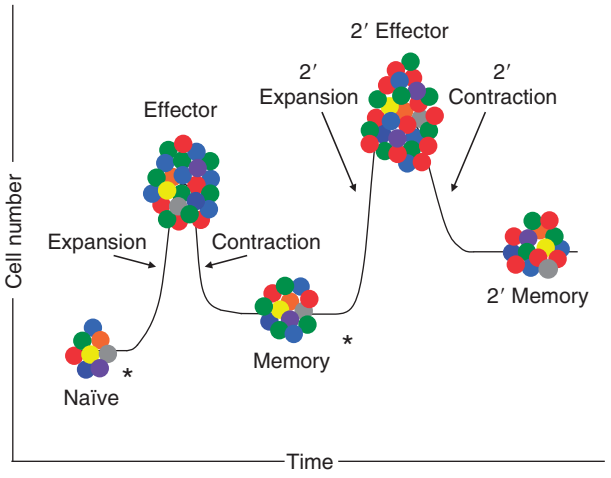

Figure 2 Changes in T-cell immunodominance can occur during primary and secondary immune responses following acute viral infections. Viruses elicit T-cell responses to a range of individual viral epitopes. These responses are not necessarily equal and in the example depicted the T cells specific for the 'green' epitope are immunodominant following the primary infection. This pattern of immunodominance is maintained during the memory phase but secondary exposure to the virus results in an anamnestic recall response during which the 'red' epitope-specific T cells predominate. Asterisk indicates when exposure to the virus occurred.

Our understanding of the precise determinants of immunodominance is incomplete; however, the hierarchy of T-cell responses is likely to be shaped by many factors. The magnitude of responses to individual viral epitopes is influenced by properties of the host's T cells including precursor frequencies and the avidity of the T cells for the presented viral antigen, as well as viral related factors including the ability of viral peptides to bind MHC complexes, the abundance of presented antigen, the kinetics of viral protein synthesis, and the types of cells which present the viral antigens. Changes in the patterns of immunodominance have been reported most notably during the course of persistent viral infections, as well as following secondary exposures to viruses which have been previously controlled (**Figure 2**). In the case of lymphocytic choriomeningitis virus (LCMV) infection of C57BL/6 mice, the NP396 epitope is co-dominant following well-controlled acute infections, and CD8 T cells specific for this epitope respond most vigorously during secondary exposures to LCMV. By contrast, during persistent LCMV infections, responses to this usually dominant epitope can become completely undetectable. During Epstein–Barr virus (EBV) infections shifting patterns of immunodominance are observed as responses to immediate early and early viral proteins are initially detected, but as viral latency becomes established responses to lytic cycle proteins decline and responses to latent viral proteins predominate. These observations demonstrate that not all antiviral T cells respond equally and suggest that certain specificities of T cells may be more effective at combating particular viral infections.

Induction of Cell-Mediated Immunity during Viral Infections

As a virus infection becomes established in the host, a series of molecular and cellular signals are initiated which activate cell-mediated immune responses. These signals include the production of interferons, other cytokines, and inflammatory mediators, in addition to the mobilization of local dendritic cells. Dendritic cells are thought to provide a critical cellular link for priming naive CD4 and CD8 T cells (**Figure 3**). It has been proposed that these cells are especially prone to infection by viruses which facilitate their role as cellular sensors for signaling the occurrence of an infection. Even if dendritic cells are not permissive to active infection with particular viruses, they can also present antigens through cross-priming to CD8 T cells, as well as to CD4 T cells via the classical exogenous antigen processing pathway.

The primary activation events which induce cell-mediated immunity predominately occur in secondary lymphoid organs including regional lymph nodes and the

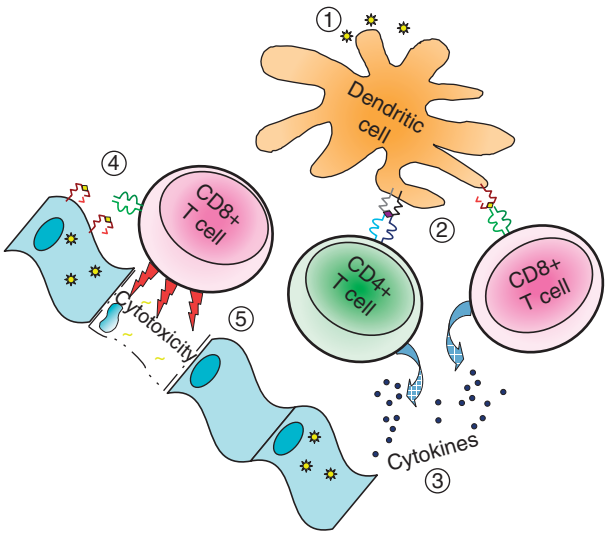

Figure 3 The induction and function of cell-mediated immune responses. (1) The presentation of viral antigens by professional antigen-presenting cells is a critical step in initiating cell-mediated immune responses. (2) Recognition of cognate peptide–MHC complexes by CD4 and CD8 T cells stimulates their proliferation and differentiation into effector cells. (3) Antigen-activated effector CD4 and CD8 T cells can express cytokines such as IL-2, TNF-α, and IFN-γ. These cytokines have important roles in coordinating the antiviral immune response and can also have direct antiviral effects. (4) Once activated antiviral T cells disperse into tissues where can they respond locally, at the sites of viral infection. (5) If viral peptide–MHC complexes are recognized, then effector CD8 T cells can elaborate cytotoxic effector functions which kill the infected cells. CD4 T cells can also become cytotoxic during certain infections; however, their impact is less promiscuous as they recognize the MHC class II complexes which are only expressed by professional antigen-presenting cells.

spleen. During the early stages of viral infections dendritic cells residing at the initial sites of infection take up viral antigens, become activated, and migrate to regional lymph nodes. Within the lymph nodes these dendritic cells encounter naïve T cells which are circulating through these organs as part of their normal immunosurveillance protocol. Engagement of TCRs on the naive T cells with viral–peptide MHC complexes presented by the dendritic cells results in sequestration of the T cells and launches the antiviral T-cell response (**Figure 2**). The ensuing proliferation and differentiation of virus-specific T cells also occur in conjunction with inflammatory mediators such as interferons and other danger signals. Many parameters, including the duration and strength of antigenic stimulation, co-stimulatory interactions, the presence of cytokines, and the provision of CD4 T cells help guide the developing response. These early events play a critical role in driving the generation of both the effector T cells as well as the subsequent establishment of the memory T cell pool.

CD8 T Cells

One of the most impressive aspects of CD8 T-cell responses is the massive proliferation of these cells which occurs during the initial phase of many viral infections (**Figures 2** and **4**). Experimental studies of acute LCMV infection of mice have demonstrated that antiviral CD8 T cells can increase over 10 000-fold during the first week of infection; over 50%, and perhaps even more, of the host's CD8 T cells are LCMV-specific at the peak of the response! Marked expansions of virus-specific CD8 T cells are a common feature of many virus infections including influenza, vaccinia virus, EBV, yellow fever virus, and early following human immunodeficiency virus (HIV) infection. During this expansion phase the patterns of gene expression change promoting the synthesis of cytokines and cytotoxic effector molecules as well as alterations in surface molecules including cytokine receptors and adhesion molecules. This results in an expanded pool of virus-specific effector cells with functional attributes necessary to control the infection. The ensemble of virus-specific effector cells which emerge during the acute phase of the infection is remarkably heterogeneous and comprises of subsets which differ in their epitope specificity, clonal abundance, effector potential, expression of adhesion molecules and cytokine receptors, and ultimate fate. Although the initial activation of T-cell responses occurs in secondary lymphoid organs, the effector cells become dispersed throughout the host. In this way the T cells are available locally, at the sites of infection, where they operate to eliminate the host of virally infected cells.

CD8 T cells are potent antiviral effector cells due to their ability to produce both inflammatory mediators as well as cytotoxic effector molecules (**Figure 3**). CD8 T cells are commonly referred to as cytotoxic T lymphocytes (CTLs), which emphasizes their ability to kill virally infected target cells. These killing functions are triggered as the effector T cell become activated following engagement with a virally infected target cell displaying an appropriate peptide–MHC complex. The subsequent release of perforin and granzyme molecules by the T cells ensures the swift destruction of the infected cell. Ideally, this targeted removal of the infected cell occurs before progeny virus is released. Alternative Fas and TNF-dependent cytotoxic mechanisms have been reported but their *in vivo* significance in killing virus infected cells is not well defined. In addition to their direct killing functions, CD8 T cells also produce a range of cytokines and chemokines. In the laboratory the production of these effector molecules is often used to detect the presence of antiviral T cells. Most importantly, within the infected host the production of these soluble mediators, such as IFN-γ and TNF-α, can also help clear viral infections without causing death

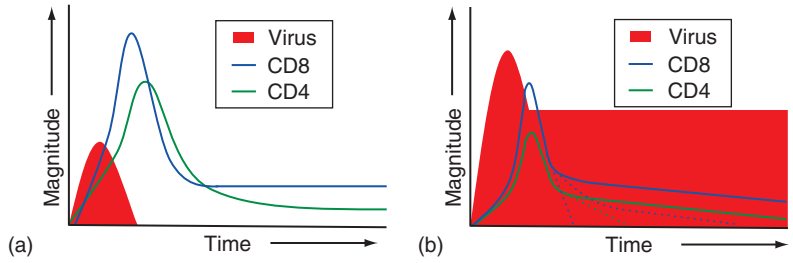

Figure 4 Successful and unsuccessful T-cell responses during acute and chronic viral infections. (a) During acute viral infections massive T-cell responses can be induced which play a principal role in clearing the infection. Following the resolution of the infection, the responding T-cell pool is downregulated but a long-lived pool of memory T cells becomes established which helps protect against subsequent viral exposures. (b) During chronic viral infections T-cell responses are elicited but a variety of phenotypic and functional defects manifest as these responses succumb to exhaustion. A gradation of exhausted phenotypes is often observed, ranging from an inability to produce effector cytokines to the complete deletion of virus-specific T cells.

of infected cells. This cytokine-mediated purging of infected cells has been most convincingly shown during viral hepatitis.

CD4 T Cells

CD4 T cells are traditionally known as helper T cells because of their ability to provide help to B cells and CD8 T cells, resulting in antibody production, class switching, cytotoxic T cell activity, and memory development. In addition to assisting cells of the adaptive immune system, CD4 T cells produce an array of cytokines and chemokines that stimulate cells of the innate immune system, such as macrophages and neutrophils, to traffic to the sites of infection and elaborate their effector activities. It has also been demonstrated that CD4 T cells are directly capable of antiviral functions, through the production of IFN-γ and, in some circumstances, by inducing lysis of virally infected cells (**Figure 3**). Thus, CD4 T cells are critical constituents of the cell-mediated immune response to viral infections; however, it should be emphasized that innate immunity as well as humoral immune responses, which are helped by CD4 T cells, are key components of the host overall antiviral response.

Like CD8 T cells, naive CD4 T cells circulate through secondary lymphoid organs in a relatively quiescent state. Following recognition of antigen in the context of MHC class II, a cascade of signaling events is initiated within the CD4 T cell which results in activation, proliferation, and differentiation into an effector CD4 T cell (**Figure 3**). Classically effector CD4 T cells have been divided into two polarized subsets based on their cytokine production profile. T helper 1 (Th1) cells primarily produce IFN-γ and are critical for the immune responses to various viral infections, as well as infections with intracellular bacteria. This subclass of effector cells is typically associated with antiviral cell-mediated immunity. Conversely, T helper 2 (Th2) cells predominantly secrete the cytokines IL-4, IL-5, and IL-13, assist with the eradication of helminth infections, and have historically been linked with the production of antibodies and humoral immune responses.

In recent years, the definition of CD4 T-cell subsets has expanded beyond Th1 and Th2 cells, with the importance of unique populations of regulatory CD4 T cells and also IL-17 producing 'Th17' cells becoming evident. Regulatory cells are pivotal for preventing autoimmunity by suppressing the activation of autoreactive T cells. Regulatory T cells are typically characterized by the expression of the transcription factor Foxp3 and by the production of the suppressive cytokines IL-10 and TGF-β. Relatively little is known regarding the significance of these CD4 T-cell populations during viral infections; however it has been proposed that regulatory T cells are both beneficial to the host, by limiting immunopathology, and detrimental, by dampening effector functions.

T-Cell Memory

Ideally, the primary immune response overwhelms the infection and results in the complete eradication of the virus from the host. If the infection is successfully resolved then the expanded pool of effector T cells does not remain constitutively activated. Instead, a downregulation phase ensues during which typically the majority (<90%) of the virus-specific T cells present at the peak of the immune response die by apoptosis. The remaining 5–10% of T cells survive the contraction phase and constitute a long-lived pool of memory T cells (**Figures 2** and **4**). In this way, a beneficial memory of past infections is established as, by comparison with naïve hosts, an increased number of virus-specific T cells are maintained which are tuned to rapidly respond if they re-encounter infected cells. The population of memory T cells which emerges following the resolution of the infection and restoration of homeostasis is not uniform, as phenotypic and functional

diversity is apparent even within subsets of memory T cells which recognize the same viral epitope. This is well illustrated by the classification of memory T cells into broad categories termed effector- and central-memory T cells. These subsets have been defined based upon their anatomical location, functional quality, proliferative potential, and expression of surface molecules.

Since T cells neither recognize nor neutralize the infectivity of viral particles they do not confer sterilizing immunity and cannot prevent secondary infections. Nevertheless, as the host cells become infected, preexisting memory T cells which developed following prior viral exposures can mount robust recall responses. These anamnestic responses are characteristically more rapidly induced, greater in magnitude, and possibly more functionally competent than primary T-cell responses. Such pronounced secondary responses help protect the host by contributing to the swift control of the infection thereby reducing the morbidity and mortality. Memory T-cell responses are not the only components of secondary immune responses as these cells act in conjunction with antiviral antibodies to protect the host during viral reexposures.

Analysis of both clinical specimens and experimental animal models has demonstrated that acute viral infections can induce very long-lived memory T-cell responses (**Figure 4**). Studies using experimental mice have demonstrated that memory CD8 T cells reactive against various infections such as LCMV, vaccinia virus, and influenza are maintained at remarkably stable levels for over 2 years following infection. By contrast, CD4 T-cell responses are not as consistent and have been reported to gradually decay over time. Although natural exposures to viruses lead to the formation of immunological memory, these advantageous responses are also induced following vaccinations. Vaccines are successful in protecting the host against subsequent infections because of their ability to promote long-lived memory responses. In humans the longevity of T-cell responses has been investigated in detail following smallpox vaccination. Smallpox-specific T-cell responses are detectable in individuals who received a single dose of the vaccine 75 years previously! Notably, the findings suggested that the responses do decline slowly with predicted half-lives of 8–15 years.

Persistent Viral Infections

Although T-cell responses can be highly effective at controlling acute infections and contribute to protective secondary responses, persistent viral infections do arise and are often associated with the development of phenotypically and functionally inferior responses (**Figure 4**). These types of infections include many viral pathogens which are of significant public health importance such as HIV and hepatitis C virus (HCV). A common feature of these infections is that T-cell responses are initially induced but qualitative and quantitative defects become apparent as the generation of robust sets of effector cells, as well as the progression of memory T-cell development are subverted. By comparision with successful T-cell responses elaborated during acute viral infections, a spectrum of phenotypic and functional defects have been detected during persistent infections. The production of cytokines including IL-2, TNF-α, and IFN-γ, as well as cytotoxic effector molecules such as perforin may be diminished or abolished, and decreased proliferative potential has also been observed. The severe loss of effector activity as well as the physical deletion of antiviral T cells which can occur during persistent infections has been termed exhaustion (**Figure 4**).

The parameters which contribute to T-cell exhaustion are not fully understood. Comparative analysis of T-cell responses to viral infections which result in different levels of antigenic exposure, such as influenza, cytomegalovirus, EBV, HCV, and HIV, indicate that antiviral T cells may adopt different preferred phenotypic and functional set points. Experimental studies suggest that many factors including, but not limited to, viral targeting and destruction of dendritic cells, the production of immunosuppressive cytokines such as IL-10, the depletion of CD4 T cell subsets, and the induction of weak neutralizing antibody responses can all contribute inferior cell-mediated immune responses. Changing viral loads may also impact the functional quality of the T-cell response. During acute HCV infection antiviral CD8 T cells transiently lose the ability to produce IFN-γ, but recover from this 'stunned' state as the viral loads are brought under control. Importantly, this suggests that under certain conditions the exhaustion of virus-specific T cells may be prevented or even reversed. Several reports have now demonstrated that during persistent LCMV, HIV, and HCV infections, antiviral T cells can express the inhibitory receptor PD-1. Antibody-based therapeutic treatments to block this receptor have been shown to promote proliferation of previously exhausted T cells and restore their functional activities. This is a promising experimental observation; however, the jury is still out on whether this approach will be a beneficial treatment for persistent infections of humans.

Immunopathology

Since viruses are obligate intracellular pathogens they must infect permissive host cells in order to replicate. Infected cells die as a direct result of the virus' lytic replication cycle or are killed as a consequence of the

actions of the antiviral immune response. Although immune-mediated destruction of virally infected cells is necessary to contain the infection, it can also result in immunopathology, which represents collateral damage to the host caused by the actions of the immune response. A classical example of immunopathology occurs following intracranial infection of adult mice with LCMV. Mice infected by this route succumb to a characteristic lethal disease and expire approximately 1 week following infection. Death can be prevented by immunosuppression of the mice, which has shown that the disease is a consequence of a vigorous CD8 T-cell response rather than due to the infection *per se*. HBV-associated viral hepatitis is another instance where anti-viral CD8 T-cell responses, which are attempting to clear the infection, cause liver damage in the infected individual.

Most viral infections are associated with the development of an IFN-γ-producing Th1-CD4 T cell response. In various animal models, the absence of CD4 T cell help during viral infection results in impaired clearance of the infectious agent. However, not all CD4 T-cell responses are beneficial as the induction of inappropriate types of CD4 T-cell responses can be deleterious to the host, due to immunopathology. In the 1960s, a group of young children were administered a formalin-inactivated vaccine for respiratory syncytial (RS) virus and following exposure to live RS virus, these children exhibited enhanced infection rates and immunopathology linked to increased frequencies of eosinophils and neutrophils within the airways. Animal studies have indicated that the vaccine was associated with a Th2-biased virus-specific immune response (increased levels of IL-4 and IL-13, as well as eosinophil recruitment to the lungs) that upon live infection displayed many of the signatures of immunopathology which manifested in these vaccinated children. Supporting experiments suggest that immunization to promote the Th1 responses or ablation of Th2 responses prevents the development of these pathological effects following live viral infection.

Immune Evasion

Arguably, one of best indications of the importance of cell-mediated immunity in controlling viral infections is the observation that many viruses have evolved strategies to evade the actions of the host immune response. There is, however, no one universal evasion mechanism; instead, viruses have adopted various preferred approaches to escape antiviral T-cell responses. A common strategy is to change the amino acid sequence of T-cell epitopes or nearby flanking residues that impede the recognition or processing of the antigenic peptide. Many viruses rely on error-prone polymerases in order to replicate, which favor the incorporation of mutations in progeny viral genomes. The resulting variant viruses will have a selective advantage if the amino acid substitution abolishes the ability of the epitope to associate with MHC molecules, negatively impacts recognition of the epitope by T cells, or prevents antigen processing.

In addition to mutating epitope sequences, many viruses encode specific molecules which function to interfere with the antiviral immune response. Both MHC class I and class II antigen-presenting pathways are targeted by several viral proteins. These immune evasion molecules block antigen presentation in various ways, ranging from preventing the transport of antigenic peptides into the endoplasmic reticulum to inhibiting the egress of peptide-loaded MHC complexes. The end result of these inhibitory strategies is to impair immunological surveillance. Although there is much anecdotal evidence that interference with antigen processing diminishes cell-mediated immune responses, experimental studies using murine cytomegalovirus (MCMV) question this notion. Infection of mice with mutants which lack several viral genes known to block antigen processing did not effect the ability of the host to elaborate an anti-MCMV CD8 T-cell response.

Glossary

Adaptive immune system Comprises T cells, B cells, and antibodies. Elements of the innate immune system are required for initiation of the adaptive immune response. The adaptive immune system recognizes specific antigenic epitopes. Immunopathology is mainly mediated by the adaptive immune response to viral infection.
Antibody Antibodies are secreted by plasma cells and can neutralize viruses, bind to the surface of infected cells, activate the complement system, and form immune complexes. Antibodies are an important part of the adaptive immune response.
B cell Each B cell has a specific type of antibody molecule on its surface (B cell receptor). Viral proteins are recognized by B cell receptors. B cells mature into plasma cells that secrete large amounts of antibodies.
Complement A protein cascade system mainly found in serum. The cascade can be activated by immune complexes of viral proteins and antibodies. The protein cascade generates chemotactic peptides for phagocytic cells, proteins that can coat viral particles, and lyse viral membranes.
Cytokines Proteins that can be produced by various cells within the body. These proteins are produced in response to infection. Particularly, immune cells but other cell types have cytokine receptors. Cytokines mediate inflammation and can modulate the immune response through cytokine receptors.
Immune complex A complex between antibody molecules and antigens. These complexes can activate the complement system through the Fc receptor on the antibody molecules and can lodge in glomeruli and small vessels causing immunopathology.
Immunopathology Disease resulting from the immune response to infection causing tissue injury and damage.
Innate immune system Comprising phagocytic cells (macrophages and neutrophils), complement system, natural killer (NK) cells, and various cytokines that can act within minutes to hours after infection. Recognition is to patterns of microbial structures, not specific epitopes.
Major histocompatibility complex (MHC) A region encoding highly polymorphic proteins that are involved in immune recognition of T cells, some cytokines and proteins of the complement cascade. This region is coded for by genes on human chromosome 6 and on mouse chromosome 17.
Natural killer (NK) cells A population of lymphocytes that can kill virus-infected cells. NK cells can secrete large amounts of the antiviral cytokine IFN-γ. IFN-γ can also activate macrophages. NK cells are part of the innate immune system.
T cell T cells are mature in the thymus. These lymphocytes recognize viral peptides in the context of MHC molecules through the T-cell receptor on the surface of T cells. T cells can kill virus-infected cells and release potent antiviral cytokines such as interferons.

Introduction

When a virus infects a vertebrate host, an immune response is rapidly generated against the virus. This immune response will often determine the survival or death of the host in acute infections or the establishment of a persistent infection. Tissue damage or pathology can result due to the antiviral immune response. This is different from direct viral effects where virus infection of cells can lead to tissue damage and apoptosis. A vigorous antiviral immune response is responsible for the immunopathology associated with acute and persistent/chronic virus infections. There is a necessary balance between viral clearance by the immune system and pathology induced by the immune system in attempting to clear the virus (**Figure 1**).

One important component of the adaptive immune system is the lymphocyte. Due to specialized receptors on the surface of lymphocytes (T cell receptor (TCR), B cell receptor (BCR)/antibody molecule), these cells are able to recognize or discriminate between different antigenic peptides derived from microbes or self-proteins. Lymphocytes can be divided into several broad populations. These cells can act directly to lyse or kill virus-infected cells (discussed below) or produce antiviral substances such as cytokines (interferons (IFNs), tumor necrosis factor (TNF)) that have antiviral activity but also can disturb the host's cell function or by themselves cause cellular and tissue injury. Lymphocytes in collaboration with cells of the innate

immune system can also kill virus-infected cells or secrete antibodies with antiviral neutralizing capacity (discussed below).

One population of lymphocytes are the B cells which are bursa or bone marrow-derived lymphocytes. These lymphocytes express BCRs on their surfaces called immunoglobulins or antibodies (**Figure 2**). The antibodies are secreted from differentiated B cells called plasma cells. Different antibodies can bind to specific viral proteins or antigens; but in general, one specific antibody is originally derived from one B cell and can recognize a unique epitope. Antibodies can neutralize viruses by attaching to the surface of the virion, thus inhibiting the attachment, penetration, or uncoating phases of viral replication (**Figure 2**, arrow 1). Antibodies can also bind to virions in the blood (viremia) or to viral proteins (such as hepatitis B virus surface antigen), and form antigen–antibody complexes (immune complexes) (**Figure 2**, arrow 2). If the complexes are of the appropriate size, glomerulonephritis can occur due to immune complex deposition (discussed below). Immune complexes are also engulfed by Fc receptor bearing cells of the innate immune system found in the liver and spleen. However, since immune complexes are often infectious, by this means, Fc or complement expressing cells can also be infected. However, this process aids in clearance of virus from the blood, thereby limiting the viremia. Infected cells can be killed by antibodies specific for viral proteins expressed on the surface of virus-infected cells. This requires the presence of complement proteins. Complement proteins binding to the Fc portion of the immunoglobulin (**Figure 2**, arrow 3) activate the complement cascade leading to the formation of the complement membrane attack complex on the cell membrane and eventually cell lysis. Antibodies via the Fc portion of the immunoglobulin molecule can bind to Fc receptor positive cells (macrophages and NK cells – two cell types of the innate immune system) (**Figure 2**, arrows 4 and 5). The Fab portion of the immunoglobulin (antigen recognition site) gives specificity for the killing of the virus-infected cells. Therefore, antibodies can participate in clearing/neutralizing circulating free virus, as well as

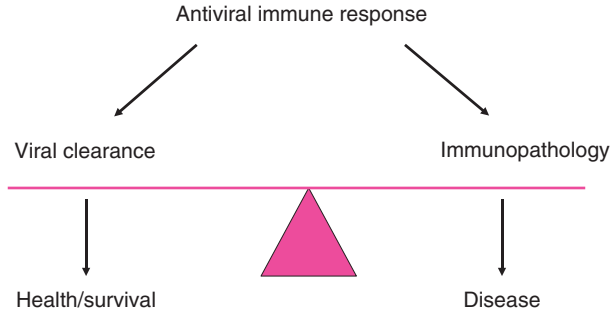

Figure 1 The antiviral immune response is a balance between viral clearance and immunopathology. One direction leads to survival of the host, whereas the other can lead to disease.

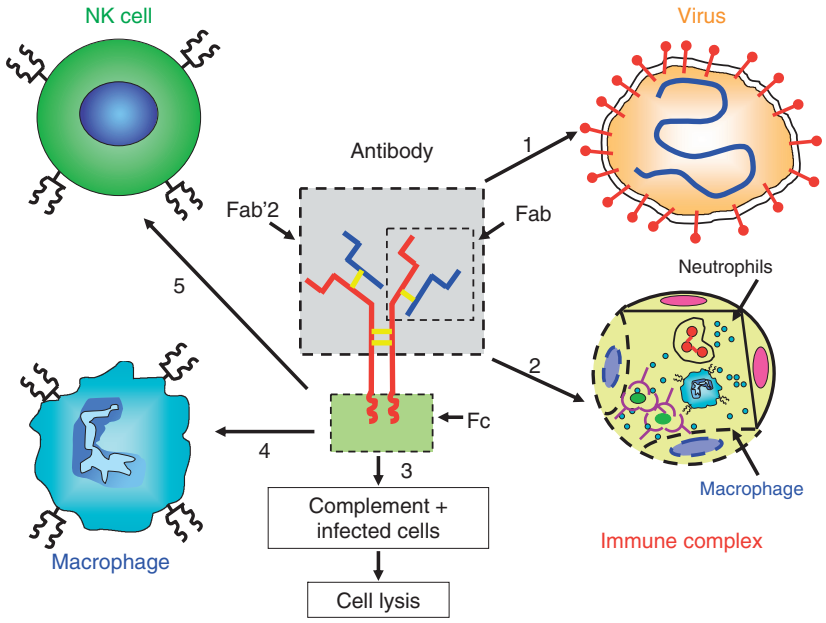

Figure 2 Antiviral antibodies can play an important role in viral clearance and/or disease. The Fab portion of the antibody molecule can bind and neutralize the virus (arrow 1). Antibodies binding to viral proteins or virions can form immune complexes that can lead to immune complex disease (arrow 2). Antibody binding to virus-infected cells through the Fc portion of the antibody molecule can activate the complement system leading to lysis of the infected cell (arrow 3). The Fc portion of the antibody molecule can also bind to Fc receptors in macrophages and NK cells. The antibody-coated macrophages and NK cells can kill infected cells via antibody-dependent cell-mediated cytotoxicity (arrows 4 and 5).

killing virus-infected cells with the help of complement and cells of the innate immune system. However, the number of antibody molecules required to kill a cell is usually in excess of 1×10^6, which makes this an inefficient process.

T cells represent another population of lymphocytes that participates in viral clearance and immunopathology. T cells can be further divided into two subpopulations, $CD4^+$ and $CD8^+$ T cells (**Figure 3**). T cells with the surface molecule CD4 are called T-helper cells (Th) due to their ability to secrete certain cytokines that 'help' B cells to differentiate into antibody producing plasma cells and 'help' the subpopulation of T cells expressing CD8 molecules to acquire cytotoxic or killer cell activity. $CD4^+$ T cells are 'restricted' by major histocompatibility complex (MHC) class II molecules. The MHC class II molecule presents viral peptides as a complex that is recognized by TCRs on $CD4^+$ T cells. The $CD4^+$ T cells can be further subdivided, depending on the types of cytokines they secrete, into $CD4^+$ Th1 T cells that are involved in delayed-type hypersensitivity immune responses and $CD4^+$ Th2 T cells that help B cells. When activated $CD4^+$ Th1 T cells secrete IFN-γ that has antiviral activity and can also in turn activate macrophages. These activated macrophages, cells of the innate immune system, can kill virus-infected cells indirectly by releasing reactive oxygen species and toxic cytokines, such as TNF or lymphotoxin (LT) that lyse cells by what is known as bystander killing. The $CD4^+$ T-cell population is also involved in the maintenance of antiviral T-cell memory. T-cell memory is key for immune individuals to respond to subsequent infections with the same or similar viruses. The $CD4^+$ T-cell population also contains a subset of T cells that also express a surface protein, CD25, and an internal protein called FoxP3. These T cells have the ability to modulate the adaptive immune response, and therefore are known as T-regulatory cells.

The $CD8^+$ T-cell population is intimately involved in viral clearance and immunopathology. $CD8^+$ T cells kill virus-infected cells by two mechanisms and are very efficient usually requiring recognition of ten or fewer viral peptide molecules in association with the MHC class I complex (see below). The first mechanism is by release of perforin molecules that form pores in the target cell's membrane similar to the complement membrane attack complex. The second mechanism involves the interaction of FasL-Fas on the T cell and the infected cell, respectively. Fas is a member of the TNF receptor family. Fas binding to its ligand leads to activation of caspase 8, a death signal in the infected cells that results in apoptosis. The cytotoxic T-lymphocyte (CTL) killing of virus infected cells occurs when infected cells are killed in a MHC class I restricted manner (TCR on $CD8^+$ T cells recognizing viral peptide complexed to class I molecules) prior to the maturation of infectious virus thus reducing the virus' ability to replicate and disseminate within the body. This supplements the action of antiviral antibodies that can neutralize infectious virus. Memory $CD8^+$ T cells form during the antiviral immune response and are long-lived T cells that can protect animals in the event of subsequent infections with the same virus.

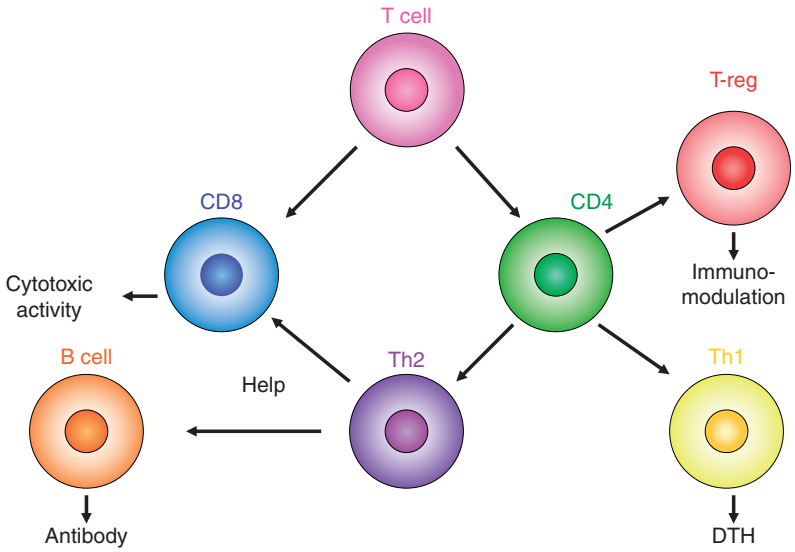

Figure 3 T cells can be divided into different subpopulations depending on their function. $CD8^+$ T cells have the ability to kill virus-infected cells and are restricted by MHC class I molecules. $CD4^+$ T cells can be further subdivided. Some $CD4^+$ T cells have the ability to provide 'help' to other T cells and B cells. Others can act as regulatory cells modulating the function of other T cells. $CD4^+$ T cells can also be directly involved in inflammatory responses through the production of various pro-inflammatory cytokines.

Thus B cells, $CD4^+$ and $CD8^+$ T cells, in conjunction with complement and cells (NK, macrophage, neutrophil) of the innate immune system, are responsible for viral clearance. These are also the cellular participants that are involved in immunopathology associated with virus infections.

Immunopathology

Antiviral immune responses are responsible for the immunopathology associated with acute and persistent/chronic virus infection. Immunopathology is determined by several factors. These involve contributions from both the host and the virus. Host factors include the age of the individual, genetic makeup of the host (MHC and non-MHC genes), route and/or site of infection, and whether the immune system is intact or immunocompromised. Characteristics of the virus consist of the strain or type and the size of the inoculum/dose.

Age of the host can play an important role in determining whether an individual survives, becomes immune, or acquires a persistent infection. For example, infection with lymphocytic choriomeningitis virus (LCMV), an arenavirus, has different outcomes depending on the age of the host. The natural host of the virus is the mouse. Its genome is comprised of two segments of RNA and is ambisense. The two RNA segments are encased by a nucleocapsid protein forming the nucleocapsid that is surrounded by a lipid envelope embedded with two viral glycoproteins. For the most part LCMV is noncytolytic and does not induce cell death after infection. Neonatal infection, infection of newborn mice with LCMV, or of adult mice with immunosuppressive variant(s) results in a persistent infection where many tissues are infected and mice survive. At this early age, the mouse's immune system is not fully developed and the mouse is not able to mount a functional CTL response. It was first proposed by Burnet that mice persistently infected with LCMV were immunologically tolerant to the virus (the host's immune system is not able to recognize the virus and mount an immune response). Accordingly, this purported immune tolerance to LCMV was why the virus was able to persist. However, seminal studies by Oldstone and colleagues demonstrated that mice persistently infected with LCMV were not tolerant. These mice produced antivirus antibodies and routinely developed glomerulonephritis. The inflammatory lesions in the kidneys were due to LCMV–anti-LCMV immune complex deposition in the glomeruli activating the complement cascade and recruiting of cells of the innate immune system leading to disease (to be discussed below) (**Figure 2**, arrow 2). Similar findings followed for congenital murine retrovirus infections.

In contrast, if mice are infected as adults with a moderate dose of LCMV (nonimmunosuppressive variant) by an extraneural route of infection (outside the central nervous system (CNS)) little or no immunopathologic disease is observed. Anti-LCMV CTLs are induced that are able to clear virus-infected cells. A portion of these LCMV-specific T cells go on to become memory T cells. Subsequent intracerebral (ic) infection of an adult immunocompetent immune mouse results in far less inflammation and immunopathology in the CNS and the animal survives. Interestingly, after ic LCMV infection of adult nonimmune mice, virus is able to replicate in certain epithelial cells. After about 5–7 days post infection the infected mouse mounts a robust anti-LCMV CTL immune response which is responsible for inflammation in the choroid plexus, ependyma, and leptomeninges causing choriomeningitis. Death is due to the action of the anti-LCMV CTL immune response altering the blood–brain barrier and initiating brain edema. This infection illustrates several of the factors involved in immunopathology. The age of the host is critical, since in very young animals the immune systems are not fully developed. These animals are immunocompromised, that is, unable to mount an effective CTL response allowing a noncytolytic virus-like LCMV to persist. Other studies have shown the importance of CTL in initiating immunopathology and death. Adult mice whose T cells are ablated or inhibited and then infected with LCMV via the ic route of infection develop a persistent infection and do not die of the choriomeningitis. Adoptive transfer of immune spleen cells, immune T cells, or LCMV-specific $CD8^+$ T cells into LCMV carrier mice leads to clearance of viral infection. Thus, this experiment complements studies of acute infection and substantiates the role of the antiviral T cells in clearance of virus and termination of infection.

Mice that are infected as newborns or earlier with LCMV develop a persistent infection, but are not without immunopathology. As mice infected at birth or earlier develop into adults, they produce anti-LCMV antibodies that can bind to viral antigens (present due to the persistent infection) forming immune complexes. Depending on the size of the immune complexes and numbers formed, the complexes deposit in the glomeruli of the kidneys due to the filtering action within the glomeruli. As a consequence of immune complex deposition in the glomeruli, the complement cascade is initiated releasing chemotactic peptides that recruit and activate polymorphonuclear leukocytes (PMNs) and macrophages into the glomeruli. These activated cells release inflammatory cytokines, such as TNF and interleukin (IL)-1, and reactive oxygen intermediates, as well as lysosomal enzymes that induce inflammation and immunopathology resulting in glomerulonephritis. The extent of glomerulonephritis induced by persistent LCMV infection varies and depends

both on the strain of mouse (genetic influences discussed below) and strain of virus.

The genetic composition of the host can play an important role in whether immunopathology occurs. For example, infection with Theiler's murine encephalomyelitis virus (TMEV), a picornavirus related to the cardioviruses, has different outcomes depending on the strain of the host. As with LCMV the mouse is the natural host. Because of the availability of inbred mice and mapping of their molecules, particularly MHC and background genes involved in innate immunity, the mouse has been an exquisite model to measure not only host genetics but influence of viral genetics as well. TMEV is a positive stranded RNA virus. The genome is approximately 8000 bases in length. The icosohedral capsid is comprised of four viral proteins. The virion is not encapsidated by a membrane. TMEV can be divided into two groups depending on neurovirulence. The GDVII subgroup is comprised of viruses that are highly neurovirulent. Members of the TO subgroup are less neurovirulent. Ic infection with the DA strain of TMEV (TO subgroup) into adult C57BL/6 mice leads to an antiviral $CD8^+$ T-cell response that clears the virus from the CNS and other tissues of the body. There is limited inflammation in the CNS but mice survive and are immune to subsequent infections with TMEV.

In contrast, ic infection of SJL/J mice with the DA strain of TMEV induces an antiviral $CD8^+$ T-cell response which is not able to clear the virus. Therefore, DA virus is able to establish a persistent infection in the CNS. Immunopathology results as a consequence of a chronic anti-TMEV immune response attempting to clear virus-infected cells in the CNS. Infected SJL/J mice eventually develop large areas of inflammation and demyelination in the spinal cord with a spastic paralysis. Genetic differences in the MHC complex between the two strains of mice are implicated in whether one mouse strain is able to clear the virus and the other mouse strain is not able to clear the virus resulting in disease. In addition, innate immune responses are also genetically determined. Therefore, the early inflammation in response to infection is encoded within the genome and varies from individual to individual.

The initial site of infection is important. A peripheral infection with LCMV in an adult mouse generates a robust anti-LCMV CTL response and immunity. Since the virus is not present in the CNS or only a few cells are infected, the CTL response clears the virus and little pathology ensues. Infection by the ic route also induces a vigorous CTL response. However, a significant number of meningial cells are infected with the virus. CTLs recognize virus-infected cells in the meninges lysing the cells via a perforin-mediated mechanism. This contributes to the death of the mouse. Therefore, the site or route of infection and, which cells are infected by the virus, are important factors.

The strain of the virus can play a major role in immunopathology, as shown by the following two examples. As mentioned previously TMEV can be divided into two groups depending on neurovirulence. The GDVII subgroup comprises viruses that are highly neurovirulent. An intravenous (IV) or ic infection of mice with the GDVII virus will result in the virus killing the mouse in 7–10 days. The death is due to the virus' ability to infect large numbers of neurons and directly kill these cells. In contrast, infection of mice (SJL/J) with viruses from the TO subgroup with 100 000–1 000 000 times more virus leads to mild acute disease with TMEV establishing a persistent infection in the CNS. The chronic anti-TMEV immune response results in extensive demyelination and inflammation. The pathology is caused by the antiviral immune response comprising antibodies capable of neutralizing the virus, $CD4^+$ and $CD8^+$ T cells recognizing virus-infected cells and either directly killing the infected cells, as in the case of antiviral $CD8^+$ T cells or TMEV antibody and complement, or killing the infected cells via bystander mechanisms which are mediated by $CD4^+$ T cells and the effector/killer cells are macrophages (as in delayed-type hypersensitivity responses).

CNS infection of adult mice with LCMV leads to the generation of antiviral $CD8^+$ T cells and infected mice die about 7–10 days later as the $CD8^+$ T-cell response develops. As mentioned above there is extensive infiltration of T cells and mononuclear cells in the meninges, alterations in the blood–brain barrier, and edema. In contrast, infection of adult mice with a variant of LCMV, clone 13, that differs in two amino acids from wild-type Armstrong LCMV, induces an immunosuppression due to infection of dendritic cells which are then not able to arm and expand T- and B-viral-specific cells. The variant LCMV is able to persist in adult mice. These persistently infected mice also develop immune complexes in their kidneys. Different strains of virus, such as clone 13, can initiate different types of disease leading to immunopathology.

The amount of virus the host first encounters can set the stage for later disease. For example, high doses of certain strains of LCMV when given by the IV route results in dissemination to the various lymphoid tissues. Virus can replicate to high titers at these sites constantly stimulating the antiviral T cells leading to 'CTL exhaustion'. This is likely due to both the continual stimulation of the TCR by antigen presenting cells leading to the apoptosis of LCMV-specific CTLs and to infection of dendritic cells. With the depletion or failure to generate virus-specific CTLs, LCMV is able to establish a persistent infection. This is in contrast when low or moderate amounts of LCMV are used to infect mice. The infected mice are able to mount an effective CTL response, virus is cleared, and animals are immune.

In summary, immunopathology results from an imbalance between the immune system's ability to clear the

virus and resulting tissue damage due to the antiviral immune response. These can take the form of antibody and complement, $CD4^+$ T cells and $CD8^+$ CTLs causing tissue damage in the process of eliminating virus and virus-infected cells.

Glossary

Fingerlings A life-cycle stage when young salmonids are one finger in length.
Fry Newly spawned fish that have fully absorbed their yolk sac.
Milt The sperm from the male fish.
Parr A young salmonid with parr marks (dark blotches) on the sides, before migration to the sea.
Smolts Salmonid fish going through smoltification, physiological changes that will allow fish to change from life in freshwater to life in the sea. The smolt state follows the parr state.

Introduction

Infectious pancreatic necrosis (IPN) was originally recognized as an acute and highly contagious disease of juvenile salmonids which typically occurs at the time of commencement of feeding of fry. The clinical manifestation of the disease has, however, changed over the last two decades. IPN outbreaks are still observed during the first few weeks after commencement of feeding of fry and also later in the freshwater phase, typically in 10–20 g fish. The most remarkable change in the clinical manifestation of the disease, observed since the mid-1980s, is the number of outbreaks in post-smolts after seawater transfer, and this has emerged as a significant problem, particularly in salmon farming. The disease pattern is seen in many of the major Atlantic salmon-producing countries such as Chile, UK, and Norway. The mortality rates in the freshwater stage vary considerably from negligible to almost 100%, while disease outbreaks in seawater typically result in 10–20% cumulative mortality, and can reach 70% in individual sea cages. This variation in mortality has been ascribed to factors related to the host species (e.g., the age and/or genetic resistance of fish) and environmental stressors. Virus characteristics such as variations between virus serotypes and strains and viral infection loads can also play an important role in determining mortality rates.

Virus Classification

Infectious pancreatic necrosis virus is the type species of the genus *Aquabirnavirus* within the family *Birnaviridae*. The disease caused by infectious pancreatic necrosis virus (IPNV) in salmonid fish is characterized by necrosis of the exocrine pancreas, which is the origin of the name of both the disease and the type species. However, aquabirnaviruses have been isolated from a wide variety of freshwater and marine fish species, as well as from marine invertebrates worldwide, and are associated with a wide range of host pathologies. Aquatic birnaviruses are

an antigenically diverse group of virus, and somewhat difficult to classify.

Serological classification based on neutralizing antibodies against surface epitopes separates isolates into serogroups A and B. Serogroup A contains nine serotypes (A1–A9) comprising most of the isolates, whereas serogroup B consists of only one serotype. Due to a lack of standardization of the methods, serotyping has been supplemented with, and partly replaced by, genetic classification. Phylogenetic analysis based on the VP2 coding region of genomic segment A suggests that aquabirnaviruses may be clustered into six genogroups that correspond to the previously established serotypes. Genogrouping based on 310 basepairs (bp) at the VP2/NS junction region has identified seven genogroups, the additional genogroup comprising Japanese aquabirnavirus isolates (**Figure 1**). More distantly related is the blotched snakehead virus which is currently an unassigned member of the family *Birnaviridae* and it has been proposed to be classified in a new genus.

There are no agreed species demarcation criteria for the genus *Aquabirnavirus*, and this has led to difficulty in nomenclature. Distantly related strains may cause similar pathologies, whereas closely related strains may range from avirulent to very virulent. Closely related strains are found in both farmed fish and marine species in the same geographical region. Therefore, the species concept does not apply very well to members of the genus *Aquabirnavirus*. Another aspect contributing to this is the intrinsic variability of RNA viruses such as the aquabirnaviruses, is the error-prone process of nucleic acid replication.

Genomic Organization and Virus Structure

The IPNV virion is 60 nm in diameter and a single-shelled, icosahedral structure with no envelope (**Figure 2**). The virus genome consists of two segments of double-stranded (ds) RNA. For serotype Jasper, segment A comprises 3097 bp and the smaller segment B comprises 2784 bp.

Genome segment A (**Figure 3**) contains a large open reading frame (ORF) encoding a 106 kDa polyprotein (NH_2-VP2-protease (VP4)-VP3-COOH), which is cotranslationally cleaved to generate pVP2 (the precursor of VP2), VP4, and VP3. The processing of the large polyprotein is controlled by VP4, which is a viral protease with a serine/lysine catalytic dyad. The cleavage sites have been identified at the pVP2–VP4 and VP4–VP3 junctions, and the structure of VP4 has recently been elucidated by X-ray crystallography. The pVP2 precursor is processed further into the mature VP2 which is the major capsid protein and, in addition, three small peptides are generated that can be detected in virus particles. VP2 spontaneously self-assembles into particles with a diameter of about 25 nm, suggesting that late maturation is to avoid premature assembly during particle morphogenesis. Although studies have indicated that some elements of VP3 may be exposed on the surface of the virion, serotype-specific and neutralizing antibodies are almost exclusively directed against continuous and discontinuous epitopes of VP2. VP3 is an internal capsid protein associated with the viral genome. By applying the yeast two-hybrid system in combination with co-immunoprecipitation, VP3 has recently been shown to bind to VP1 and to self-associate strongly. In addition, VP3 has been shown to bind specifically to dsRNA in a sequence-independent manner. The binding of VP3 and VP1 is not dependent on the presence of dsRNA.

Genome segment A also contains a small ORF that proceeds and partly overlaps the large ORF encoding the 106 kDa polyprotein. The smaller ORF encodes a highly basic, arginine-rich 17 kDa polypeptide that has been detected in infected cells but has not, to date, been conclusively demonstrated to be present in purified virus particles. This apparently nonstructural protein, designated VP5, is encoded by most but not all IPNV strains that have been examined. In an Asian IPNV strain, an anti-apoptotic effect has been demonstrated for VP5 and this may aid viral replication in the initial phase of infection. However, the amino acid sequence of VP5 is not well conserved and the anti-apoptotic effect does not occur in all IPNV strains encoding the polypeptide.

Segment B encodes a 90 kDa protein (VP1) which functions as an RNA-dependent RNA polymerase (RdRp). This enzyme directs the transcription of nonpolyadenylated mRNA from genome segments A and B. Within the virus particle, VP1 occurs as both a free polypeptide and covalently linked to the 5′ terminus of each genome segment.

Antigenic Structure and Neutralization Sites of the Virus

The VP2 is the type-specific antigen in which neutralizing sites reside within the hypervariable region. Several attempts have been made to identify the neutralization domains of VP2 and the findings reported are summarized in **Table 1**. The region comprising amino acid residues 183–335 has been found by several authors to contain neutralizing epitopes.

Virus Propagation and Cytopathic Effects

IPNV replicates in the cytoplasm and a single cycle of replication takes 16–20 h. IPNV infects a wide range of cultured fish cells, including CHSE-214, RTG-2, and BF-2 cells, all of which are routinely used for laboratory propagation of the virus. IPNV replicates well at temperatures ranging from 15 to 22 °C, resulting in a characteristic cytopathic effect. Available information on attachment, penetration, and uncoating is limited. Purified virus

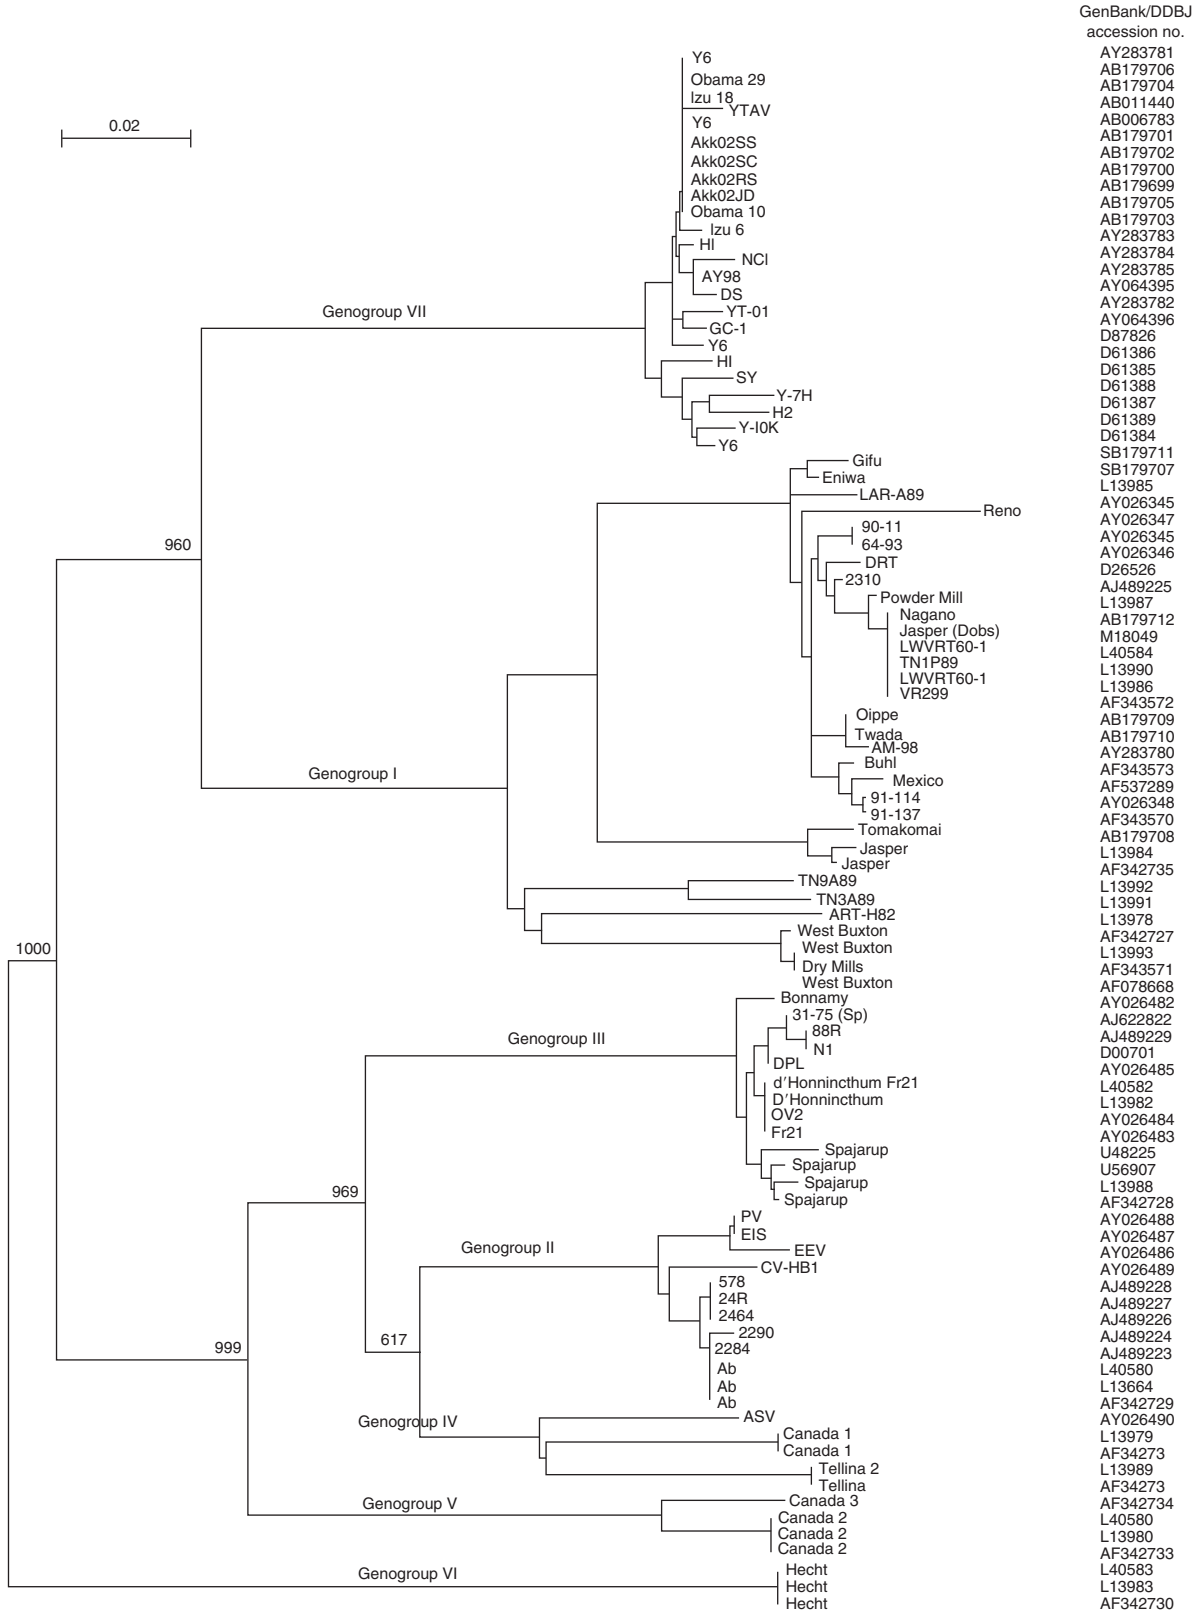

Figure 1 Molecular phylogenetic tree based on nucleotide sequences of the VP2/NS junction among 93 worldwide isolates of IPNV and other aquabirnaviruses, and corresponding GenBank/DDBJ accession numbers. Bootstrap values form 100 replicates are shown at major nodes. Scale: 0.02 replacement nucleotides per site. Reproduced from Nishizawa T, Kinoshita S, and Yoshimizu M (2005) An approach for genogrouping of Japanese isolates of aquabirnaviruses in a new genogroup, VII, based on the VP2/NS junction region. *Journal of General Virology* 86: 1973–1978, with permission from Society for General Microbiology.

attaches to CHSE-214 cells by specific and nonspecific binding to cell membrane components. After binding, IPNV can be observed in endosomes after 20–30 min, suggesting that viral entry occurs by endocytosis. Entry does not appear to be dependent on the acidic pH of the endosomes, and the virion RdRp (VP1) is active without proteolytic treatment of the virion, indicating that uncoating may not be a precondition for virus replication. VP1 can be guanylylated *in vitro* whereupon it becomes a primer for *in vitro* RNA synthesis. Unlike other viral VPg polypeptides, VP1 self-guanylylates *in vitro* in a template-independent manner, and the guanylylation site has been mapped to serine 163. Segment A mRNA is synthesized in larger amounts (2–3 times) than segment B, reflecting the relative abundance of the viral proteins. Assembly of virions takes place in the cytoplasm of infected cells, and virus release occurs via cell lysis.

Apoptosis is induced in CHSE-214 cells following IPNV infection and the so-called 'McKnight' cells associated with sloughing of mucosal cells in the intestines of juvenile salmonids suffering from IPN resemble apoptotic cells morpologically. Similar apoptotic bodies are also found in the liver of Atlantic salmon post-smolts suffering from IPN (**Figure 4**).

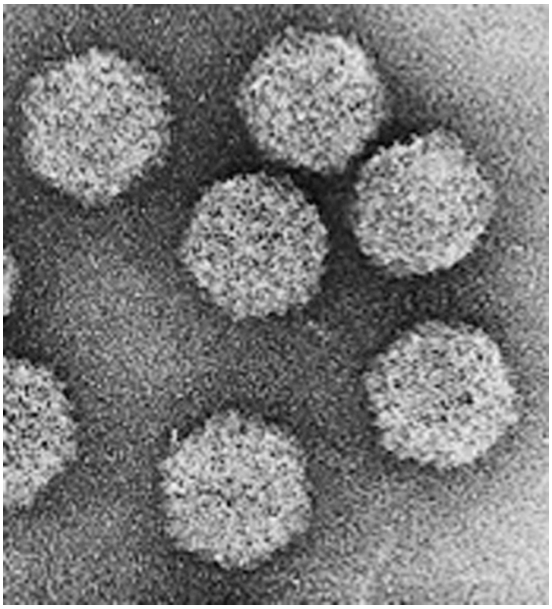

Figure 2 Negative staining of IPNV serotype Sp grown on Chinook salmon embryonic (CHSE-214) cells and purified by density gradient centrifugation.

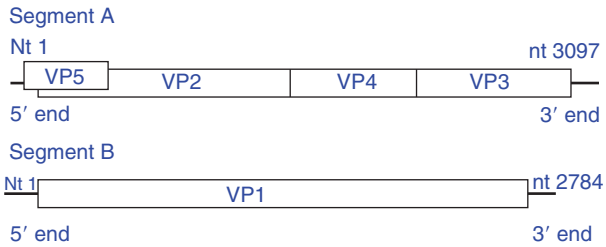

Figure 3 Schematic presentation of the genomic organization of IPNV depicting the proteins encoded by genome segments A and B.

Acute Infections

IPNV causes acute disease in juvenile salmonids and is the major pathogen of concern in brook trout (*Salvelinus fontinalis*), rainbow trout (*Oncorhyncus mykiss*), and Atlantic salmon (*Salmo salar* L.) hatcheries. Outbreaks also occur in fingerlings and parr later in the freshwater phase, as well as in post-smolts after transfer to seawater.

Salmonid fish suffering acute IPNV infection display darkened skin, abnormal behavior such as whirling or swimming on the side, and a visibly distended abdomen. Whitish threads of debris are often seen hanging from the anal orifice. At necropsy, common findings are ascites and hemorrhages in perivisceral adipose tissue, and the liver is often pale. Histopathologically, IPN is characterized by acute multifocal necrosis of the exocrine pancreas. In cases of more protracted disease, evidence of a cellular immune response can be observed. In addition to pancreatic lesions, multifocal hepatic necrosis and acute catarrhal enteritis with necrosis and sloughing of the intestinal epithelium have been reported. Viral antigen can be detected within lesions by immunohistochemistry or indirect fluorescent antibody tests.

Persistent Infections

A high proportion of fish surviving an IPN outbreak become persistently infected without apparent signs of disease. These subclinically infected individuals are of

major importance as sources of horizontal transmission of the virus. In the carrier state, there is no direct negative impact on infected individuals, although there are some indications of suppressed immune response. However, recent studies have shown that there are differences in the ability of different strains of the Sp serotype of IPNV to establish persistent infections in Atlantic salmon fry. Carrier fish shed virus in the feces but titers fluctuate over time and increase during periods of stress. In addition, persistently infected brood fish can transfer IPNV to their progeny.

Virus can be isolated from peripheral leukocytes a short time after experimental infection but not during chronic stages. The virus is located in head kidney leukocytes in fish that recover from an acute infection and most likely in macrophages or macrophage-like cells of the head kidney in persistently infected fish. It has also been shown that IPNV multiplies in adherent leucocytes isolated from carriers, although a lytic infection is not seen and, concordantly, virus is not found in the supernatant medium from cultures of isolated head kidney macrophages. Similarly, IPNV is able to induce persistent, non-lytic infections in cell cultures in which a high proportion of the cells are infected but produce relatively low quantities of virus. Different strains of IPNV appear to vary in their ability to induce persistence in cell culture. Infected cells are resistant to superinfection with either homologous or heterologous strains or serotypes, and cultures can be cleared of IPNV infection by several passages in the presence of virus neutralizing antiserum. The underlying mechanisms of the establishment and maintenance of IPNV persistence *in vivo* and *in vitro* are largely unknown.

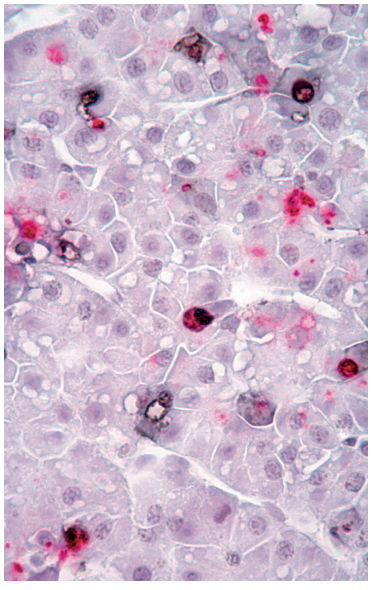

Figure 4 Liver tissue from IPNV-infected Atlantic salmon, fixed in 10% buffered formalin and embedded in paraffin wax. The tissue section was double-stained for IPNV antigen using a rabbit immune serum to IPNV Sp (red color) and for apoptotic cells based on the TUNEL method (black coloration). Note double-staining in some of the hepatocytes.

Molecular Determinants of Virulence

The mortality rate during an IPN outbreak can vary and this has been ascribed to factors related both to the host and to the virus. Viral factors influencing mortality rates are the dose of infection as well as virulence variations between serotypes and strains. IPNV strains of different serotypes are highly heterogenous and the Sp serotype is considered to be more virulent than the Ab serotype. Within the Sp serotype, different genotypes exhibit different virulence characteristics which have been studied by the use of reverse genetics.

In vitro transcribed positive-sense cRNAs of IPNV are infectious when transfected together into permissive cell cultures, allowing the recovery of genetically modified isolates. The reverse genetics technique is a valuable tool for studying the IPNV life cycle and the role of individual viral proteins in the pathogenesis of infection. Experimental studies using such recombinant IPNV strains have demonstrated that VP5 expression is not required for efficient replication *in vitro* or *in vivo*, or for virulence, or persistence of the virus. Reassortant viruses containing segment A from a high-virulence strain and segment B from a low-virulence strain, prepared by either reverse genetics or co-infection techniques, have also been used to demonstrate that segment B has no direct influence on IPNV virulence. For IPNV serotype Sp, it has been shown that certain amino acid sequence motifs in VP2 strongly correlate with virulence. Residues 217 and 221 appear to be critical determinants of virulence, and genetic signatures involving these amino acids are strongly associated with avirulent, moderately and highly virulent strains, as shown in **Table 2**. Furthermore, serial passage of the Sp serotype in cell culture leads to the attenuation of virulence as a result of an A→ T mutation at amino acid residue 221.

Table 2 Point mutations in VP2 result in a marked reduction to almost complete loss of virulence whereby 217 and 221 are key determinants

Amino acid residues of VP2			*In vivo virulence characteristics*
217	221	247	
T	A	T	Highly virulent
T	T	T	Avirulent
P	A	A	Moderately virulent
P	T	A	Avirulent

Substitution of threonine for proline at residue 217 (T217P) reduces the virulence of the strain, producing a mortality rate approx. 50 % lower than the high-virulent variant (TAT). Similarly, single amino acid substitutions of alanine for threonine at residue 221 render highly virulent strains (TAT) almost avirulent. Passage in culture of high virulent strains is associated with motif changes in position 221 (A to T) for TAT ant PAA variants, each of which results in avirulence.

Table 3 Summary of neutralizing domain, virulence determinants and the cell culture adaptation characteristics of IPN virus

Characteristics	*VP2 amino acid residues*
Immunogenic domain	183–337
Virulence determinants	217, 221, 247 (Sp serotype)
Cell culture adaptation	221 (Sp serotype)
Antibody neutralization	Not known

Serotype-specific findings have been indicated.

In summary, the neutralizing domain, the virulence determinants, and the cell culture adaptation with subsequent loss of *in vivo* virulence seem to be located in the VP2 hypervariable region for IPNV, although there is a limited number of serotypes and strains of the IPN virus that have been characterized for their virulence signatures and cell culture adaptation traits (**Table 3**).

Epidemiology

It has long been known that survivors of an IPN outbreak become carriers and surviving fish continue to shed virus without any apparent clinical symptoms, and subclinical infection is important for horizontal transmission of virus. The efficiency by which the virus is spread in a population of susceptible individuals varies between strains and there are indications that this might correlate with virulence characteristics whereby highly virulent variants are more efficient at spreading. Transmission of the virus to progeny has been shown to occur vertically via eggs in brook trout and rainbow trout. The virus is possibly present inside the eggs since there are indications that surface disinfection of the eggs is not fully effective in preventing the introduction of IPNV to hatcheries. One possible route of intra-ovum introduction is via the milt, by adsorption of virus to the sperm head.

Surveys for the prevalence of IPNV have concluded that most North Sea salmon farms harbor IPNV carrier fish, making selection for IPNV-free brood fish difficult (prevalence in Scotland is 80%). Once introduced to a hatchery, the virus is difficult to eliminate, as it is stable in water and relatively resistant to many disinfectants. It is also still not clear whether seawater outbreaks of IPN are the result of persistent infection obtained during the freshwater period or exposure from a marine source.

Control of IPN through Management

Good management includes the environment of fish to minimize stress and to reduce the likelihood of transmission of the pathogen. This is particularly important at the time of first feeding of fry, when smolt are transferred to sea and during the first few months after sea water transfer.

Transfers of fish between farms are considered as one of the highest risks in the transmission of IPNV. Another factor is the movement of eyed eggs and fry between hatcheries, common in Norway and other salmon-producing countries.

Vertical transmission has not been conclusively demonstrated in Atlantic salmon but there is evidence from other salmonid species to indicate that vertical transmission is a strategy utilized by IPNV.

Disease Control through Vaccination

There are few scientific publications addressing or documenting the effect of vaccination against IPN and most of what has been published has focused on the immune responses elicited by vaccination. Vaccination with an *Escherichia coli*-expressed VP2 recombinant protein or insect baculovirus-expressed subunit vaccine based on all structural proteins of IPNV induces specific antibody responses in Atlantic salmon. For *E. coli*-expressed proteins, it has also been shown that vaccination will confer higher secondary antibody titers in immunized fish compared to nonvaccinated controls. Similar observations have been made for inactivated vaccines based on whole virus. Reliable challenge models for IPN in Atlantic salmon post-smolts have only recently been established and this partly accounts for the lack of scientific data on protective immunity. It has been shown that partial protection can be induced in Atlantic salmon immunized with a baculovirus/insect larvae-expressed subunit vaccine. However, the level of protection was below that required under field conditions in a commercial setting.

DNA vaccination against IPNV has also been attempted in Atlantic salmon. Fish were immunized with plasmids encoding the entire polyprotein of segment A and shorter variants of the protein, and subsequently challenged with virulent IPNV strains. A reasonable protection was attained with constructs expressing the entire segment A but it is difficult to draw a firm conclusion as to the potential that lies in the use of DNA vaccines for protection against IPNV infection since the number of published studies is few.

Despite the sparse knowledge of the immunity to IPNV, the first commercial, recombinant subunit (VP2) vaccine was introduced in Norway in 1995 and has come into use throughout the industry. By 2 years after introduction of the vaccine, 68% of the fish transferred to sea were vaccinated and the national coverage had increased to 85% in 2002. Vaccines based on killed, whole-virus are also currently available in Norway, the UK, and Chile. The extent to which the use of the vaccine has influenced the prevalence of IPNV has not been ascertained.

Disease Control through Breeding

There are few published papers related to the genetic resistance to IPN in Atlantic salmon or other fish species. In Norway, IPNV challenge experiments in Atlantic salmon fry (around 0.20 g size) have shown 15–30 % of the variation in mortality between family groups can be explained by genetic factors (heritability). Therefore, there is a potential for improving resistance to IPNV through breeding programs where brood fish are selected on the basis of off-spring performance.

Another approach is to select brood fish based on survival following disease outbreaks, but the latter strategy presents a risk of bringing the infection over to offspring. One option is to expose pedigreed populations of fish to the field challenge, with some of the unchallenged full-siblings remaining in biosecure conditions for breeding of unchallenged brood-stock.

Introduction

Infectious salmon anemia virus (ISAV) is the causative agent of infectious salmon anemia (ISA), a disease of farmed Atlantic salmon (*Salmo salar*). ISA primarily affects fish held in or exposed to seawater. The disease appears as a systemic condition characterized by severe anemia and hemorrhages in several organs. Mortality during an outbreak of ISA varies significantly. Daily mortality in affected net pens ranges from 0.2% to 1%, but may increase during an outbreak and the cumulative mortality may exceed 90% in severe cases.

ISA was recognized in 1984 in Norway, and was soon identified as a contagious viral disease. The disease increased in prevalence and showed a peak in 1990. In the following years, the incidence of ISA was greatly reduced by the implementation of legislatory measures or husbandry practices based on general hygiene. These included mandatory health control in hatcheries and health certification for fish, restrictions on transportation of live fish, regulations of disinfection of wastewater from fish slaughterhouses and of water supplies to hatcheries. Approximately 10 years after the first recognition of ISA, the causative virus, ISAV, was isolated in cell culture using the SHK-1 cell line established from Atlantic salmon head kidney. The subsequent investigations showed that the morphological, physiochemical, and genetic properties of ISAV are consistent with classification in the *Orthomyxoviridae*.

Virus Properties and Classification

ISAV is a pleiomorphic, enveloped virus, 100–130 nm in diameter, with 10–12 nm surface projections (**Figure 1**). The virus hemagglutinates erythrocytes of several fish species and it has receptor-destroying and membrane fusion activities. Endothelial and leukocytic cells are the main target cells and the virus replicates by budding from the cell membrane. ISAV has two main surface glycoproteins: the hemagglutinin-esterase (HE) responsible for the receptor-binding and receptor-destroying activities, and a fusion protein (F).

The buoyant density of virus particles in sucrose or cesium chloride is 1.18 g ml^{-1}. The virus is stable at pH 5.7–9.0. The virus replicates in the salmon cell lines SHK-1, TO, and ASK, with a replication optimum of 10–15 °C. Some strains also replicate in the CHSE-214 cell line. There is no replication in SHK-1 cells at 25 °C or higher and, even at 20 °C, the yield of virus in SHK-1 cells is only 1% of the yield at 15 °C.

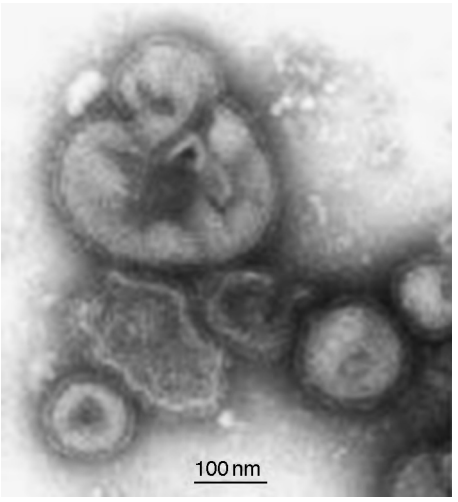

Figure 1 Electron micrograph of negative-stained ISAV particles purified from infected cell culture medium. Photo by Ellen Namork, The Norwegian Institute of Public Health, Oslo, Norway.

The 14.3 kb genome consists of eight single-stranded RNA segments of negative polarity in the size range of 1.0–2.4 kb. The amino acid identity between the ISAV proteins and those of other orthomyxoviruses is low (13–25%), and the organization of ISAV genes is unique. ISAV is therefore classified as the type species of the genus *Isavirus* within the family *Orthomyxoviridae*.

Geographic Distribution and Host Range

After the first recorded outbreak in 1984, ISA was considered to be a uniquely Norwegian disease. In 1996, a disease in Canada (New Brunswick) designated as hemorrhagic kidney syndrome was verified as ISA. The disease has thereafter been reported in Scotland (1998), the Faroe Islands (2000), and in the USA (Maine, 2001).

While natural outbreaks of ISA have only been described in Atlantic salmon, the virus may survive and replicate in other salmonid fish under experimental conditions. ISAV has been detected in wild Atlantic salmon and brown trout (*Salmo trutta*). Outbreaks of ISA in farmed Atlantic salmon have occurred mainly during the seawater stage, but indications of disease outbreaks in the freshwater stage have been reported. Disease and transmission are readily induced experimentally in Atlantic salmon kept in either freshwater or seawater. Wild Atlantic salmon are susceptible to ISA and show the same clinical signs as

farmed fish when experimentally infected. The virus has been isolated from apparently healthy rainbow trout (*Oncorhynchus mykiss*) in Ireland (2002). ISAV has also been reported to have been isolated from Coho salmon (*Oncorhynchus kitsutch*) in Chile, but this observation needs to be confirmed. Subclinically infected feral salmonids (Atlantic salmon, brown trout, and sea brown trout) have been identified in Scotland and Norway by reverse transcriptase-polymerase chain reaction (RT-PCR). However, reports of RT-PCR-positive samples from marine, nonsalmonid fish (Atlantic cod (*Gadus morhua*) and pollock (*Pollachius virens*)) need to be corroborated as samples were collected from the vicinity of cages holding ISA-diseased Atlantic salmon.

ISAV replication has been demonstrated in experimentally infected brown trout and in rainbow trout, but disease and mortality have only been produced in rainbow trout by experimental infection. ISAV has also been detected by RT-PCR in experimentally infected Arctic charr (*Salvelinus alpinus*) but neither virus replication nor clinical signs of disease have been demonstrated. ISAV could be reisolated from Pacific salmon species (*O. mykiss*, *Oncorhynchus keta*, *O. kitsutch*, *Oncorhynchus tshawytscha*) injected intraperitoneally with various Canadian and Norwegian virus isolates but no mortality was observed. Pacific salmon are therefore considered more resistant to ISA than Atlantic salmon but should not be ignored as potential virus carriers. Among marine fish, ISAV is able to propagate in herring (*Clupea harengus*) after bath challenge, but attempts to induce infection in pollock have failed. There are no indications that ISAV can infect mussel (*Mytilus edulis*) or scallops (*Pecten maximus*).

Transmission, Vectors and Reservoir Hosts

Epidemiological and experimental studies have shown that ISA may spread by water-borne transmission. The risk of ISA is closely linked to geographical proximity to farms with ISA outbreaks or to slaughterhouses and processing plants. The spread of the disease over long distances may be caused by transportation of infected fish by well boats.

The virus may be shed into the water by various routes such as skin, mucus, feces, and urine. The most likely route of virus entry is through the gills and skin lesions but transmission by coprophagy has also been proposed. ISAV may retain infectivity for long periods outside the host. No significant loss in virus titer was observed after incubation of virus supernatants for 14 days at 4 °C and 10 days at 15 °C, and infectivity of tissue preparations is retained for at least 48 h at 0 °C, 24 h at 10 °C, and 12 h at 15 °C. A 3-$\log_{10}$ reduction in virus titer after 4 months storage in sterile seawater at 4 °C has been observed, but ISAV survival time in natural seawater may be shorter.

There are indications that ISAV may be transmitted vertically. ISAV has been detected by real-time RT-PCR in fertilized eggs from ISA-diseased brood fish. However, it is not known if this represents infective virus as recovery of virus by isolation in cell culture was not performed. Eggs, fry, and juveniles from ISAV-infected parents have been demonstrated ISAV-positive by real-time RT-PCR. On the other hand, ISAV could not be detected in progeny from healthy but virus-positive brood fish. Furthermore, ISAV has been detected by real-time RT-PCR in Atlantic salmon parr and smolt sampled from hatcheries, that is, from the freshwater stage. However, there are no verified field observations that can confirm vertical transmission of ISA disease. Nevertheless, the detection of virus in progeny from infected brood fish and the few reported outbreaks in the freshwater stage indicate that this route of transmission cannot be excluded.

The sea louse (*Lepeophtheirus salmonis*) has been suggested as a possible vector for ISAV, but it is not clear if this is by passive transfer or active virus replication. Reservoir hosts of ISAV have not been identified, but the virus replicates in sea trout, which are abundant in Norway in fiords and coastal areas in the vicinity of the fish farms. However, the possible role of sea trout as a reservoir host for ISAV can only be speculated at this time.

Genetics

Nucleotide sequences of all eight ISAV genome segments have been described. The genome encodes at least 10 proteins (**Table 1**). Segments 1, 2, and 4 encode the viral polymerase subunits PB1, PB2, and PA, respectively. Segment 3 encodes the 68 kDa nucleoprotein (NP). Segments 5 and 6 encode the two major surface glycoproteins: the 50 kDa fusion (F) protein, and the 42 kDa HE responsible for receptor-binding and receptor-destroying activities. The two smallest ISAV genomic segments each contain two overlapping reading frames (ORFs). Two mRNAs are transcribed from genome segment 7 – one is collinear with the viral RNA (vRNA) and the other is spliced in an arrangement similar to the two smallest gene segments of influenza A virus. The unspliced mRNA of segment 7 encodes a nonstructural protein that has been suggested to interfere with the interferon type 1 response of the cell. The protein encoded by the spliced mRNA has not yet been characterized. No splicing of transcripts from segment 8 ORFs has been detected, indicating that ISAV uses a bicistronic coding strategy for this genomic segment. The smaller ORF1 encodes a 22 kDa matrix protein, while the collinear mRNA transcript from the larger ORF2 encodes an RNA binding structural protein of about 26 kDa with putative interferon antagonistic properties. ISAV gene segments and the respective encoded proteins are summarized in **Figure 2**.

Table 1 Genome segments and encoded proteins of ISA virus

Segment (kb)	*Encoded protein*	*ORF (bp)*	*Protein (kDa)*
1 (2.3)	Polymerase, PB2	2127	80.5[a]
2 (2.3)	Polymerase, PB1	2169	79.5[a]
3 (2.2)	Nucleoprotein, NP	1851	66–74[b]
4 (2.0)	Polymerase, PA	1840	65.3
5 (1.7)	Fusion, F	1332	53
6 (1.5)	Hemagglutinin-esterase, HE	1176[c]	38–46[b]
7 (1.3)	Two open reading frames		
	• ORF1 = nonstructural (NS)	903	34
	• ORF2 = spliced protein	369	17.5
8 (1.0)	Two open reading frames		
	• Matrix, M	588	22–24
	• as RNA-binding protein	726	26

[a]Estimations based on amino acid sequence.
[b]The estimated molecular masses of some of the proteins differ slightly in the literature, probably due to differences in experimental conditions. For HE, this could also be due to differences in glycosylation as well as in the highly polymorphic region (HPR).
[c]Length of ORF for the reference ISAV isolate Glesvaer/2/90. The length varies between isolates due to the HPR characterized by deletions/gaps. The proposed ancestral ORF sequence is estimated to 1236 bp.

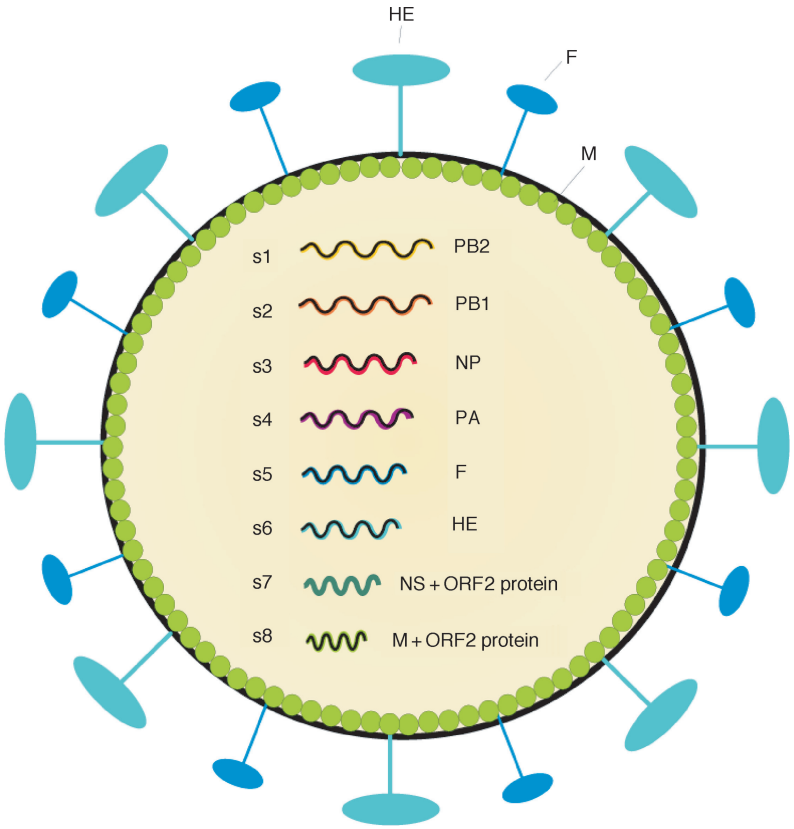

Figure 2 Schematic diagram of the ISAV virion. The two smallest genomic segments (segments 7 and 8) each contain two open reading frames (ORFs). The proteins encoded by each ORF is yet to be characterized. s, Genomic segment; PB2/PB1/PA, polymerase subunits; NP, nucleoprotein; F, fusion protein; HE, hemagglutinin-esterase; NS, nonstructural protein; M, matrix protein. The 3′- and 5′-terminal structure of vRNAs, and the ISAV transcription strategy, resemble those of influenza viruses. As for all members of the *Orthomyxoviridae*, each ISAV genome segment contains partially self-complementary termini that are essential for the replication process. However, compared to the 12–13 nucleotides conserved in the influenza A virus, only 8–9 nucleotides are conserved in ISAV, most likely reflecting the lower replication temperature optimum for this virus. As for the influenza viruses, the terminal 21–24 nucleotides are predicted to form self-complementary panhandle structures important for transcriptional regulation of viral RNA. ISAV also exerts cap-stealing in the host cell's nucleus, transferring 8–18 nucleotide 5′-cap structures from host mRNAs to the viral mRNAs and affecting the normal transcription and protein synthesis in the cell. ISAV mRNAs are polyadenylated, a process that is regulated from a signal 13–14 nucleotides downstream the 5′-terminus of the vRNAs. Altogether, the ISAV replication strategy is similar to those of the other orthomyxoviruses.

ISAV isolates vary in virulence, as observed by differences in disease development and clinical signs in field outbreaks and in experimental trials using genetically standardized fish. However, analysis of important virulence factors is still in its infancy. The ISAV genome is highly conserved, both over time and geographical distance, with 98–99% overall nucleotide similarity between Norwegian isolates. However, small, but relevant, differences between isolates both within and between defined geographical areas do exist, and analysis of the 5′-terminal end of the HE gene has demonstrated the presence of two major groups of isolates, one European and one North American. The European group may be further divided into three major subgroups.

The surface glycoprotein HE gene displays the highest sequence variation (94–97%) which is mainly concentrated in a small highly polymorphic region (HPR) of the HE protein that is predicted to lie immediately outside the viral envelope. Variation in this region is characterized by the presence of gaps rather than single-nucleotide substitutions. The polymorphism has been suggested to arise from differential deletions of a full-length precursor gene (HPR0) as a consequence of strong functional selection, possibly related to a recent or ongoing crossing of a species barrier. All HPRs described to date can be derived from such a full-length precursor sequence. Furthermore, the presence of a long HPR0 gene has been detected by RT-PCR in wild Atlantic salmon. The variation in HPR is most likely an important virulence factor as virus isolated from diseased fish always contains a deletion in this region.
